therapeutic approach to selected cases of infertility. Briefly, my basic hypothesis was that the anxiety and tension these infertile women experienced could be manifested as tubal spasms that interfered with the normal transport of the ovum to the uterus; this was the psychosomatic basis of their infertility. My therapeutic approach to their problem was to place these women on a program of hypnotic training designed to increase muscular relaxation and blood flow so that their hypothesized tubal spasms would be reduced.

Clinical Subjects

Twenty patients were referred to me over a number of years because of infertility. All these patients had been infertile for at least four years, one for fifteen years, another for twelve years (see Table 1). All of these patients had anxiety and tension, fear, distress, and unhappiness. Some of them had been operated on to see if there was anything wrong with their ovaries. They had undergone various medical regimens. They'd been recommended to psychiatrists for psychotherapy, but they didn't want pschotherapy—they wanted a baby.

On the whole these patients, both the successes and the failures, were a homogeneous group. They all complained of being "nervous," "anxious," "worried," "tense," "frustrated," "hopeless," "easily upset," "tired," unable to relax or to sleep well, easily reduced to tears, and always feeling that "things are just too much, too overwhelming." All were either definitely overweight or underweight. Their general health, however, despite complaints, was fairly good.

Of the total group, the two oldest patients, both successful, and three of the other women, were married to men who had fathered children in previous marriages. Three of the successes and four of the others had borne a single child, conceived during the first year of marriage, and followed by periods of infertility ranging from four to eight years. A few had practiced contraception during the first year of marriage only.

METHOD

The actual methodology employed with these patients is difficult to describe since it was based upon the presentation of ideas, the establishment of good interpersonal relationships and the use of hypnosis to facilitate and ensure adequate responses. Also, each patient was handled separately, and the duration and rapidity of therapy varied from one patient to the next, as did the exact order of procedure. The preliminary step in each case, however, was the same: A slow, carefully worded explanation was offered to each of them; much of their previous medical treatment served to give weight to the ideas presented. To each patient it was emphasized that the failure of conception might derive from tension, particularly muscular, from spasms, particularly tubal, and from faulty blood circulation that in turn would result from the spasms and muscular tension. Because of these significant possibilities, it was proposed that we employ hypnosis as a special aid in dealing with these psychosomatic manifestations. The purpose of this explanation was not a presentation of established scientific facts, but merely a communication of ideas in general to elicit patient cooperation.

The procedure with each patient was as follows:

1. Hypnotic training resulting in trances which varied from light to medium and deep. Sometimes, only a utilization of hypnotic fixation of attention was required to induce trance.
2. A reorientation of the patient concerning the purposes of therapy. They had all been referred for psychotherapy because of tension, anxiety, nervousness, and general maladjustment. The explanation was given carefully and slowly that their need for psychotherapy was a secondary need, that their primary need was maternal satisfaction, and only in the event of absolute failure in this regard would they need psychotherapy.
3. The reaching of an agreement with each of them to the effect that an earnest experimental procedure would be employed with them in an effort to meet their primary needs.
4. A systematic hypnotic training in which each woman was taught what was described as "basic, easy, tensionless physiological functioning ordinarily learned spontaneously but, in your case, requiring special effort and instruction."
5. A systematic progression from commonly known physiological manifestations related to altered blood flow such as blushing to a postulation and suggestion of less familiar but comparable manifestations of altered blood flow and blushing in different parts of the body, particularly the pelvic area.

HYPNOTIC TRAINING

The actual initiation of hypnotic training was essentially the same for each patient. Since they all complained of tension and fatigue, the "beginning step" was to teach them simple relaxation by employing an hypnotic technique of body relaxation. Once this had been learned and their interest well enlisted, the experimental procedure was developed in the following steps, each one being repeated again and again if necessary to meet the patient's learning needs:

1. Relaxation of entire body with feeling of restfulness and comfort.
2. Transformation of that feeling of comfortable relaxation into one of physical heaviness, sluggishness, inertia, and "utter tiredness."
3. Restoration of feeling of comfort and relaxation.
4. Teaching the "partitioning of the body," i.e., simultaneously, "right leg comfortably relaxed," "left leg painfully tired, heavy, sluggish and inert;" "right arm feeling normal," "left arm rested and full of energy."
5. Teaching of rigidities, i.e., simultaneously "right arm stiff and rigid as an iron bar," "left arm relaxed and comfortable;" "left leg fixed and rigid and immoveable," and "right leg at ease and comfortable and mobile."

The above training was relatively easily accomplished. Depending upon the patients' capacities to learn, the procedures were repeated until they seemed to comprehend adequately. However, the next step in the hypnotic training was more difficult. Their

capacities for visual, auditory, and tactile imagery were tested and appropriate suggestions were offered to each patient, according to individual abilities, to experience vividly a sense of coldness and "goose bumps," of warmth, hotness, and perspiration, of blushing, shame, and embarrassment, of sunburn, hotness, and pain, of the roughness of sandpaper, and of rasping.

When all of this seemed to have been learned adequately as a general phenomenon, the patients were asked to learn it in the same "partitioned" manner as the relaxation had been learned. Thus, each patient was systematically taught: "Right hand cold, left foot hot, face warm, hands cold, face blushing, body cold, right breast cold, left breast warm, all embarrassed and all cold, all happy and all warm, all embarrassed and all warm," until the patient was ready to accept and act upon any experiential suggestion given.

The patients were then finally allowed to extend whatever manifestations of heightened blood flow they could experience to the pelvic area. Thus some learned to experience warmth, hotness and perspiration in their pelvises while others experienced blushing, embarrassment and sensual warmth. In the next section I will describe in more detail the experiences of Anne as a typical case illustrating the above process.

RESULTS AND CASE STUDY

Table 1 summarizes the pertinent data on the successful patients.

In summary, of the twenty infertile women with whom I worked, the ten who stayed with me all became pregnant within a range of two to thirteen months. Ten of those twenty women had children. Of the ten that did not become pregnant the longest I treated any one of them was five months. These unsuccessful cases terminated their work with me because they became discouraged that hypnotic therapy didn't seem to be working fast enough. They wanted their pregnancies too soon—often expecting success within the first month. The following case study of Anne was typical of the clinical course in the successful cases.

ANNE: A CASE STUDY

Anne had been married twice, the first time to a man who had been divorced from his first wife by whom he had fathered several children. Anne married him and they lived happily for a while, but she desperately wanted a baby. All of their endeavors produced no pregnancy, despite Anne's wandering from one physician to another. She stayed with one good physician for a whole year, and then she sought out another good physician for a whole year. Finally she divorced that first husband because she wanted a baby, and she married another divorced man who had fathered several children by his first wife. Seven years went by with this husband, and there was no baby. So she had spent twelve years in all trying desperately to conceive. Finally, because of the severity of her tension, anxiety, and fear, her physician sent her to me for psychotherapy. Anne stated clearly that she didn't want psychotherapy, she wanted a baby—she had tried plenty of psychotherapy in the past.

TABLE 1
CHARACTERISTICS OF THE INFERTILE WOMEN SUCCESSFULLY TREATED

Patient Identity	1	2	3	4	5	6	7	8	9	10
Age (in years)	25	28	28	31	31	33	33	34	36	38
Infertile Period (in years)	4	5	6	3	11	7	8	8	12	15
Pervious Children	0	1	1	0	0	0	1	0	0	0
Treatment Period (in months)	7	2	13	3	10	5	6	2	2	9

Hypnotic Training

So, utilizing all the things that I knew about what you can do to physiological behavior with hypnosis, I trained Anne to go into a nice profound hypnotic trance, telling her that she could think about the various parts of her body separately. I pointed out to her that her right arm could get very very cold, and her left arm very very hot. I taught her that her right arm could get very very tense and her left arm could get very relaxed. Then I taught her to separate the various parts of her body in different fashions . . . left leg being relaxed, right arm being very tense, the left arm being very hot, the right leg being very cold. And I bounced these various physiological reactions around in her body until she really understood. Then I taught her that she could sit quietly in her chair and she could get a feeling of intense blushing in her face. I suggested that she get a feeling of intense warmth in her thighs, which would mean a blushing of her thighs; then a coldness in her chest, and then a warmth in her breast, so that I bounced these various physiological processes around within her. Then I explained to her something about the physiological processes of menstruation. And I suggested that she really learn how to relax her pelvis, and to relax it completely, thoroughly, to get a tremendously warm feeling in her pelvis, then let go of that relaxation, and then re-develop the relaxation and the warm feeling, until Anne had the feeling that she could relax her pelvis completely, and have it feel warm and comfortable.

My motivation for using this technique came from my suspicion that there might possibly be a tubal spasm. So I told Anne that, and I spent quite a number of hours with her during the first month of therapy. For the first time, she had a normal menstrual period without cramps. She was very pleased with this, but she informed me that she wanted that sort of thing to stop (menstruating). And I told her it would, but that she should practice this matter of pelvic relaxation and this feeling of comfort, and that during sexual relations there should be a tremendous feeling of comfort and relaxation throughout her body, and especially in her pelvis.

Anne had first come to me in October at which time she was just completing a period. She had normal periods in November and December. Then she came to see me just after Christmas and said, “I got my Christmas present-you made me pregnant!” Then she flushed and said she didn’t mean it the way the words sounded, but that she had had such enjoyable sexual relations, and that it felt so relaxed and so comfortable, that she was absolutely certain that the physiological relaxation that I had taught her had enabled her to become pregnant.

Now I think all of you ought to consider this matter of re-educating the physiological responses of the body. If we can do it in one area, we can do it in another. If we can correct constipation, if we can correct retention of urine, why can't we correct tubal spasm. The point is, we ought to expect to find solutions rather than passively accepting a decree of "uncurable." Such an attitude of expectancy is far more conducive to our task of exploration, discovery and healing.

Breast Development Possibly Influenced by Hypnosis: Two Instances and the Psychotherapeutic Results

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, January, 1960, 11, 157-159.

Common experience has demonstrated repeatedly that unconscious attitudes toward the body can constitute potent factors in many relationships. Learning processes, physical and physiological functioning, and recovery from illness are, among others, examples of areas in which unrecognized body attitudes may be of vital significance to the individual. Hence the question is pertinent: To what extent can specific forms of somatic behavior be influenced purposefully by unconscious forces, and what instances are there of such effects? The two following cases, aside from their hypnotic psychotherapeutic significances, are presented as indicative of a possibly significant problem for future research concerning unconscious purposeful influence upon breast development.

CASE 1

A 20-year-old girl was brought by her older sister for a single hypnotherapeutic interview because of failure of breast development, despite good nipple development. The girl was found to be seriously maladjusted emotionally, had failed some of her college courses, and was afraid to seek employment. She was, and since childhood had been, deeply religious, but her religious understandings and convictions included an undue element of austerity and rejection of the physical body. Additionally, it was learned that she was engaged to be married to a 47-year-old alcoholic welfare recipient, because, as she resentfully declared, with no breasts she was not entitled to more.

She readily developed a medium-to-deep trance and manifested a markedly passive attitude. The suggestion was offered to her that she read carefully and assiduously the Song of Solomon, and that she recognize thoroughly that it glorified the Church, and before the time of the Church, it glorified the human body, particularly the female body in all its parts. She was admonished that such should be her attitude toward her body, and that perhaps an attitude of patient expectancy toward her breasts might aid in some further development. It was further explained to her that as she obeyed instructions she was to feel with very great intensity the goodness of her body, particularly the goodness of her breasts, and to sense them as living structures of promise, and in which she would have an increasing sense of comfort and pride. These suggestions variously phrased were repetitiously presented to her until it was felt that she had accepted them completely.

The outcome almost two years later of this one hypnotherapeutic session may be summarized as follows: (1) The breaking of the engagement to the alcoholic; (2) weekly

reading of the Song of Solomon; (3) return to college and successful completion of the courses previously failed; (4) enlargement of social and recreational life; (5) successful employment; (6) recent engagement to a young man of her own age group whom she had known for several years; (7) independent reports from her and her sister that breast development had occurred to the extent of "one inch thick on one side, about one and one-half inches on the other side."

Comment

That significant therapy was accomplished for this patient cannot be doubted. That her breasts actually enlarged is not a similar certainty, since an objective confirmatory report was not obtainable. But there is a definite possibility that physical processes, comparable in nature and extent to those which occur in "psychosomatic illness," may have resulted in what might, as a parallelism, be termed "psychosomatic health."

CASE 2

A 17-year-old girl was first seen in her home because of her seriously pathological withdrawal responses to the failure of her breasts to develop, despite the adequacy and maturity of her physical development otherwise. She had a history of extensive medical treatment, extending over five years, with much experimental endocrinological therapy. The only results had been an increasing failure of emotional adjustment, and the possibility of a mental hospital was under consideration.

She was found hiding behind the davenport, and upon her being discovered there, she rushed behind the piano. When she learned that "no more medicines or needles" would be employed, superficially good rapport was established, possibly because she regarded the situation as offering a better means of escape or withdrawal. She was found to be a good hypnotic subject, readily developing a light-to-medium trance.

The first interview, after several hours' effort in winning her cooperation, was spent primarily in appraising her personality assets, both in and out of the trance state. During the interview she was found to have a Puckish sense of humor, with dramatic overtones, and this was utilized as the opening gambit for the therapeutic approach. This was initiated by reminding her of the old song about how the toe-bone is connected to the foot-bone, etc. When her interest had been fully aroused, a paraphrase was offered in relationship to the endocrine system, and it was pointed out that, even as the foot-bone is connected to the ankle-bone, so is the "adrenal bone" connected with the "thyroid bone," with each "supporting and helping" the other.

Next she was given suggestions to feel hot, to feel cold, to have her face feel uncomfortably hot, to feel tired, and to feel rested and comfortable. She responded readily and well to these suggestions, whereupon it was suggested effectively that she develop an intolerable itch upon her feet. This itch she was then to consign with dramatic intensity, not to the nethermost depths, but to the "barren nothingness" of her breasts, a fitting destination for so intolerable an itch. However, in further punishment of it, the itch

would become a constantly present, neither pleasant nor unpleasant, noticeable but undefined feeling, rendering her continuously aware of the breast area of her body. This involved series of suggestions was formulated for the multiple purposes of meeting her ambivalences, puzzling and intriguing her, stimulating her sense of humor, meeting her need for self-aggression and self-derogation, and yet doing all this without adding to her distress and in such fashion and so indirectly that there was little for her to do but to accept and to respond to the suggestions.

Then the suggestion was offered that, at each therapeutic interview, she was to visualize herself mentally in the most embarrassing situation that she could possibly imagine. This situation, not necessarily to remain constant in character, would always involve her breasts, and she would feel and sense the embarrassment with great intensity, at first in her face, and then, with a feeling of relief, she would feel that weight of embarrassment move slowly downward and come to rest in her breasts. She was given the additional posthypnotic suggestion that, whenever she was alone, she would regularly take the opportunity to think of her therapeutic sessions, and she would then develop immediately intense feelings of embarrassment, all of which would promptly "settle" in her breasts in a most bewildering but entirely pleasing way.

The rationale of these suggestions is rather simple and direct. It is merely an effort to parallel in relationship to her breasts, but in a pleasant, constructive manner, such unfortunate destructive psychosomatic reactions as "terrible, painful knots in my stomach over just the slightest worries."

The final set of hypnotic instructions was that she was to have a thoroughly good time in college. (By these suggestions all discussion of her withdrawn behavior and college attendance was effectively bypassed.) It was explained that she could, in addition to handling her academic work adequately, entertain herself and mystify her college mates delightfully by the judicious wearing of tight sweaters and the use of different sets of "falsies" of varying sizes, sometimes not in matched pairs. She was also instructed to carry assorted sizes in her handbag in case she decided to make an unexpected change in her appearance, or, should any of her escorts become too venturesome, so that she could offer them a choice with which to play. Thus her Puckish activities would not lead to difficulties.

She was first seen in mid-August and given weekly appointments thereafter. The first few of these were used to reiterate and reinforce the instructions previously given her and to insure her adequate understanding and cooperation.

Henceforth she kept, by permission, three out of four appointments "in absentia. " That is, she would seclude herself for at least an hour, develop, in response to posthypnotic suggestions, a medium-to-deep trance state, and in this state, as far as could be learned, she would review systematically and extensively all previous instructions and discussions and whatever "other things" that might come to her mind. No effort was made to determine the nature of those "other things," nor did she seem to be willing to volunteer information, except to the effect that she had thought of a number of other topics. The

other appointments she kept in person, sometimes asking for information, sometimes for trance induction, almost always for instructions to “keep going. “ Occasionally she would describe with much merriment the consternation she had caused some of her friends.

She entered college in September, adjusted well, received freshman honors, and became prominent in extracurricular activities. During the last two months of her therapy she kept her visits at the level of social office calls. In May, however, she came in wearing a sweater and stated with extreme embarrassment, “I’m not wearing falsies. I’ve grown my own. They are large medium size. Now, tell them to stop growing. I’m completely satisfied.”

Her college career was successful, and subsequent events are entirely satisfactory. At the writer’s request she underwent a complete physical examination, with special reference to her breasts, a report of which was sent this writer. She was physically normal in every regard.

Comment

Whether or not the hypnotherapy had anything to do with her breast development is not known. Quite possibly the development may have been merely the result of a delayed growth process. It may have been the result of all the medication she had received. Or it may have been a combined result of these, favorably influenced by her altered emotional state. But at all events the psychotherapeutic results that derived from getting her to enter college and to enjoy life, instead of a continuing of her previous pattern of psychopathological withdrawal, cannot be denied.

However, in all fairness it must be recognized that there is a significant possibility that the therapy she received, through the mobilization of unconscious forces by hypnosis, may have contributed greatly to her breast development.

Psychogenic Alteration of Menstrual Functioning: Three Instances

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, April 1960, 2, 227-231.

That menstruation may be precipitated, delayed, interrupted, or prolonged by strong emotional stress is a common observation. Usually such effects are unexpected and seemingly beyond the volitional control of the individual. Unquestionably, speaking biologically, lack of volitional control is as it should be. Nevertheless, the readiness with which an abnormal alteration of some physiological functioning is effected is often in sharp contrast to the difficulty encountered in attempting medically a purposeful directing of those same processes. Hence any instances indicating an intentional purposeful control, whether conscious or unconscious, of physiological functioning ordinarily beyond volitional influences suggest the possibility of significant research.

Following are three separate clinical accounts of an intentional, purposeful interference with the menstrual cycle. Two of the women deliberately employed hypnotic experience to effect special personal purposes, while the third utilized in a new fashion a psychosomatic pattern of reaction established in other relationships, doing this just after she had been carefully trained hypnotically for a possible correction of this pattern.

CASE 1

A young woman, an experienced hypnotic subject, had many times been much annoyed by the insistent sexual importunities of a certain man. His behavior on one occasion had disclosed to her that he had an extreme olfactory aversion for menstruation and that he invariably detected the odor and would resort to laborious methods to avoid even the slightest physical contact with a menstruating woman. She had also learned that he kept a timetable on his female acquaintances.

She was invited to a physically confining 10-day social function, which happened to be scheduled for the same time as the mid-period of her menstrual cycle. After she had accepted, a letter from the man apprised her of the fact that he, too, was an invited guest, and in this letter he suggested that they see much of each other during the entire social gathering.

She consulted this writer about the possibility of "having an early period." The frequent effects of psychological attitudes and reactions upon menstruation were explained to her, and it was then suggested posthypnotic ally that, throughout the week preceding the social function, she think and feel and sense and function as if it were the week

immediately preceding her menses. She agreed to this, and the posthypnotic suggestions were reinforced by a detailed explanation to her, in a state of ordinary awareness, of what she could expect her body to do.

She accepted the man's invitation after amending it in her reply to include daily afternoon and evening "cheek-to-cheek" dancing, an item that he fervently promised her in the return mail.

At the social affair some hours after she had induced the man to declare boastfully to the guests that he was "really out of circulation" because of a "promise to dance cheek-to-cheek" with Miss, X, her menstrual period began and lingered for 10 days instead of the usual five or six, during which time she thereby thoroughly punished the man for all of his previous affronts.

Comment

That the alteration of her menstrual cycle was simply a coincidence appears improbable. She was well aware of what she wanted to accomplish before she sought professional advice. This was given on an experimental basis. The subsequent events were in actual accord with her wishes and were also a reasonably logical outcome of the suggestions given her. Subsequent inquiry in both the trance and waking states yielded no significant information except that she had accepted the suggestions and her body had "felt the way it always does a week before my period. But I don't know how I did it."

CASE 2

An artist's model with a regular menstrual cycle and a history of profuse flow with the first few days was offered an unexpected assignment in nude posing on the second day of her period. She had had previous unsatisfactory experience with intravaginal tampons and was about to refuse the assignment when she recalled her previous experimental work with a physician interested in hypnosis and psychosomatic medicine. This led her to accept the assignment with the intention of employing autohypnosis, with which she was experienced, to inhibit her menstrual flow. A telephone call to this writer confirmed her in her intention, but no helpful advice could be given to her except that she should rely upon the capacity of her unconscious mind to function competently.

Shortly before reporting for work, she developed an autohypnotic trance and in some manner unknown to her conscious mind she inhibited the flow from 7:00 P. M. until her return home at 11:00 P. M., after 2½ hours of posing in the nude. She employed no precautions; and, as she explained, she "forgot" her period "both psychologically and physiologically." "I didn't remember after I came out of the autohypnotic trance that it was my menstrual period, and I didn't recall that fact until the flow steadily resumed as I was preparing for bed. I just forgot it as completely physiologically as I did psychologically. I still don't know how I did it."

On another occasion, where the values of the situation were significant, this same young woman discovered that her regular menstrual period would intervene and bar her attendance. Again she consulted this writer, who explained that the appearance of the menses was often temporally altered by various physiological forces, and hence, in view of her past experience in inhibiting menses, she might try the experiment of delaying her period. Instead, because she thought it the safer procedure, she induced her period 10 days early.

Subsequently she postponed her period experimentally for 10 days, beginning the period of delay the day before her period was to begin, and after the usual molimina had indicated that the menses were about to begin.

Comment

This second account is essentially an experimental study on the part of the woman. She was interested in her body and what it could do. Her knowledge of psychosomatic medicine and her extensive knowledge of hypnosis provided an ample background for her own personal investigation. How she accomplished her various purposes is not explained by her simple assertion of "forgetting physiologically." Yet one can draw somewhat of a parallel with the "forgetting" of intense hunger that can be effected by a pleasing interest. At all events her findings suggest that experimental investigations of psychosomatic alterations of physiological functioning are feasible.

CASE 3

An out-of-state woman, much in love with her husband, invariably reacted with severe physical symptomatology, prolonged from one to three weeks, whenever she became sufficiently distressed emotionally. Her symptomatology variously included marked hematuria, protracted diarrhea, severe nausea and vomiting with excessive weight loss, and disabling headaches and backaches. These conditions invariably developed suddenly, almost always after a quarrel with her husband because of her unwarranted and unreasonable jealousy. As she explained, "My sickness, no matter what kind, disappears like magic just as soon as I feel punished enough. In an hour's time I'm well, but I'm usually pretty washed out." She sought therapy to free herself from this psychosomatic pattern, and she had arranged to be away from home an indefinite length of time.

In taking her general history, she was found to have a pain-free 30-day menstrual cycle with almost exact regularity, and she carried a small calendar appointment book in which she had marked for the entire year the date of her expected periods with a notation of their actual date of occurrence. Her book was examined from January to September, and in two instances the expected date and the actual date differed by one day only.

She was found to be an excellent somnambulistic hypnotic subject, and the second and third interviews were spent in training her hypnotically for therapeutic work. On the evening of the third interview, in accord with a previous arrangement, she attempted to reach her husband by long-distance telephone and failed. (She had not made allowance

for the difference in time zones.) She developed a furious rage, went out walking, encountered a strange man, and for the first time in her life engaged in illicit sex relations. She reported this to this writer the next morning with much contrition, and added that her period was due in three days and she hoped she would not become pregnant. She postponed further interviews, stating that she would call after the second day of the expected period.

Six days later she came in to declare that she was pregnant and that she was going to seek employment and pay her own expenses throughout the period of her pregnancy. She demanded that she be placed in a deep trance and instructed emphatically that this pregnancy be impressed upon her as the final somatization of her emotional outbursts. She explained that the pregnancy would give her an adequate period of time in which to mend her "habit of always and always taking my mad out on my body." When doubt was expressed about the certainty of the pregnancy, she was emphatic in asserting that her intense awareness of her own physical experience with three previous pregnancies (the last one eight years previously, contraception since then) left no doubt in her mind. The only instruction given her in the trance, in response to her request, was that she meet her situation adequately.

She secured employment that day and was not seen until six weeks later. She brought in letters addressed to the writer from two independent obstetricians, each of whom stated that she gave good physical evidence of pregnancy and both of whom commented, at her request, upon her unusually extensive and unusually early breast engorgement in relation to her pregnancy. After the letters were read, she requested that the writer call each of the obstetricians and verify the letters, but without betraying to either that she had been examined by another physician. The telephone calls merely confirmed the letters, but one obstetrician recommended a laboratory test as "confirmatory alone." The other, when asked about this, stated that he was confident about his examination findings, but would order a laboratory test if desired. Both expressed surprise at the extent of her breast development and stated an interest in following the breast development, which seemed to indicate a pregnancy much further advanced. This was related to the patient, and she listened quietly, then asked that she be hypnotized. In the deep trance she asked that she be instructed to discuss everything on her mind.

This was done, and she launched into a discussion of her wishes and fears concerning an abortion and her aversion to such a procedure. She debated the matter back and forth, then took up the plans she was formulating for giving birth to her child secretly and in some way securing an adoptive home for it. She wanted no advice or instruction from the writer, except in the form of encouraging her to pursue her ideas as freely as she could. She finally asked to be aroused from the trance with an amnesia for what had been discussed. Out of the trance she explained that she would telephone for an appointment "some time."

Eight weeks and four days from the expected date of the missed period, she came in for an interview, bringing letters, again from two different independent physicians. These letters contained the statement and a laboratory report to the effect that physical

examination showed normal menstruation and that this was confirmed by a laboratory report of vaginal smears. She asked that a telephone call be made to each of them, again with the request that no betrayal be made that she had consulted another physician. Each physician confirmed his report and expressed curiosity as to why any woman would want a medical and laboratory examination and a special examination of her breasts to confirm a normal menstrual period. Both mentioned that, since she was an out-of-state patient, the suspicion had arisen that something illegal was involved, and hence the examinations had been most thorough. However, when she requested the letters which were to be addressed to the writer, it was apparent to them that her problem was emotional rather than legal.

The patient explained, "I just wanted you to be certain I hadn't secured an abortion, so that you would listen to me. Four days ago I woke up that morning and I knew I wasn't pregnant. I realized that I had just punished my body the way I always do when I get mad. I felt my breasts. They were smaller, the swelling had gone out of them, and they were just tender around the nipples, the way they always are just before I menstruate. So I called my boss and said I was sick and I couldn't come in, and I just stayed in my room to enjoy menstruating. It started about 11:00 A.M. and in just the usual way. And that afternoon I called doctors for appointments and explained I wanted a laboratory examination made of my vagina. I got the appointments for the next day because I always flow very lightly until after the first night. Then I had to wait until I had the lab reports, and that's why I only got here this afternoon. But now something makes me think you should hypnotize me so I can tell you what's in my unconscious mind."

In the trance state the patient explained that the sexual episode had been seized upon "to teach me a lesson. I just remembered every feeling I ever had in my pregnancies and I just made my body have those feelings, and that made me believe I was pregnant and that helped me to feel all the pregnancy feelings better. I even noticed how I started to walk like I was pregnant. I just got every one of the feelings that I learned when I was really pregnant. And I was so worried about being pregnant and what I would do and how I could stick to my job. Finally, I went to bed one night feeling just completely whipped, knowing I'd have to take my responsibilities absolutely completely. I fell asleep exhausted, and the next morning I woke up feeling wonderful, knowing I wasn't pregnant. Tell me I'm all through punishing my body. I know I am, but I want you to tell me, too." There was some additional discussion, but the above contains the essential communications.

A friendly correspondence has been maintained with this patient at fairly regular intervals for more than four years. She has had no further physical symptomatology in relation to the emotional distress. Her pathological jealousy has disappeared. Her husband's acquaintance has been made, and he also assures the writer that his wife's previous emotional outbursts and physical reactions are past history and that she is remarkably happy and well-adjusted.

Comment

This case report is a definite instance in which a patient adapted an established pattern of severe, prolonged, somatic disturbances of sudden onset and disappearance, in reaction to states of emotional stress, to a new and different personality problem involving a special order of physiological processes. It presents the intriguing problem of how extensively and how elaborately unconscious forces and motivations can be utilized to mobilize physiological functions in a systematically directed fashion. Considerable information exists in the literature about 'laboratory procedures in the conditioning of body behavior, but there is little available information on how the learnings derived from body experiences can be utilized to influence or direct selected physiological processes.

SUMMARY

These three case reports indicate, each in a different way but each in relationship to hypnosis, that somatic learnings derived from body functioning can be utilized meaningfully but in an unknown fashion. Additional such case reports could conceivably serve in the further confirmation of these findings and in the development of more understandings in this important, complex field.

Appearance in Three Generations of an Atypical Pattern of the Sneezing Reflex

Milton H. Erickson

Reprinted with permission from *The Journal of Genetic Psychology*, 1940, 56, 455-459.

Previous to the submitting of this report inquiry made of the young woman had found her mistakenly confident that no one else in her family showed this peculiar pattern of sneezing behavior. Recently an opportunity for direct inquiry and observation disclosed that the sneezing behavior of the young woman's mother was essentially identical with that of the daughter and the granddaughter. Unfortunately, however, no day-by-day record could be secured. Further direct inquiry disclosed no other instance of such unusual behavior in the family.

The purpose of this short note is to report the observation in a young woman of an atypical pattern of the sneezing reflex which was originally considered to be strictly a personal mannerism or habit of marked individuality. The error of this assumption, however, was disclosed by the reappearance of this same peculiar pattern of sneezing behavior in her new-born daughter and the subsequent discovery that an essentially identical pattern was exhibited by the young woman's mother. The situation which led to the making of this report was as follows:

Close observation of the young woman over a period of years disclosed her sneezing behavior to be that of always expecting and usually experiencing, generally within one to two seconds, a second sneeze in rapid succession to the first. Inquiry disclosed that this pattern of paired sneezes was of lifelong duration, that she had taken pride in it as a child, and that she could not remember ever having observed similar behavior in others, including her family. In this last recollection, however, she was mistaken, since, after this study had been completed originally, the author discovered by direct observation and inquiry the same peculiarity in her mother's sneezing behavior.

As a consequence of this peculiar pattern of sneezing, the young woman has developed a definite modification of her general behavior, in that on the occasion of a sneeze she arrests her activity to await a second sneeze, and should it fail to occur, she experiences a somewhat distressing sense of incompleteness. This same feeling of expectancy is also described by her mother.

Those fully aware of this young woman's oddity in sneezing tended to regard it purely as an individualism, an acquired habit based upon some chance occurrence in her early childhood, and fostered until it had become an ingrained habit. She herself regarded it as an innate, rather than as an acquired, pattern of behavior over which she had no control, constituting nothing more than an amusing physiological peculiarity and she offered the

explanation that it might be similar in character to the sneezing reflex encountered in relation to bright light or to temperature changes.

Exposure without her knowledge to nasal irritants, particularly substances to which she is allergic, does not alter this sneeze pattern, but serves rather to bring it markedly into relief, as does upper respiratory infection.

In 1938 this young woman became a mother. About three weeks later, upon her return home from the hospital with the baby, the infant was observed to sneeze twice in rapid succession. No particular attention was paid to this except to note it casually. During the next few weeks, probably because of various allergic reactions shown by the baby, many observations were made of paired sneezes in the infant and of the persistence, after the first sneeze, of the general muscular tension and facial grimaces suggestive of an anticipatory response to another sneeze, all very much in duplication of the sneezing behavior of the mother.

When approximately two months old, the baby developed an upper respiratory infection and sneezed frequently and consistently in sets of two, with the time interval between sneezes never longer than a single, usually sharp, inhalation of breath. On relatively rare occasions this inhalation would be spasmodic in character and then, instead of a single sneeze, there would be a series of two to six in rapid succession, a finding also true for the mother.

When interest was first taken in the baby's paired sneezes, both parents began watching for singles. By the time the infant was three months old a total of three single sneezes had been noted, while there had been scores of pairs. During the next few weeks, however, a constantly increasing frequency of single sneezes was noted and led to the making of a belated record of every sneeze heard. This account was begun when the baby was slightly more than four months old. A similar record was kept on the mother, the two records differing only in completeness, since all of the mother's sneezes were listed, while only those heard by either of the parents when with the baby could be recorded. Unfortunately, however, no day-by-day record on the grandmother could be secured, and it was necessary to rely upon careful inquiries. As a control measure, close attention was paid to the sneezing of five other people, two of whom suffer from numerous allergies, to note the occurrence of paired sneezes. In addition the author watched carefully for double or multiple sneezing among his numerous associates, but in no instance was a pattern of double sneezing discovered.

After the record had been kept for a considerable length of time, another peculiarity, not shown by the mother, was noted in the baby's sneezing—specifically, a light reflex sneeze. This type of sneeze tended to occur upon sudden exposure to bright light, such as being taken out-of-doors into the bright sunlight, the turning on of the electric lights at night, or the sudden flashing of a bright light into the child's eyes, and, as far as could be determined, the distribution of single and paired sneezes followed the general pattern. After making this discovery, the parents tended to avoid sudden light stimulation,

reducing somewhat the previous frequency of sneezes. In Table 1 the sneezes listed as light reflexes are known instances only. In all probability the actual total is greater.

Other observations made while keeping the record, which extended over a period of nearly four months, were that for both cases the ratio of paired to single sneezes remained essentially constant from day to day, and that upper respiratory infection and exposure to allergens served only to increase proportionately the frequency of both types of sneezes. It is also of interest to note that previous to the keeping of the record the mother believed that only rarely did she herself sneeze singly. In addition, despite the close watch kept on the sneezing behavior of a large number of people, no similar pattern was found, although a few instances of occasional multiple sneezing were observed.

COMMENT

Frequently in a specific type of behavior involving organic and psychic patterns of response, the differentiation is difficult between the behavior constituting a functioning of innate physiological and neurological processes and the behavior constituting a response of the personality itself to organic processes over which it may have little or no control. Nevertheless the attitude taken by the personality may serve markedly to alter or to distort the strictly somatic aspects of the total behavior process, and particularly is this considered to be the case when some relatively simple form of physiological behavior involving definite psychic responses manifests a striking individuality peculiar to the person.

TABLE 1
DISTRIBUTION OF SNEEZES

	Mother	*Daughter*
Single sneezes	32	125
Paired sneezes	105	212
Triple sneezes	17	20
Multiple sneezes (more than three)	4	5
Light reflex sneezes	0	20

Hence when some process of physiological or neurological behavior shows apparently purposeless and illogical variations in accord with what could reasonably be expected to result from personality factors, the assumption is made that the personality has seized upon that innate behavior and added to it learned behavior serving other and remoter purposes of the personality, as is often to be noted in psychoneurotic symptomatology.

At first thought this might seem to be the case with the young woman, especially so since her mother's sneezing behavior could furnish an opportunity for an imitative performance. However, the appearance of the same pattern in the granddaughter long before the possibility of imitation clearly indicates either an inheritance or a remarkable coincidence. In this connection references may be made to the recent extensive experimental studies on the startle pattern by Landis and Hunt (1939), who found that, "Complicated bodily responses exist and are exhibited in a pattern-like fashion—startle, Moro reflex, sneezing, coughing, and so on," and that the general pattern of these

responses tends to remain constant regardless of age, sex, and race. To this may be added that variations in the pattern may be inherited.

An Addendum to a Report of the Appearance in Three Generations of an Atypical Pattern of the Sneezing Reflex

Milton H Erickson

Reprinted with permission from *Perceptual and Motor Skills*, 1964, 18, 309-310.

In the *Journal of Genetic Psychology* in 1940 this author reported the appearance in three successive generations of an atypical pattern of the sneezing reflex. A young mother, her infant daughter, and the grandmother all show a pattern of occasional single sneezes, a large number of paired sneezes, a few triple sneezes, and rare multiple (more than three) sneezes. Respiratory infections, allergens, and the light-reflex sneeze did not alter the character of the sneeze pattern of the infant.

There was available no information on the grandmother's siblings, male or female. The grandfather, the father, and the young mother's two brothers showed only the usual sneeze pattern.

Since the publication of that paper four more children were born to the young mother, two boys, two girls. None of these showed any unusual sneeze pattern. In addition there were three slightly older step-children, two boys and one girl. The publication of the original paper aroused their interest and they spent much time and effort in attempting to learn to sneeze in pairs or triples. None succeeded.

The author employed hypnosis on a variety of *Ss* to teach them a double or triple sneeze pattern or any other variation from their established pattern. He also attempted by hypnosis to abolish the pattern of light-reflex sneezing shown by some people—that is, sneezing when stepping out of comparatively dim light into bright sunlight, or of responding by sneezing when an electric light is suddenly turned on. All such hypnotic studies resulted in only transient successes eventuating in failure, or else in no alterations at all.

In the years that have passed since the infant’s noticeable sneezing pattern led to the publication of the observations, the infant has grown up and become the mother of a baby boy who also manifests his mother’s, his grandmother’s, and his now deceased great-grandmother’s sneezing pattern, which remained in all of them a continued phenomenon. This child’s father has a normal sneeze pattern. Obviously then, the pattern is not sex-linked as was originally tentatively suggested.

Since preparing this report a mother and her only daughter have been encountered, both of whom consider their double sneeze pattern as completely normal. The mother’s parents and siblings, however, did not sneeze double and neither did the daughter's only

child, a son, nor her husband. The report was validated by the author's own observations and inquiries.

This paper may be concluded with the same final statements as the first study, namely, ". . . references may be made to the recent extensive experimental studies on the startle pattern of Landis and Hunt (1939, *The Startle Pattern*, New York: Farrar & Rinehart) who found that, 'Complicated bodily responses exist and are exhibited in a pattern-like fashion . . . startle, Moro reflex, sneezing, coughing, and so on,' and that the general pattern of these responses tends to remain constant regardless of age, sex, and race. To this may be added that variations in pattern may be inherited." One more statement can now be added, namely, that such variations are not necessarily a sex-linked inheritance.

Time Distortion in Hypnosis: I

Linn F. Cooper

Reprinted from The Bulletin, Georgetown University Medical Center, 1948, 1, No. 6, April and May, pp. 214-221.

Despite the fact that time perception is one of the most basic of human experiences, it is subject to wide variations. The commonest of these is observed in the dream, where the subject may experience many hours, or even days, of dream-life in the course of but a few minutes of solar time. Another instance of the distortion of time perception is found in cases where persons in danger have related how the scenes of their life passed slowly before their eyes in a matter of seconds or minutes. Such experiences are encountered by near-drowning persons or those having falls. Time passes more rapidly for the aging than for the young, and certain drugs, notably marijuana, are said to alter time perception. Disorders of time modality as a personal experience are found in organic brain lesions, the psychoses and psychoneuroses, and in delirium and toxic states. Pleasure may shorten the sensation of time, and pain increase it. "Time flies on Love's wings," and yet, "The watched pot never boils."

The following studies were begun in an attempt to determine whether or not time sense could be deliberately distorted in the hypnotized subject, and, if so, whether the subject could utilize "slowed" time by engaging in mental activity. As will be seen, an affirmative answer was obtained in both instances.

ABBREVIATIONS AND DEFINITIONS

W. T.—world time—solar time as measured by watch or metronome.

P. T.—personal time—subjective, experiential, or psychological time.

E. P. T.—estimated personal time-estimate, by the subjects, of the length of an interval of their experiential time.

S. P. T.—suggested personal time—a time interval suggested to the subject under hypnosis, as in, "There will be 10 minutes between the two signals," or, "You will have 10 minutes for this."

A. T.—allotted time-the time, in world time, that is allotted to a test by the operator. It is not told to the subject. Thus it may be suggested to the subject that she will have 10 minutes for a problem, while the actual interval between signals is only 10 seconds.

D. R.—demonstrated rate—in the counting experiments the subject was frequently asked to demonstrate, by counting aloud, the rate at which she counted hallucinated objects. This was done both during trance and posthypnotic ally. In the former instances the subject had finished the test and was presumably not in a phase of response to suggestion.

(D. R.)(E.P.T.)—demonstrated rate multiplied by estimated personal time—a product used in the counting tests. It indicates the count that would be reached if the subject counted at the demonstrated rate for a period equal to the estimated personal time.

A description of a test will illustrate the use of these terms. Example: The following suggestions are given:

"You're back on the farm and are going to churn some butter."

"Tell me what you see." (Subject describes the scene in some detail. She is sitting on the back porch, with a crockery churn half full of milk. She mentions the paddle with the "cross-piece on it," and the hole in the top of the churn through which the paddle passes.)

She is interrupted at this point by the observer, who continues:

"Now just stay there for a while and listen carefully. You're going to churn that milk, and it's going to take you 10 minutes, which will be plenty of time. While churning, you're going to count the strokes. I shall give you a signal to start and another signal, at the end of 10 minutes, to stop. Here comes the signal-Start."

Three seconds later, by world time, the "stop" signal is given as follows: "Now stop. The 10 minutes are up."

"Now make your mind a blank. Your mind is a blank."

"Now tell me about it. Tell me what you did, how high you counted, and how long you were churning."

She reports that she counted 114 strokes and churned for 10 minutes. Everything was very real to her. The churning became more difficult toward the end as the butter formed, and this slowed things down. She heard the churning and had plenty of time. At the "stop" signal the entire scene faded from view.

When asked to demonstrate, by counting aloud, the rate at which she operated the churn, she counted to 60 in one minute, adding that toward the end the strokes became slower because of the increased resistance from the butter. Continuing:

"I'm going to wake you up by counting to 10. You will remember all about this experience and tell me about it."

On waking she is again asked to give a report. Her story is similar to the above, including the number of strokes counted, the time estimate, and the demonstrated rate.

In this example, then, the world time (W. T.) and the allotted time (A. T.) was 3 seconds, the suggested personal time (S. P. T.) 10 minutes, the estimated personal time (E. P. T.) 10 minutes, and the demonstrated rate (D. R.) 60 strokes per minute.

The product of the demonstrated rate times the estimated personal time (D.R.)(E.P.T.) is 600. Yet the subject insists that she took only 114 strokes, that she counted each stroke individually, and that she was occupied for the full 10 minutes. When asked, posthypnotically, about the discrepancy, she has no explanation to offer.

METHOD

In brief an inquiry was made into the relations between the "world time" and the "subjective" or "experiential" time involved in various experiences suggested to the hypnotized subject. The "experiences" were listening to a metronome, counting hallucinated objects, and a diverse group of familiar activities. In some cases a time interval (S. P. T.) was suggested; in others, none. An "allotment of world time" (A. T.) was employed in many of the tests.

The subject was a young woman of 36 years of unimpeachable integrity, known to the writer for 10 years. She had had a high school education and worked as a secretary-stenographer. During the earlier tests she had no idea as to the purpose of the experiment, and accepted the suggested time intervals as real. Later she was told the truth and expressed great surprise. It was her first experience with hypnosis. The experiments were done daily for eight days and were consecutive except for an interval of one day between the first and second session. Hypnosis was induced 33 times, the trances lasting from five minutes to 45 minutes. Induction was very easy, and suggested experiences were clear and "very real." She not only "saw" clearly, but could "hear" conversations and other sounds, and could "feel" things she handled. She was unaware of odors or tastes. Emotions were "felt," sometimes spontaneously, and she was always aware of the passage of time. In comparing her suggested experiences to dreams, she described them as "making more sense," and added that "I lived them, whereas in a dream I'm more of an onlooker." It was noted that the simplest suggestions caused a rich and detailed hallucinatory production on all occasions. For this reason simple suggestions such as "You're standing in the street in Memphis" were generally employed, the subject spontaneously supplying details.

Invariably there was amnesia concerning the trance unless the suggestion was given under hypnosis that recollection would be retained posthypnotic ally. Such a suggestion was frequently given and is to be inferred wherever the subject is reported to have described her trance experiences while awake.

World time was measured by a stopwatch or a metronome.

"Personal time" was determined by asking the subject to estimate it.

Hypnosis was deep enough to produce amnesia, and catalepsy if suggested, but light enough to permit free discussion by the subject.

Because of the very nature of the experiments mathematical analysis cannot be applied to the results. The tabulation of measurements and calculations is done merely to show general trends.

METRONOME EXPERIMENT

A metronome was started at one stroke per second, and the hypnotized subject was told the rate. The suggestion was then made that the metronome was being "slowed down" to one stroke per minute. The subject confirmed this apparent slowing. She was then told that she would be given a signal (tap on the forearm), at which time she would start to review in her "mind's eye" some of her schooldays during the fifth grade, seeing in her imagination the school, the teacher, and her companions. She would do this for 10 *minutes*—that is, 10 strokes of the metronome—at the end of which time she would be notified to stop.

The metronome was stopped after 10 beats—10 *seconds*, world time—and the subject was waked up. On questioning, the following significant experiences were recounted:

a. The metronome was most certainly "slowed down."
b. A good 10 minutes had elapsed between signals.
c. c. She had "lots of time," and saw clearly the school and her classmates.
d. d. She expressed great surprise when told that the metronome had not changed rate and that actually her experience had taken only 10 seconds.

Observations similar to the above were repeated on numerous occasions, and subsequent studies showed the following:

a. With the "suggested rate" of the metronome at one stroke per minute the subject, asked to count the strokes aloud, did so at a rate of about one every five seconds rather than one every 60 seconds.
b. b. When the "slowed" metronome was stopped without the subject's knowledge, she continued to "hear" it and count the beats.

From this it was concluded that the "slowing" of the metronome experienced by the subject was an hallucination of hearing, and that during this hallucination the actual striking of the instrument was inaudible.

EXPERIMENTS IN COUNTING

There were two groups—an earlier one, Group A, made up of some 15 tests, and a later one, Group B, consisting of four tests, and which will be considered first. In all, a group of objects was suggested to the subject, and she was directed to count them.

Group B

The technique employed is similar to that illustrated in the example given in the section on abbreviations. Table 2 shows the results of four tests run at one session. The following comments are in order:

a. It is probably quite impossible for the average waking person to count 137 objects, "one by one," in three seconds of world time, much less 862 objects. Not only did the subject allege just this, but she insists that she did not hurry. For instance, in counting the cows she "walked around the edge of the field. They were very close together." With the cotton— "I used both hands and moved the bag accordingly. I picked only the ripe bolls, leaving the green ones alone. Sometimes I stopped and looked under the leaves to make sure that I had not missed any." We have already mentioned how the churning slowed down as the butter formed. It is quite obvious that the subject truly "lived" these experiences.

b. The product (D.R.)(E.P.T.) is invariably larger than the count. In other words, if the subject had counted at the demonstrated rate for the estimated time, she would have counted far higher. Yet she insisted that she kept busy throughout. She had no explanation to offer for the discrepancy, nor do we.

Group A

Prior to the above, many tests on counting had been run, but a different form of suggestion was used, and different signals. Table 1 shows the results of four of these. An example follows:

"You now see a bushel basket of potatoes."

"Now tell me what you see." (Subject here describes the scene.)

"When I give you the signal, those potatoes are going to be turned out onto the floor and you're going to count them. Take your time about it."

"I now raise your left arm. It will stay raised until you have finished counting, when it will drop to your side."

"Here's the signal—Start counting." And, as the arm dropped,

"All right, make your mind a blank. Now your mind's a blank." The time between the signals was noted and recorded.

The essential difference in the technique is that here, in Group A, no time interval is either allotted or suggested to the subject. She merely counts until the task is finished. Furthermore, whereas the signal to start is given by the operator in both groups, in Group A there is no true stopping signal, although the subject does indicate when she has finished by dropping her arm.

But why is there such a vast difference in rate of counting? It will be noted that in Group B the allotted time (A. T.) was rather short-three seconds. This figure was chosen because in other tests—i.e., taking walks—with a suggested personal time in one hour the task was completed in an allotted time of five and three seconds. When the allotted time was cut much below three seconds, however, the subject reported that she had been interrupted before her hour was up. Now, it is of great interest to note that in the Group B tests three seconds of allotted time (A. T.) sufficed, whether the suggested time (S. P. T.) was 10 minutes or an hour and 20 minutes. This makes one wonder whether, for a given individual, a suggested experience may not be "lived" within a more or less fixed interval of world time—i.e., three seconds.

We were unable to induce our subject simply to count at a specified rate. In response to the suggestion, "In the 10 minutes following the signal, you will count to 800. I'll let you know when time is up," the subject counted merely to 29 in 10 seconds, world time.

Group A included a number of counting tests. Objects counted other than those mentioned were books in bookcases, persons passing in a crowded street, sheep, houses passed while walking or driving, freight cars, sewing machine stitches, etc. There was almost always a marked discrepancy between the estimated personal time and the number of objects counted in that time. When asked about this, the subject not infrequently explained her slow counting by reporting that "I had to move the potatoes in the top layer before I could count the ones below," or, "The cattle got in each other's way at the gate," or, "I had to get down on my knees to count the books on the lower shelves," or "I had to lift the chicks out of the incubator and set them down on the floor as I counted, and that took time." These reports were all obtained while the subject was awake. Special precautions were taken, incidentally, in all the reporting to make certain that the subject was not unconsciously adding new "experiences" to those she was supposed to be recalling from her trance. On repeated occasions reports taken during the trance were compared with those taken posthypnotically, and there were never any appreciable differences.

Notes concerning the counting tests:

a. Where there was no allotted time or suggested personal time, that is, in Group A (Table 1) the counting rate in world time was slower than in Group B (Table 2), where there was an allotted time of only three seconds.
b. As shown by the demonstrated rates, 36 to 76 for Group A and 60 to 80 for Group B, the subject thought that she was counting fairly slowly. Yet actually she was

often "counting" very rapidly, the average rates being 204 and 6120 per minute for Group A and B, respectively.

c. She "lived" these experiences, and they were, to her, very real. At no time was she aware of hurrying.
d. On posthypnotic interview she stated that the "counting" and the "thinking" she did during trance differed in no way from normal counting and thinking.

PROBLEMS

In these tests the subject was presented with a problem to consider, and given both an allotted time (10 seconds, world time) and a suggested personal time (10 minutes) for its completion. The following example will illustrate the technique:

"I'm going to give you a problem to solve in 10 minutes. After I tell you the problem, you will receive a signal, at which you will start working on it. At the end of 10 minutes I shall give you the signal to stop. You will have plenty of time."

TABLE 1

Group A	*W.T.*	*S.P.T.*	*Count*	*E.P.T*	*D.R.*	*(D.R)x (E.P.T.)*
Counting cows	65 sec.	—	664	30 min.	36/min.	1080
Counting soldiers	82 sec.	—	90	10 min.	72/min.	720
Counting churn strokes	100 sec.	—	115	10 min.	76/min.	760

W.T. – World Time
A.T. – Allotted Time
S.P.T. – Suggested Personal Time
E.P.T. – Estimated Personal Time
D.R. – Demonstrated Time

"Now here is the problem. A young girl is in love with a young man who wants to marry her. However, the girl has an invalid mother who is dependent upon her and to whom she feels obligated. She hesitates to marry because she does not wish to burden her fiancée with her mother, and yet she is very anxious to get married and does not wish to sacrifice her entire life to her mother. These young people want your advice."

"When I give you the signal, you're going to think this situation over from all points of view and afterward tell me what conclusion you came to." "Here comes the signal—Start."

Ten seconds, world time, later she was told, "Time is up. Now tell me about the problem."

The subject reported that she saw and talked to a young man and a girl about this, their problem. She discussed the matter at length with them, asking the girl various questions and receiving answers. She suggested that the girl work after marriage in order to support her mother, who, she felt, should not live with the young people but rather with some friend her own age. She did not think that the girl should give up her life to her mother, but on the other hand she shouldn't shirk her responsibility. She should marry by all means. She talked mostly to the girl. "The boy didn't have much to say."

Her account of this experience was amazing in the fullness of detail and the amount of reflection that it apparently indicated. This was especially surprising in view of the fact that in waking life the subject is not prone to speculate on matters. When told that she had thought the problem through, not in 10 minutes but rather in 10 seconds, she was astounded.

Numerous other problems were presented from time to time, among them the following:

> Should a young girl, daughter of well-to-do parents, seek a job?
> What are the relative merits of government and private industry employment?
> Are you in favor of compulsory military training?
> What do you think about segregation of the Negro in the South?

TABLE 3

Activity	*W.T.*	*S.P.T.*	*E.P.T.*
Walking	65 sec.	30 min.	30 min.
Picnic	130 sec.	"all day"	9 hrs.
Day's activities	115 sec.	day	9½hrs.
Walking	10 sec.	none	30 min

See Table 2 for explanation of abbreviations.

TABLE 4

Activity	*S.P.T.*	*A.T.*	*E.P.T.*
Walk a.	1 hr.	5 sec.	1 hr.
Walk b.	1 hr.	3 sec.	1 hr.
Walk c.	1 hr.	1 sec.	"30 or 40 mins."

See Table 2 for explanation of abbreviations.

In every case the reports gave evidence of careful and thorough consideration, and the estimated personal time interval was always the same as the suggested one. She didn't have to hurry. She always "saw" something—that is, she saw and talked to the young couple; she saw the girl who was discussing the job; she saw a government office building and a factory; in considering the segregation problem she was watching a group of poor and shabby blacks in a small southern town. A fishbowl with names in it appeared while she was considering compulsory military training.

The last test done was given a suggested personal time of 10 minutes but an allotted time of only three seconds. The subject reported that she seemed to be working on it for 10 minutes, and gave a very complete account of her "thoughts."

OTHER EXPERIENCES

All sorts of activities were suggested to the subject, among them the following: Reviewing previous periods of her life in her "mind's eye." Listening to a band. Taking walks. Going on picnics. "Reliving" periods of her life. Dreaming.

Sometimes she would be told to engage in a given activity for a suggested length of time, and to signal by dropping her raised arm when the time was up. Table 3 shows the relation between suggested personal time and world time in some of these cases.

Usually there was both an allotted time (A. T.) and a suggested personal time (S. P. T.), the interval being designated by signals. Almost without exception the subject's estimate of the interval was the one that had been suggested to her. However, where the A. T. was too short, the estimated personal time would be less than the suggested one "because you interrupted me before the hour was up." This led to a series of "one-hour walks" with gradually decreasing allotted times. "The walks," incidentally, were over the same "route" each time. Table 4 shows the results.

In one test the subject was simply told that a band was playing and that she was to listen to it. She was interrupted after 30 seconds and reported that she had been listening for nine minutes. No time had been suggested to her.

On several occasions dreams were experienced as the result of suggestion. Time in these dreams showed the same sort of distortion that is seen in normal ones. Their duration was indicated by the subject dropping her arm when the dream was over.

DISCUSSION

We do not feel qualified to say what the nature of hypnotically induced experience is. What, if any, relation does the "counting," and the "thinking" of this subject, under hypnosis, bear to such activities carried out by her while awake? What is this amazing state of affairs that permitted this subject—"in her mind," of course, but with complete sense of participating—to pick and count 862 cotton bolls in three seconds, carefully selecting each one and occasionally looking beneath the leaves "to make sure that I had not missed any"? We do not know.

We are certain, however, that our subject's sense of time was altered, more or less at the will of the operator, and that in this altered time which he bestowed upon her she had experiences that were very real to her. These, while occurring at a normal rate as far as she was concerned, actually moved incredibly fast according to world time. Furthermore they were experiences that, to a considerable degree at least, "made sense." This in itself is indeed intriguing and causes one to wonder if, under hypnosis, judgments may not be made, and decisions arrived at, in a mere fraction of the world time ordinarily required. Also, it makes one wish that ideas could somehow be introduced into the human mind with a speed proportional to that of the mental activity of this hypnotized subject.

Time Distortion in Hypnosis: II

Linn F. Cooper and Milton H. Erickson

Reprinted with permission from *The Bulletin Georgetown University Medical Center*, 1950, 4, 50-68.

GENERAL INTRODUCTION

In a previous communication (Cooper, 1948) findings were presented which indicated that time sense can be deliberately altered by hypnotic suggestion. Thus a 10-second interval by the clock might seem to be one of 10 minutes to the hypnotized subject. Furthermore the individual concerned might report that he had had an amount of subjective experience in the form of hallucinated activities, thought, feeling, and the like—all proceeding at a normal rate-that was more nearly appropriate to the subjective 10 minutes than to the brief 10 seconds recorded by the clock. One of the inferences from these results is that mental activity, under the conditions described, can take place at extremely rapid rates while appearing, to the subject, to progress at customary speeds. In the present paper a further inquiry is made into this phenomenon. After a brief consideration of time it proceeds to the presentation of experimental results, followed by an analysis of the findings and a discussion of their significance.

Notes on Time and the Concept of Time Distortion

> Einstein has made the following statement: The experiences of an individual appear to us arranged in a series of events; in this series the single events which we remember appear to be ordered according to the criterion of "earlier" and "later." There exists, therefore, for the individual, an I-time, or subjective time. This in itself is not measurable. I can, indeed, associate numbers with the events, in such a way that a greater number is associated with the later event than with an earlier one. This association I can define by means of a clock by comparing the order of events furnished by the clock with the order of the given series of events. We understand by a clock something which provides a series of events which can be counted. (Barnett, 1950).

While the hands of a clock move form one position to another, an infinite number of other changes take place in the cosmos. And wherever that phenomenon which we call awareness exists, there is probably a sense of the passage of time, and a sense of sequence. In other words subjective experience seems to be inseparably interwoven with time sense, which, as is true of other primary experiences, is indefinable. Yet we all know what it is, and we apparently conceive of it as a magnitude, for we speak of a long or a short time, and readily compare intervals one with another. And our perception of it as a magnitude differs from that of another magnitude—space—in a strange way. Time seems to be of us, and inseparable from our very existence. Furthermore one is tempted to think

of subjective time as extending from future to past in a direction at right angles, so to speak, to all other experience.

Although we cannot at present measure subjective time, we can gain some idea of the seeming duration of an event or interval by asking a person, "How long did it seem?" He may then reply, "It seemed like 10 minutes," meaning, of course, that his sense of the passage of time was approximately that which he generally experiences when the clock hands advance a certain distance—i.e., 10 minutes. Were we to inform him that actually the clock had advanced by only five minutes, he might reply, "It seemed longer than it was [by the clock]." Thus we all come to associate a certain quantity of subjective time with a given amount of movement of the clock hands. Exactly how we do this is not known, but certainly we are aided by observed changes in the physical world. At any rate it is common experience that a given world time interval may seem longer or shorter, depending upon the circumstances. When the difference between the seeming duration of an interval and its actual duration is great, we say that time distortion is present.

Time distortion is most commonly seen in the dream, where many hours of dream—life may be experienced in but a few minutes by physical time. Furthermore, the phenomenon is not infrequently encountered in times of danger or narrow escape, where intervals of but a few seconds may seem to be greatly prolonged. In such cases the long subjective interval may be filled with thoughts and images proceeding at an apparently normal rate, and movement in the physical world, actually often very rapid, may appear to be in "slow motion." It is by no means rare for the individual involved to report that in the emergency his performance was improved because he seemed to have more time for decisions.

There are numerous other conditions under which time distortion occurs. Thus a given interval may seem to be prolonged in the presence of pain, discomfort, anxiety, anticipation, or boredom. On the other hand it may seem shortened during pleasure, amusement, or interest.

The perception of time may be altered also by organic brain lesions, certain drugs, the psychoses and psychoneuroses, delirium, and toxic states. In general time seems to pass more rapidly for the aging than for the young.

Welch (1935-1936) has made a study of time distortion in hypnotically induced dreams, and Erickson (1937) has reported the phenomenon in a hypnotized subject who was reliving past events. Inglis had a subject who claimed to be able to being about an apparent slowing of observed physical phenomena at will, and to have employed this ability to advantage while boxing, when it aided him in placing blows.

Finally, time sense can be deliberately altered by hypnotic suggestion and a predetermined degree of distortion thus effected, as reported in an earlier communication.

Finally, time sense can be deliberately altered by hypnotic suggestion and a predetermined degree of distortion thus effected, as reported in an earlier communication.

Depending upon the circumstances, certain changes in subjective experience may accompany time distortion. The following outline present some of the more important of these:

The Narrow Escape:
- A given world time interval seems prolonged.
- Sensory experience:
  - All sensory experience may seem to be slowed down, action appearing to occur in "slow motion." Actually, high speeds in the physical world are often involved.
- Non-sensory experience:
  - Thought, imagery, etc., are often much increased in amount per unit of world time. As far as the person involved is concerned, the activity seems to proceed at a normal rate.

The Dream:
- A given world time interval may seem much prolonged.
- Sensory experience:
  - Physical stimuli are usually not experienced as such.
- Nonsensory experience:
  - Much dream activity may take place in a short world time interval. This activity appears, to the dreamer, to proceed at the normal rate.

Hypnosis (with "slowed" time):
- A given world time interval may seem much prolonged.
- Sensory experience:
  - In the few cases where sounds have been "injected" into hallucinatory experiences, their apparent duration was increased.
- Nonsensory experience:
  - Much activity may take place in a very short world time interval. This activity appears, to the subject, to proceed at a normal rate.

Boredom:
- A given interval seems prolonged.
- Sensory experience:
  - No change.
- Nonsensory experience:
  - No change.

DEFINITIONS AND ABBREVIATIONS

P.T. —personal time—I-time-subjective, experiential, or psychological time.

E.P.T. —estimated personal time—estimate, by subjects, of the length of an interval of their experiential time.

S.P.T. —suggested personal time—a time interval suggested to the subject under hypnosis. In these experiments the subjects came to think of this as "special

time." Hence such expressions as "You're going to spend 20 minutes of your special time . . ." were frequently used.

A.T. —allotted time—the time, in world time, that is allotted to a test by the operator. It is not told to the subject. Thus it may be suggested to the subjects that they will have 10 minutes for a problem, while the actual interval between signals is only 10 seconds.

D.R. —demonstrated rate—in the counting experiments the subjects were frequently asked to demonstrate, by counting aloud, the rate at which they counted hallucinated objects. This was done both during trance and posthypnotically. In the former instances the subject had finished the test and was presumably not in a phase of response to suggestion.

(D.R.) (E. P. T.) —demonstrated rate multiplied by estimated personal time—a product used in the counting tests. It indicates the count that would be reached if the subject counted at the demonstrated rate for a period equal to the estimated personal time.

(D.R.) (W.T.) —demonstrated rate multiplied by world time-the count that would be reached if the subject counted at the demonstrated rate for a period equal to the world time.

Time Distortion—a marked difference between the seeming duration of a time interval and its actual duration as measured by the clock.

A description of a test will illustrate the use of these terms:

"You now see a large bag full of jelly-beans on a table. . . . Now tell me what you see." The subject describes the scene.

"Stay there, please, and listen to me. When I give you the starting signal by saying 'Now,' you're going to spend at least 10 minutes (of your special time) taking them out of the bag one at a time, counting them as you do so, and placing them on the table in piles according to color. Please don't hurry. At the end of 10 minutes I'll give you the signal to stop." "Here comes the starting signal. 'Now.'"

Ten seconds later—"Now make your mind a blank please. Your mind is now a blank. Tell me about it, please."

The subject reports that he counted 401 candies and gives the approximate number in the black, white, and red piles. Others were blue, yellow, green, and pink. He tells how the piles were located, and notes that some of the black ones fell on the floor. He tells of wondering whether the spotted white ones, which he used to know as "bird's eggs," are still flavored with banana. He counted "one by one," without hurrying, counting for what

seemed to be about eight minutes. There were no omissions. When asked to demonstrate, by counting aloud, the rate at which he worked, he counts to 59 in one minute.

In this example, then, the world time (W.T.) and the allotted time (A.T.) was 10 seconds, the suggested personal time (S.P.T.) 10 minutes, the estimated personal time (E.P.T.) 8 minutes, and the demonstrated rate (D.R.) 59 per minute.

SUBJECTS

The subjects were divided into two groups, an earlier one of four, which worked for a period of seven weeks, and a later one of two, which worked a little over a week. All except one had had a college education. All were much interested in the experiments, cooperative, and eager to improve their performance. They were paid by the hour.

Subjects A, B, C, D were not informed concerning the nature of the problem until the end. With subjects E and F, on the other hand, this was discussed at the start.

Table 1 gives further information about them.

METHODS

In essence the experiments consisted in suggesting to the hypnotized subjects that they perform certain hallucinated activities and in studying the relationship between the experiential and the physical time involved. In the majority of tests an allotted time (A.T.) was used. In a few instances the hallucinated activity was explored by means of injected sound signals.

TABLE 1

Subject	*Age*	*Sex*	*Marital*	*Education*	*Occupation*	*Interest*	*Number of tests*	*Experimental hrs.*	*Prev. hypnosis*
A	25	M	M	College	Student	Psychology	213	39½	Some
B	23	F	M	College	Student	Psychology	202	31	None
C	23	F	S	College	Student	Psychology	184	32	5 hrs.
D	32	F	M	College	Teacher	Music	139	35	None
E	18	F	M	High School	Housewife		41	12	None
F	28	M	M	College	Student	Psychology	29	7	Some

There follows a partial list of the activities used:

Buying various things
Counseling
Counting various objects
Dancing
Dreaming
Free association
Group discussion
Housework
Listening to a metronome
Listening to music

Making decisions
Mathematics
Painting
Sewing
Seeing movies and plays
Thinking
Walking and riding
Watching games
Writing letters

Induction of a simple trance state was effected by suggestions of sleep. Posthypnotic amnesia was routinely suggested with the earlier group of subjects, but was only partially successful. The later group was told that they could remember the trance experiences if they so desired.

As a rule the suggestions were read from cards to insure uniformity. Timing was done with a stopwatch. There were two kinds of sound signals used, one the striking of a (damped) tumbler with a metal knife; the other a note on a pitch instrument.

The work was done in the afternoon, the usual session lasting an hour. During trance the subjects lay supine on a bed with their eyes closed.

Notes on Suggestions

In the following discussion a completed activity is one which progresses to the fulfillment of certain stipulated or implied conditions (none of them concerning the duration), at which point it reaches completion. Examples are drawing a picture, making some toast, counting a given number of objects, walking a certain distance, etc. Incomplete, or continuous, activities are those which do not progress to such a limit.

It will be noted that we have defined the completed activity as being limited by considerations other than duration. This is done in order to permit a special treatment of the time factor.

The degree of time distortion and the amount of subjective experience occurring within the experiential time interval depend upon various factors. Important among these are the absence of presence of an allotted time (A.T.) and its duration, the assigning of an incomplete or a completed activity, and the absence or presence of a suggested personal time (S.P.T.) and its magnitude. A classification of suggestions according to these considerations will be given below.

Suggestions were introduced by the expression, “Now give me your attention please. When I give you the starting signal by saying ‘Now,’ you are going to. . .” The activity itself was then suggested. If it was felt advisable to “clear” the subjects’ minds of residual scenes before the above introductory statement, they were told, “Now any scenes that

you've been witnessing are disappearing from view. They have now disappeared, and your minds are now a blank."

The method of termination of an activity depended upon the absence or presence of an allotted time.

(a) In the absence of an allotted time (A.T.), and when the suggested activity was a completed one, the subjects were instructed to notify the operator when they had finished the assignment. They were told, "When you've finished, you'll let me know by saying 'Now.'" This was also done with incomplete activities without an allotted time (A.T.), which were always given a suggested personal time (S.P.T.) in these experiments.

(b) In the presence of an allotted time (A.T.) the termination of the activity was, of course, brought about by the operator. It was our practice to say nothing to the subjects concerning the fact that they would be told when to stop. One may, if one wishes, say, "After a while I'll tell you to stop." Or, in those cases where a suggested personal time (S.P.T.) is used, "At the end of so many minutes [constituting the S.P.T.], I shall tell you to stop." The actual terminating suggestion, given when the allotted time (A.T.) had expired, was "Now make your mind a blank. Your mind is now a blank." No mention of the allotted time (A.T.) as such was ever made to the subjects while in trance.

In assigning a suggested personal time (S.P.T.) to an activity the following form was used: "—you're going to spend (at least) 10 minutes (of your special time) watching a baseball game." The phrases in parentheses were used frequently in the later experiments. The "at least" gives a certain leeway to the subject, and the "special time" gives expression to the uniqueness of distorted personal time, a concept which the subjects came to appreciate of themselves.

In the classification of activity suggestions, code designations are built upon the following symbols:

A.T.0—no allotted time was used.
A.T.+—an allotted time was used.
A—an incomplete activity.
B—a completed activity.
1—no mention is made concerning the duration of the activity.
2—subject is told, "You'll have plenty of time," or, "There'll be plenty of time."
3—a definite suggested personal time (S.P.T.) is assigned.

Thus A.T.0, Al means that no allotted time was used, that the activity was incomplete, and that no stipulation was made concerning its duration.

Classification of Suggestion Types

I. Without Allotted Time.
Incomplete Activity.

Without suggested personal time. (Code A.T.0,A1.)
"—you're going to go walking."
With suggested personal time (Code A.T.0,A3.)
"—you're going to walk for 10 minutes."
Completed Activity.
Without suggested personal time. (Code A.T.0,B1.)
"-you're going to draw a picture."
With suggested personal time. (Code A.T.0,B3.)
"—you're going to spend ten minutes drawing a picture."

II. With Allotted Time.
Incomplete Activity.
Without suggested personal time.
(Code A.T.+,A1.)
"—you're going to go walking."
With suggested personal time. (Code A.T. +,Ae).
"—you're going to spend 10 minutes walking."
Completed Activity.
Without suggested personal time. (Code A.T.+,B1.)
"—you're going to draw a picture."
With suggested personal time. (Code A.T. +,B3.)
"—you're going to spend ten minutes drawing a picture."
Termination suggestions.
I—as in paragraph (a) above.
II—as in paragraph (b) above.

After a test activity was finished, the subjects were asked to report on their experience. The following form of request was used: "Now tell me about it please," or, "Now tell me what you did."

Other questions were then asked, such as the following:

"Was it real?"
"Were there any omissions or gaps?"
"Did you hurry?"
"How long was it?" —"How long did it take?" —"How long did it seem?"
"Were you aware of the sound signal?"
"How high did you count?"
"Did you enjoy it?"

RESULTS

Introduction

In these experiments the results consist of the reports of our subjects plus the actual time observations by the experimenter. The reports in turn are descriptions of subjective experiences while responding to suggestions in hypnosis. So amazing are they, when their time relations are considered, that the opinion has been expressed in connection with

previous, similar work that the subjects, in reporting, probably resort to restrospective falsification, elaborating on a very meager original experience in order to please the operator.

Thus we are faced at the start with the question—"Did these subjects really have the experiences they say they had?" The question is one of the utmost importance and is, by its very nature, most difficult to answer. The difficulty arises from the fact that purely subjective phenomena cannot be shown to another person and thus proven to exist by demonstration. It is true that, because we all claim to have such experiences as dreams, emotion, thought, sensation, and the like, we readily grant that our neighbors also have them. Consequently these phenomena have come to be accepted as realities that are experienced by mankind as a whole. However, the sort of experience reported in this and in a previous paper has been had by too small a group to attain acceptance in this manner. Moreover we cannot at present know these alleged phenomena "by their fruits," for they have not yet been correlated sufficiently with behavior, nor has "operational" mental activity yet been demonstrated to occur more rapidly in "prolonged" time than normally.

The best we can do under the circumstances is to give an account of our subjects' reports, which are fairly numerous and uniform, and to hope that the reader will find them interesting and will speculate upon their significance. Indeed, our ignorance of the nature of subjective phenomena per se is abysmal. Yet in a sense these are the most "real" part of existence. Our relatively great knowledge of the physical world has been won largely as the result of our ability to apply to it the process of measurement. This process, unfortunately, can be used only indirectly in the study of the subjective time to be in the nature of a magnitude—which won't stand still long enough to be measured. It is obvious that we need some other tool for our work, possibly a tool of new and strange design.

Table 2 gives some of the significant data on certain tests. These were selected because they show the performance of the subjects at their maximum proficiency after adequate training.

Generalizations from Results

The following generalizations can be made on the basis of our results.

There is a marked difference between subjects as regards their ability to produce the various phenomena under study. This is to be expected, and it is mentioned here in order to call attention to the fact that the amount of training required is variable within wide limits. Thus one subject may require only three hours training while another may require 20.

In all cases the reports were simple narrative accounts of a recent experience, given in much the same way as any waking person might go about answering the request, "Tell me what you did this morning?" The amount of detail varied with the individual. Because of the time required for complete reporting, the subjects were usually asked to be brief.

All subjects showed the phenomenon of time distortion, and all were able to engage in mental activity during the prolonged subjective time intervals. This activity proceeded at a rate considered normal or usual so far as the subject was concerned, yet its amount was greatly in excess of what the world time interval would ordinarily permit.

TABLE 2

Subject	*Code*	*Activity*	*W.T.*	*A.T.*	*S.P.T.*	*E.P.T.*	*Count*	*D.R.*
A	A.T.0 B1	Walking one mile	59”			13’		
A	A.T.0 B1	Watching movie short	1’35”			12’		
A	A.T.0 B1	Walking to school	1’			20’		
B	A.T.0 B1	Walking to school	6”			20’		
B	A.T.0 B2	Painting a picture	1’			15’

C	A.T.+ B3	Counting flowers (150)*		10”	10’	10’	145	
C	A.T.+ B3	Counting pearls (200)*		10”	10’	10’	100	

W.T.—world time.
E.P.T.—estimated personal time.
A.T.—allotted time.
D.R.—demonstrated rate, in terms of items counted per minute
S.P.T.—suggested personal time.
*—subject to count at least this number.

In all cases performance improved with practice.

All four subjects who worked with the metronome were able to effect marked slowing of the instrument. With two of these, practice was required.

Four out of the five subjects who practiced counting activities during time distortion achieved satisfactory results. The fifth had difficulty but showed progressive improvement, and there is reason to believe that she would succeed with further training.

All subjects were astonished by the things they did, some of them strikingly so, when informed of the facts.

Sound signals could be introduced into hallucinated experiences in all cases in which this was tried with sufficient care. Their position in the experiential time interval corresponded fairly well to that in the world time interval.

Individual Reports

The following two case reports are presented:

(1) "What would you like to do now?"

"My husband molds bullets for his gun. I could be counting them as he makes them."

"For how long do you want to do this?"

"For 10 minutes."

The following suggestions were then given:

"When I give you the starting signal by saying 'Now,' you're going to spend at least 10 minutes of your special time counting bullets as your husband makes them."

"If the sound signal is given, you will be aware of it."

"Here comes the starting signal—'Now.'"

The pitch instrument was sounded from the fourth to the seventh second.

At the end of 10 seconds—"Now make your mind a blank. Your mind is now a blank."

"Now tell me about it."

"It was at a molding party of the club. There was quite a crowd there. I counted for maybe six minutes and ran out of bullets, so I waited for more. I. didn't count the full 10 minutes. While I was counting them, this other boy walked up—he was talking and

waving his arms. The pot of lead tipped over. It burned his foot rather badly. I got up but then sat down again and continued counting. The others were running all over the place. The remainder of the lead we put back on the stove. I counted 493. That's when I stopped and waited. Then later I got up to 546. "

"Did you hurry?"

"I didn't hurry too much as I was counting, but I kept busy."

"Was it real?"

"Yes."

"When I give you the signal to start, please show me, by counting aloud, how you counted the bullets. Now."

Subject counted at a rate of 54 per minute. "Were you aware of the sound signal?"

"When they spilt the lead, it sizzled a lot."

"How long was the sizzling?"

"It seemed like three or four minutes."

(This interpolation of the sound signal into the hallucinated activity will be discussed later.)

(2) "What would you like to do now?"

"To package some cookies. I used to do this."

"For how long?"

"Twenty minutes."

The following suggestions were then given.

"When I give you the starting signal by saying 'Now,' you're going to spend at least 20 minutes of your special time packaging cookies. As you do this, you'll count them. If the sound signal is given, you will be aware of it. Here comes the starting signal—'Now'."

The pitch instrument was sounded from the fifth to the eighth second.

At the end of 10 seconds—"Now make your mind a blank. Your mind is now a blank."

"Now tell me about it please."

"I was down in the basement. There were worktables. I was counting. I counted them as I put them in the smaller sacks. I counted 1,003. That was all I got. In the middle the telephone outside rang on and on. Just after that there was so much cookie dust all over that I started to sneeze. I sneezed 10 or 12 times. I just couldn't stop. I dropped one package. I didn't answer the phone."

"When I give you the signal to start, please show me, by counting aloud, how you counted the cookies. 'Now'."

Subject counted at a rate of 60 per minute. "How long did the telephone ring?"

"It must have been five or six minutes. No one answered it outside." "When I say 'now,' please recall parts of the scene and see if you can tell me what the count was when the phone started ringing and when it stopped."

"It was about 498 when it started, and 889 when it stopped."

"Was it real?"

"Yes."

"Were there any omissions?"

"None."

"How long was it?"

"Probably 23 minutes."

The code designation for the two above tests, and for the one below, is A.T. +,A3.

The following account gives one an idea of the richness of these subjective experiences:

Having said that she would like to spend a half hour riding in an automobile, the subject told how she and her sister, both children at the time, sat on the back seat of the car and counted cows seen along the way. Her sister won the game, counting 45 to her 42. Then they decided to count license numbers bearing the letter C. This was slow, for there was but little traffic. They both saw the same ones, 14 in all. Then they stopped at a roadside stand to buy lemonade from a little girl with pigtails and several missing teeth because they "felt sorry for her." The experience was continuous, without omissions of any kind, and seemed to last "a half hour easy." Asked if she enjoyed it, she replied, "Oh yes!" Actually this elaborate response to the simple suggestion "You're going to spend at least a half-hour of your special time riding in an automobile, and it's going to be a nice ride," took place in an allotted time of 10 seconds.

Counting

By far the most dramatic results were those obtained in the counting experiments. These were usually run as incomplete activities, with a short allotted time (A.T.) and a moderately long suggested personal time (S.P.T.) In a few instances, however, the suggestion was put in the completed form by saying,

"Since you can easily count 30 in a minute, you will have no difficulty counting at least 300 in 10 minutes. Please take your time and don't hurry." This was generally done during training in an attempt to utilize the performance-increasing value of the completed activity.

Generally the subjects were given a "preview" of their surroundings in the following manner:

"You now see several large bags of gum drops on a table. Please tell me what you see."

Then, after a brief description by the subject, "Stay there now, and listen to me."

The activity suggestion was then given.

Table 3 shows the more important data on the counting tests done after proficiency had been attained.

It will be noted that the count, although much greater than the product (D.R.) (W.T.), is almost invariably less than (D.R.) (E.P.T.). Sometimes the subjects had no explanation for this. At other times they ascribed the discrepancy to the fact that part of the time was occupied otherwise than by counting.

TABLE 3

Subject	*Code*	*Counting*	*A.T.*	*S.P.T.*	*E.P.T.*	*Count*	*D.R.*	*D.R x E.P.T.*
A	A.T.+ A3	Flowers	10”	10’	8’	140		
A	A.T.+ A3	Flowers	10”	10’	7’	41	48	336
A	A.T.+ A3	Flowers	10”	10’	1-‘	35	42	420
A	A.T.+ A3	Pennies (50)*	10”	10’	3’	28	19	57

E	A.T.+ A3	Strawberries	20”	60’+	50’	600		
E	A.T.+ A3	Tomatoes	20”	60’+	40’	225		
E	A.T.+ A3	Bullets	10”	10’+	10’	546	54	540
E	A.T.+ A3	Flowers	10”	15’+	15’	973	60	900
E	A.T.+ A3	Cookies	10”	20’+	23’	1003	60	1380
F	A.T.+ A3	Nuts	20”	20’+	20’	400	66	1320
F	A.T.+ B3	Candies (200)*	10”	10’+	60’	2500	72	4320
F	A.T.+ A3	Flowers	10”	10’+	10’	60		

W.T. —world time.
E.P.T. —estimated personal time.
A.T. —allotted time.
D.R. —demonstrated rate, in terms of items counted per minute
S.P.T. —suggested personal time.
*—subject to count at least this number.
+—time suggestion was preceded by the phrase “at least.”

Sound Signals

The idea of exploring hallucinatory activities by means of injected sound signals was suggested to us by Dr. J. B. Rhine.

In one group of tests the subjects were told to take a familiar walk-from house to school. No allotted time (A.T.) or suggested personal time (S.P.T.) was used. Thus the code designation is A.T.0, Bl. A single short sound signal, produced by striking a damped glass with a metal knife, was employed at various intervals from the start. The subjects were then asked to estimate, at the end of the test, the personal time of the entire experience and the approximate location of the sound signal. The latter they usually did by considering where, in their walk, they were when they heard the signal. The accompanying figure shows the relation of the signal to world and experiential times. In other cases a pitch instrument was sounded for a known length of time during an activity with an allotted time. The subject was later asked to estimate its duration. Some of the results are shown in Table 4.

The pairs of lines represent the world time interval (a) and the personal time interval (b) for a given test. The markers show where the sound signal actually occurred in relation to the world time interval (on lines a), and its location in the personal time interval (on lines b), as determined by asking the subject how long it seemed from the beginning of the activity to the signal. Note that the subject locates the signals with fair accuracy. The chart above is based on the following data:

	World Time (secs.)		*Estimated Personal Time (min.)*	
Subject A	Signal	Total	Signal	Total
(1)	60	155	5	12
(2)	20	105	1.5	10
(3)	60	164	3.5	12
(4)	90	192	5	12
(5)	120	252	5	12
Subject B				
(1)	60	133	10	20
(2)	90	135	14	20
(3)	110	133	17	20
(4)	30	107	4	20
Subject C				
(1)	30	163	3	30
(2)	120	137	28.5	30
(3)	60	159	13	30
(4)	90	210	17	37
(5)	46	196	4	30

TABLE 4

Subject	*Activity*	*Code*	A.T.	Sess.	Est.	*Sound Signal*		
						Time	*Appearance Form*	*Est. Duration*
E	Baking cake	*A.T.+ B3*	15”	15’	10’	5th to 10th sec.	Auto horn stuck	3’ or 4’
E	Mowing lawn	*A.T.+ A3*	10”	10’	10’	3rd to 5th sec.	Squeaking	2’
E	Counting bullets	*A.T.+ A3*	10”	10’	10’	4th to 7th sec.	Sizzling lead	3’ or 4’
E	Picking flowers	*A.T.+ A3*	10”	15’	15’	5th to 8th sec.	Bird singing	5’
E	Embroidering	*A.T.+ A3*	10”	15’	15’	4th to 7th sec.	Radio static	3’ or 4’
E	Counting cookies	*A.T.+ A3*	10”	23’	23’	5th to 8th sec.	Telephone ring	5 or 6’
F	Watching basketball	*A.T.+ A3*	10”	5’	5’	5th to 6th sec.	“Funny noise”	1’
F	Picnic	*A.T.+ A1*	20”	20’	10’	10th to 15th sec.	“Like a train”	‘Quite a while’

The subjects, even though forewarned, were not always aware of the sound signal, and when they were, it was experienced in various forms.

Striking the glass, to some subjects, sounded exactly as it does normally and did not take on any significance in the hypnotic scene. More often, however, it was heard, as a somewhat similar sound, such as a tumbler dropping on the floor, one striking the side of the pitcher, an object falling on a hard surface, etc. Sometimes, however, the actual sound signal acquired an entirely different significance, e.g., the sizzling of the lead and the ringing of the telephone noted above.

Since the subjects had been led to expect a sound signal, they quite possibly anticipated it and included appropriate "properties" in their hallucination. Thus in three successive counseling scenes glass was present either as a tumbler or a pitcher.

Even so there is much food for thought here, for an object must fall before it can strike the floor and make a noise, and there must be some cause for the fall. Somehow or other all this is arranged in a most skillful way. Interestingly enough, to one subject the sound signal came just as he struck a pole with a stick. After telling about it he added, "I had anticipated hitting the pole, for I saw it in the distance." It may be that there is a definite lag between the communication of the signal to the brain and its entry into the hallucinated world as an appropriate part of the picture.

Similarly with the pitch instrument, at times it was unchanged, but more often it was altered.

The presence in our group of two musicians, one with "absolute pitch," gave us the opportunity of determining whether a sound, coming into the hallucinated world of altered time sense, would itself be altered in tone, i.e., lowered, by virtue of the new time relations. (Suggested by P. F. Cooper, Jr.). The answer apparently depends upon the degree to which the sound is disguised. In hallucinations where it was heard as a horn and an air-raid "all clear," the pitch was recognized as C. Usually, however, there was little resemblance to the original, the pitch instrument being heard variously as a bird, a fan, a squeaky lawnmower, the buzzing of a crowd of people, etc.

Of considerable significance is the fact that almost always the duration of the sound seemed much longer than it actually was. This is what we would expect in the presence of time distortion and in a way confirms the reports of the subjects. Here too we have the awareness of a physical phenomenon during time distortion, and the event seems to be slowed. Compare this with reports from persons following a narrow escape, who may say that world events appeared to be in "slow motion."

Not always was the intruder welcome, for on several occasions the hallucination was completely destroyed. On others the subject would become "nervous," irritated, or apprehensive.

In fact one subject reported that in subsequent walks, whenever he passed the spot at which he had previously been "jolted" by the sound signal, he had a sense of impending trouble. Here apparently we have an instance of conditioning to a hallucinated environment. This is evidence of the subjective reality of the experience.

Metronome

Initially a metronome was started at 60 strokes per minute, and the following suggestion then given: "You now hear a special variable speed electric metronome striking at 60

strokes per minute. Please listen to it. - - - - I'm soon going to slow it down gradually. When it's going very slowly, please let me know by saying 'Now.'"

At varying intervals thereafter this suggestion might be given—"It's going slower and slower, slower and slower—."

The metronome, of course, continued at its initial rate of 60. Three of the four subjects who were thus tested reported marked slowing. However, for one of these, the slowing did not always occur.

Next four subjects were trained to "imagine" that they were listening to a metronome. This was accomplished with little difficulty. The following suggestions were then used:

"When I give you the starting signal by saying 'Now,' you're going to imagine that you hear that metronome beating at 60 strokes a minute. As you listen, it will go slower and slower. It will slow down fairly rapidly. When it's going very slowly, you'll let me know by saying `Now.' As you listen, you will count the strokes to yourself."

All four subjects reported marked slowing, usually after an interval of less than two minutes. Along with this they almost always had visual hallucinations, generally involving a metronome. In the case of some subjects these were bizarre and elaborate and included pendulums with sliding weights, large and small hammers striking in counterpoint, flexible and adjustable shafts, men swinging hammers or beams, airplanes looping, etc. The subjects were asked to state the count and to demonstrate the initial rate and the rate during the last five or ten beats. The count generally averaged much less than 60 per minute.

Finally all four subjects were again allowed to listen to the real metronome and were given the suggestion noted in the first paragraph of this section, plus instructions to count the strokes to themselves. No further "slowing" suggestions were given. All reported slowing, and there was usually an appropriately low count. Actually the rate was unchanged.

There were, however, occasional reports in the last two exercises described above where the subject reported marked slowing although the count was not proportionately reduced. In view of the fact that these subjects could very closely approximate a rate of 60 per minute, the conclusion is inescapable that there was a purely subjective lengthening of the interval between sounds, whether real or hallucinated. Two of the subjects studied in previous experiments, incidentally, showed the same phenomenon.

Review and Practice

A few pilot experiments were run in an effort to learn whether our subjects could review for a history examination in distorted time. The results were inconclusive, but it led one of them, a professional violinist, to attempt to review certain pieces and to practice these

while in a self-induced trance, using her "special time" for this purpose. Her own account of the procedure follows.

> I put myself into a trance and then practiced in several different ways. I might see the music before me and mark the spots that needed extra practice. I would then play the different spots over and over until I got them-which helped my finger memory because I was actually playing in the trance. [This was hallucinated activity only. In other words she was "actually playing" only in the hallucinated world and did not in the physical world.]
>
> I did "passage practice"—picking hard passages and playing them in several ways to facilitate speed and accuracy.
>
> Then I went through the whole composition for continuity. In doing this in "special time" I seemed to get an immediate grasp of the composition as a whole.

Thus she was able to practice and review long pieces over and over in very brief world time periods, and she found that not only did her memory improve strikingly, but also her technical performance. This remarkable result is attested to by her husband, himself a musician. In other words she felt that hallucinated practice of these pieces, learned years ago, improved her subsequent performance.

It is impossible at present to evaluate these reports which, if confirmed, carry important implications for facilitation of the learning process. They suggest at least two possibilities for making use of distorted time in the hypnotized subject.

The first is that the memorizing of new material might be speeded up by hallucinating the frequent repetition, either in visual or auditory form, of whatever is to be learned. The second, of course, is that hallucinated practice and review be used to aid in the acquiring of new motor skills. So important are these considerations that we feel obliged to mention them, however far-fetched they may be, for their experimental investigation is fairly simple.

Coincidental Happenings

Not infrequently certain fortuitous and sometimes unwelcome things occurred and were reported. They are listed here because they so convincingly bespeak the reality of these experiences, all of which occurred during time distortion. While rowing a boat, the subject lost an oarlock.

While picking up shells, he stepped on a jellyfish.

While getting out of the way of an automobile, he tripped over the curb. "Mother helped me on with my coat. It wouldn't button. Dad buttoned the vest."

In changing a tire he found only three lugs in place. Later he found the fourth one in the hubcap.

"I hurried to get past a hayfield which was irritating my nose."

In changing electric light bulbs, the one he threw into the scrap-basket broke.

While drilling, the man next to him "passed out" from heat prostration.

Asked to sing a hymn in church, "I stood on the platform and announced to the Baptists that I was going to sing a Jewish chant. I sang it all the way through." (In an allotted time of 10 seconds!)

While burning trash, he watched the match burn down, after striking it on his pants.

"I shaved but I didn't wash my face afterward. I didn't have authority to do that." (Suggestion: "You're going to shave." A.T., 10 seconds.)

"The barn door stuck because it had been raining."

"While getting shaved, the barber spent so much time talking to the other barber that the lather began to set."

While pulling up and counting iris, "the reason it took so long was because I had to get the dirt off them."

While watching a football game, his attention was drawn away from the play by a fight in the stands.

In counting potatoes, as he removed them from a basket and placed them in a sack, some fell back into the basket and hit the rim. "I had to count them over again."

While counting candies as he removed them from a box, "there was a strawberry cream that had mashed and cracked and had run a little bit. What to do with it passed through my mind."

In counting gum-drops, he noticed that some were stuck together. "I pulled out the whole bunch and broke them off and put them in separate piles." While picking berries, the carton got so full that they kept falling out. While riding the waves during a swim, she hit the bottom.

While washing the baby, she spilled all the water.

In making sandwiches, she cut her finger with the knife, and it bled.

In counting chickens, she noticed that one had started sprouting wing feathers, and one was sick.

In playing truth or consequences, "they blindfolded me and a fellow kissed me and embarrassed me."

"The Victrola started slowly. I had to wind it again."

While roller-skating, she fell down.

While crocheting, the thread broke.

In buying shoes, she tried on four pairs first.

A student who came for counseling said, "I want you to know that I'm not here because I'm crazy."

While counting chickens, the first one defecated in his hand. Asked what he then did, he replied, "I wiped it off on the second chicken."

SPECIAL INQUIRY

After a subject had completed his or her report, various questions were asked of them, designed to clarify certain aspects of their experiences. The following section is devoted to a presentation of the knowledge thus acquired.

Falsification

One who hears a number of these accounts soon becomes intuitively convinced of their truth and of the actual existence, for the subject, of the alleged experiences. The subjects were honest individuals, interested in the research, and their waking reports agreed with those given under hypnosis. They all insisted that the reporting was an entirely different event from the original experience, and that they did not elaborate. They repeatedly resented the implications of questions directed to the discovery of possible retrospective falsification. Incidentally, during the reporting they saw scenes from the activity, but they were generally "stills." Questions directed to the "subconscious" concerning the presence of falsification were invariably answered in the negative. Finally, the locating of the sound signals, the coincidental happenings, the apparent conditioning, the spontaneous expression of emotion during reporting, and the subsequent amazement on learning the true time relations, all render retrospective falsification unlikely.

Realness

In the accomplished subject the hallucinations possess a high degree of "realness," which is fairly consistent. At tunes, however, reports will mention a lack of clearness in the imagery. Such instances are on the whole infrequent. Often, however, the definition and

clarity will be confined to those things which occupy the immediate attention, the background remaining vague.

As training develops the ability to hallucinate, so also it aids in the production of scenes that are real and true to life. Thus, with practice, there comes an increase in detail and in color. To encourage this, we daily gave our subjects the following suggestion— "In this trance any scenes you see will be very clear and any experiences you have will be very real, so that you will actually live them."

One very striking evidence of the realness of the activities is the frequent reporting of accidental or coincidental happenings. For instance, the subject who is crocheting breaks her thread, and later cuts her finger while making sandwiches or spills the water in which she is bathing her child. Another one, asked to burn some rubbish, strikes the match on his pants and watches it as it burns, or while walking past a hayfield begins to sneeze. The chalk that the angry teacher throws strikes the blackboard and breaks, and the little boy whose ears stand out so far scratches his head as he strives to find the answer to his problem. Such telltale details were frequently mentioned, and a partial list of them is given elsewhere.

It was not uncommon for the subjects to say how much they enjoyed an activity and how much they regretted its termination. At other times they would get tired or become bored. In one case a subject who had been waked was telling about an activity in which he seemed to be quite young. After telling how rough the ground was over which he had been dragging a bushel basket of apples, he asked, "Did I breathe hard?" When answered in the negative, he replied, "Then I guess I must have just imagined it." Thus the subjective reality of the experience was so great that even in the waking state he expected physical manifestations of it.

Continuity

Action was continuous in all but a very few hypnotically suggested experiences. This was ascertained by frequent questioning. In fact the subjects themselves would usually volunteer information concerning an omission or a skip. When these occurred, there was generally a shifting of scene without apparent transit from one location to the other. Another form would be a "floating" from one place to another instead of walking. One subject did this when she became bored.

In several instances a shift of scene apparently represented an amnesia, for on being asked to relive the action, the subject reported the missing experience.

The hearing of rather long pieces of music without omission by musicians is most suggestive of true continuity. One of our subjects was a skilled professional violinist, and another an accomplished amateur. They frequently reported that there were no omissions in the familiar pieces they heard or played in trance. Other subjects gave similar testimony concerning familiar popular music.

Another point that bespeaks continuity is that injected sound signals invariably arrived during hallucinatory action. In other words this type of exploration revealed no action-free intervals.

The counting experiments also support the view that continuity is present.

Time Sense

For successful "utilization" of experiential time by increased mental activity it is probably mandatory that the subjects be totally unaware of their surroundings and of world time. With some subjects this is difficult at first; with others it is easy. Three of our subjects were apparently helped by a brief talk on the relation between subjective and physical time, the dream being cited as the most familiar example of the variability of the former. The transition period which preceded the full acceptance of "special time" in these subjects was most interesting, as the following accounts will show.

The efforts of these subjects to get away from world time are worthy of note. One of them, who said she seemed always to be aware of world time, would hallucinate a weird cellophane covering for herself, into which to "escape." With this pulled down over her, she was able to hear several minutes of music, in normal tempo, during but a few seconds of world time. Her difficulties disappeared one day, and with them the necessity for these odd creations, while she was counting silently the strokes of an hallucinated metronome. She counted 27 metronome strokes in 55 seconds, and as she did so, found herself watching 3 "sky-writing" pilot in the air. She was much impressed with what she saw. "Here I am counting by myself in one kind of time and watching an airplane do fancy loops, and it seemed to me that he had so much time to kill between strokes. He had time to do all kinds of fancy loops and things, and it didn't seem strange at all. If he had been writing a word, which he wasn't, there were enough loops to take care of a six- or seven-letter word." Later she said, "I think the thing that convinced me most [of the reality of another sort of time] was seeing the airplane and noting how easily, effortlessly, or unhurriedly it was looping in between strokes. He seemed to have so much time to kill. Now I really realize that the thing to do is to relax and accept the fact that there is more than one kind of time."

Another remark that is worthy of record was made by a subject who, while in trance, refused to demonstrate the rate at which she picked flowers. When asked why she couldn't do so, she said, "I'll try, but I tell you I picked 145 in 10 minutes and I can't repeat it now because I don't have a time limit right now-neither a time limit nor a limit on the flowers I might pick. It doesn't coincide. But there I'm in a certain frame of mind-and it can't be repeated here. I can't do it incomplete—in a fragment. It's impossible. I can do it again too!"

Then, after waking, she said, "Well, I consider this a unique experience with a certain time limit and a certain amount of work to be accomplished. If the time limit or the

amount of work or both are eliminated, it is not the same experience anymore, so I can't show you in a fragment how it went, or how it was."

Some weeks later she was crystal-gazing in a trance and was asked to see herself picking the same flowers, and to count them aloud as she did so. Under these circumstances she readily complied. The demonstrated rate was 42 per minute.

Another subject, in the transition period, once tried to escape world time by "going off from the main shaft of a mine." His difficulties were further revealed in the following remarks: "Here's a funny thing now. I was conscious that the physical time was perhaps 11 seconds, but the hallucinated time seemed to be about two minutes."

"And I was able to move these marbles, one at a time, without taking a handful or anything like that and without hurrying."

"Were you aware then of two time factors?"

"Yes-I was aware of the consciousness of physical time and also of hallucinated time."

"Would it be fair to say that you weren't completely lost in the hallucinated experience?"

"No—I was engrossed in the hallucinated experience, but yet some other factor seemed to indicate that it was merely 10 or 11 seconds."

"Were you aware of that while you were counting marbles?"

"No but when I said [while reporting] `two minutes,' the other factor came into play and gave a quiver-a physical shock-to my body, and then the idea of 11 or 10 seconds came."

In some of the tests the subjects spontaneously hallucinated a watch or a clock. In others, these instruments were suggested to them. Usually, but not always, the time indicated by the hallucinated timepieces was appropriate to the subjects' experiences.

Thought

All our subjects felt that the thought processes they employed in their hallucinations were comparable to those of the waking state. In fact some of them felt that they were possibly of a superior type, there being an increased ability to consider situations as a whole. One said, "Considerations are weighed out mentally instead of verbally." We were, unfortunately, unable to give this matter the attention it deserved.

We feel that this is true thought. If such indeed be the case, then it is obvious that this all-important mental activity, at least a form of it, can take place at very rapid rates, while appearing to proceed normally. It is obvious also that such thought can deal only with concepts available through memory. Yet it is possible that the increased accessibility of

material from the unconscious might be advantageous under certain circumstances. Creative thinking likewise might be aided.

To date the ability to perform mathematical thought more rapidly while time sense is distorted under hypnosis has not been demonstrated.

Hallucinations and Dreams

We do not consider these hypnotically induced experiences to be identical with dreams, and we have never used the word "dream" in a suggestion unless we wish to produce such an entity. That our subjects were in most cases aware of a difference is evidenced by the fact that they occasionally, while resting, would say, "I went to sleep and had a dream." However, these dreams had no connection with the experimental work. Between assignments it was customary to give the suggestion, "Now let your mind wander whither it will-to pleasant scenes," in response to which they usually engaged in desultory hallucinated activity, which they did not consider the same as dreaming.

Five of our subjects were asked to compare these two types of activity, and all felt that there were differences. Their remarks follow.

Concerning hallucinated activities in hypnosis:

Hallucinations are,

—"better organized."
—"more real than dreams."
—"directed dreams."
—"very true to life, and the experiences carry on as if they were really happening."
"You are conscious of what you are doing and can control the situation better."
"They make sense, whereas dreams are often silly and impossible."

Concerning dreams:

Dreams are,

—"less meaningful."
—"often far-fetched."
"They contain nonsense and extraneous things."
"They show less continuity."
"They contain something impossible or unreal."
"In dreams the mind jumps from one subject to another, and it is as if the dreamer were looking on instead of participating in it."
"Most dreams are next to impossible."

Awareness of Surroundings

The subjects with the best performance all reported that while engaged in an assignment they were completely unaware of their surroundings. The ones who were unable to lose touch completely with the physical world had difficulties with time distortion.

Miscellaneous

The subjects all said that the hallucinated activity never started before the starting signal and that it invariably ended abruptly at the termination signal.

As an example of the sudden cessation of action, one subject told how the signal came as he was reaching for something, and his hand was in midair as the hallucination disappeared.

Aside from their intrinsic significance, these findings speak against retrospective falsification.

ANALYSIS OF RESULTS

Experiential Time

If we simply assign a completed type of activity to subjects and ask them to let us know when they have finished it, we shall find the following to be true:

a) They will complete the activity
b) It will appear to proceed at the usual rate.
c) It will probably take less than three minutes by world time
d) It will seem to the subjects to take much longer.

In other words there will be definite time distortion even though the suggestion made no stipulation whatever concerning time.

These relations are shown in an analysis of 55 tests in which the activity was a completed one, and in which there was no allotted time (A.T.) or suggested personal time (S.P.T.).

World Time.
  Average 127 secs.
  Maximum 270 secs.
  Minimum 35 secs.
E.P.T.
  Average 17 min.
  Maximum 45 min.
  Minimum 3 min.
E.P.T. was invariably longer than W.T,

It is thus seen that in hallucinatory activity in hypnosis there is apparently an inherent tendency for time distortion to occur.

Another basic consideration is the fact that the subjects will try their best to carry out whatever is suggested-to "obey orders," in other words. Thus if, with a given activity, we

use an allotted time and gradually decrease this in repeated tests, assuring the subjects that they will not have to hurry and will have plenty of time, they will learn somehow to adjust their hallucinated action to the short world time interval. They will "fit it in," so to speak. Yet they will continue to complete the assignment without hurrying, it will appear to be real in every way, and the experiential time will be appropriate. Use is made of this in training subjects, and it is of considerable importance for this reason.

A little reflection will reveal that in assigning a completed activity we assign not only a definite amount of action, but also in effect an appropriate amount of experiential time. This is especially true if we tell the subject not to hurry. The reason for this, of course, is that the awareness of action or change is invariably accompanied by a sense of the passage of time.

On the other hand, time sense itself may be prolonged without the awareness of an equivalent amount of action. This is seen in the dream, where there is often a relative poverty of action. It is also true in those hypnotically induced hallucinations where, on occasions generally involving a suggested personal time (S.P.T.), the amount of activity, though large, is still much less than would be expected when one considers the estimated personal time (E.P.T.).

We can see from the above that, in hypnotically induced hallucinations, the experiential time is influenced by some inherent factor and by the assigned activity itself.

A third consideration, and a most effective one, is the direct suggestion of a subjective time interval-the use of a suggested personal time (S.P.T.).

Amount of Action

Where an incomplete activity is used, and there is no suggested personal time (S.P.T.), the accomplishment depends upon the rate at which the subjects choose to carry out their hallucinated action and the allotted time (A.T.) or world time (W.T.).

On the other hand, where an incomplete activity is used and a suggested personal time (S.P.T.) given, the subjects will strive to fill up their suggested interval with action. Most of our counting experiments are of this type and are indeed remarkable.

With a completed activity the most important factor determining the amount of action is of course the assignment itself. Within undetermined limits, a proficient subject will complete activities as requested.

Summary

The essential points in the above discussion of the relation between type of activity, S.P.T., amount of activity, and E.P.T. are recapitulated below.

I. Incomplete activity.

1. Without S.P.T.
    Amount of action depends upon subject's chosen speed of hallucinatory action, and upon A.T. or W.T.
    E.P.T. will be appropriate to the action.
2. With S.P.T.
    Amount of action will be consistent with S.P.T. where the subject is proficient.
    E.P.T. will equal S.P.T.

II. Completed Activity.

1. Without S.P.T.
    Amount of action is determined by the suggested activity.
    E.P.T. is appropriate to the suggested activity.
2. With S.P.T.
    Amount of action is determined by the suggested activity.
    E.P.T. equals S.P.T.

It is understood of course that the subjects have had enough training to have become proficient. Thus in a sense the above statements apply to the "ideal" subject. The commonest shortcoming is an inability to accept fully a suggested personal time (S.P.T.). It is important to note, furthermore, that in these experiments the allotted time (A.T.) was never less than 10 seconds, and only rarely was the suggested personal time (S.P.T.) over 30 minutes. No attempt was made to explore the limits of performance.

It is clear from the above that hallucinated action and subjective time are to a certain degree interrelated.

Time distortion as effected in these experiments is accompanied by a marked increase in the ratio E.P.T./W.T. It is usually accompanied by an appropriate increase in hallucinated activity. In order to produce these results, then, the following conditions should be fulfilled:

For an incomplete activity:
    A familiar activity
    S.P.T. —long
    A.T. —short

For a completed activity:
    A familiar activity the completion of which requires a relatively long period of time
    S.P.T. —not of primary importance. If used, it should be appropriate.
    A.T. —short

In general:
    Subjects often find that the suggestion "Please don't hurry, you'll have plenty of time," reassures them and helps them to relax.

TRAINING

The following suggestions may be helpful in the training of new subjects. Keep concurrent reporting-that is, reporting while an hallucination is actually in progress-to a minimum. This will give the subjects an opportunity to become accustomed to dissociating themselves from their physical surroundings and becoming wholly engrossed in the hallucinated world. Without the ability to do this, satisfactory time distortion cannot be obtained. We used concurrent reporting only in the "previews" to the counting experiments.

In teaching a subject to hallucinate, a good expression to use is, "I now want you to imagine that you're in such and such a place." After a brief interval— "Now make your mind a blank. Your mind is now a blank. Now tell me what you saw."

After the ability to hallucinate has been acquired, it is best to start with either simple incomplete or continuous activities, such as looking in shop windows, with a long allotted time (A.T.) or with a simple completed activity without A.T. By a long allotted time (A.T.) we mean one or two minutes. An estimated personal time (E.P.T.) should be asked for after each activity. It will almost invariably show distortion fairly early during training. It might help to point out this distortion to the subject, who will then realize that there is nothing amiss in experiencing a subjective time interval that is out of proportion to world time.

We have usually postponed the suggestion of a personal time until subjects have acquired some proficiency with simpler procedures, on the theory that failure might discourage them.

Throughout the training, advantage is taken of the following:

a. The inherent tendency toward spontaneous time distortion in hallucinated activities.
b. The effort and the need on the part of the hypnotized subject to carry out suggestions, especially to finish a completed activity.
c. The fact that, at the beginning at least, familiar activities are more readily hallucinated than unfamiliar ones.
d. The fact that the interest and curiosity of the subjects, and their feeling of being productive, tend to improve cooperation and performance. Advantage can be taken of this by giving them sufficient understanding of what they are doing so that they accept and do not reject it.
e. The tendency to improve with practice.

As training progresses, a series of tests is run with completed activities, and a gradually decreasing allotted time (A.T.), but without a suggested personal time (S.P.T.). As mentioned elsewhere, it is not necessary, and is possibly not desirable, to give the subjects any notice to the effect that the operator is going to tell when to stop. We generally began with an allotted time of one or two minutes and cut it down by 10 to 30 seconds at each step. The subjects, "caught short" at first, will soon learn to adjust to the shorter allotted time (A.T.), and will fit their hallucinatory experiences into the interval

allowed them, without hurrying or compromising in any way. In this way they learn to work with short allotted times. How far this process can be carried is not known at present. The next step is the giving of a suggested personal time (S.P.T.). This is of special importance with incomplete activities. Some subjects readily accept this early in their training; others have difficulty doing so. The difficulty seems to arise from at least two factors—a residual awareness of surroundings and consequently of world time, and a deep conviction that it "just ain't so." Practice, and use of a deeper trance, will help overcome the first difficulty. With the second it may help to point out to the subjects that they have on many occasions during their training experienced the variability of subjective time in relation to world time. The results of some of their earlier tests will convince them of this, when shown to them. In addition, it may help to give them some such explanation as the following, which proved to be of definite assistance with some of our subjects.

> There are two kinds of time, one, the time the clock tells us, the other, our own sense of the passage of time. The first of these is known as physical, or solar, or world time. It is the time used by the physicists and the astronomers in their measurements, and by all of us in our workaday life. The second is called personal, or subjective time. Einstein refers to this as "I-time."
>
> It is this subjective time that we are most interested in here. One of the most important things about it is that it is very variable. Thus, if several persons are asked to judge the length of a five-minute interval as measured by a clock, they may have very different ideas as to the duration of the interval, depending upon the circumstances in which they find themselves. To those who were enjoying themselves, or who were absorbed in some interesting activity, the interval might well seem shorter. On the other hand, to those in pain or discomfort or anxiety, the five minutes would seem much longer. We call this time distortion, and the most familiar example of it is found in the dream. You yourself have probably often noticed that you can experience many hours of dream life in a very short time by the clock.
>
> Now, it has been repeatedly demonstrated that subjective time appreciation can be hallucinated just as you can hallucinate visual or auditory sensations, in response to suggestion during hypnosis. The subjects thus actually experience the amount of subjective time that is suggested to them. So in a sense you have a "special time" of your own, which you can call on as you wish. Moreover you have an unlimited supply of it. It is the time of the dream world and of the hallucinated world, and since it is readily available, you will never have to hurry in these tests. Furthermore it bears no relation whatever to the time of my watch, which, consequently, you will ignore.
>
> Knowing these things, you can now relax and take your time.

CONTROLS

As a control our subjects were asked to estimate both short and long world-time intervals while engaged in various activities. With the short intervals, which varied from 10 to 30 seconds, the activities were counting small objects, sorting cards, talking, and reading. The instructions, incidentally, were patterned after those used under hypnosis in assigning activities. With the longer intervals, ranging from 15 minutes to several hours, ordinary daily occupations were engaged in.

It is quite obvious from the results in Table 5 that the estimated times are in far closer agreement with the actual world-time intervals than under the type of time distortion studied in this report.

SPECIAL DISCUSSION OF PSYCHOLOGICAL AND PSYCHIATRIC IMPLICATIONS

Milton H. Erickson

The discovery or development of every new concept in science poses the difficult question of what will be its eventual significance and application. The publication of the senior author's first experimental study of time distortion impressed this writer with the possibility of new and better understanding of certain psychological functionings and consequently, of different and more searching procedures and methodologies in dealing with psychological problems. Long experience in the fields of experimental and clinical psychology and in psychotherapy has repeatedly demonstrated the tremendous importance of experiential realities in human living and, at the same time, the laboriousness and often futility of any attempt at reaching a measurable understanding of them. Certainly the findings made in the original study and confirmed by this second report suggest the definite possibility of new, readily available avenues for the

examination of those inner experiences that constitute so large a part of life, and which are so difficult to study in a rigorously scientific manner. However, no attempt will be made to offer an elaborate discussion of psychological and psychiatric implications of these two studies. Rather, a number of them will be mentioned briefly with the hope that readers will accept the task of considering for themselves those implications bearing upon fields of special interest to them.

Foremost to this writer are the implications of time distortion in the field of psychotherapy. Certainly no one questions the importance of the subjective experiential life of the individual, nor the present unsatisfactory, laborious, time consuming, and unscientific methods of studying it.

What constitutes a subjective reality? Of what seemingly pertinent and irrelevant elements is it comprised? In what way is it integrated into the total life of the person? What self-expressive purposes does it serve for the personality? What determines its validity? How does it differ from a memory, a dream, a fantasy, and from retrospective falsification? In what way is it distorted by present methods of concurrent or retrospective reporting, and how much time does it require? All of these considerations are touched upon either directly or indirectly in this study, and each of them constitutes a significant problem in psychotherapy, to say nothing of psychology in general.

The girl who, in an allotted 10 seconds, subjectively experienced in voluminous detail a 30-minute automobile ride upon which a report could be made with "stills" of the scenes, demonstrated a challenging possibility of a new approach to the exploration of the experiential past of the individual.

The subject who found it impossible to demonstrate in the waking state her experiential behavior in picking flowers because it was under a "different" time limit and work limit, and yet, weeks later in a trance state was able to demonstrate in actual accord with the previous findings, discloses the possibility of controlled studies of subjective realities.

Delusions and hallucinations have long constituted intriguing problems. They are subjective realities accepted by the person as objective realities. Yet one of our experimental subjects experienced dragging a basket of apples with such vividness that he expected the experimenter to note his forced respirations, which, similar to the basket, were only subjectively real. Nevertheless he recognized the total experience as entirely subjective but did so without it losing the experiential feeling of its objective reality. Experimental studies patterned from this and the other similar findings above might lead to a better understanding of pathological delusions and hallucinations.

Theories of learning and memory are constantly in need of revision with each new development in experimental studies in those fields. In this regard the findings on the subject who in an allotted 10 seconds took a long walk and developed a conditioned-response reaction by being "jolted" by an interjected sound signal, pose definite problems for research on learning, memory, and conditioning.

Similar is the instance of the violinist who, in allotted 10-second periods, subjectively experienced playing various compositions with practice effects as attested by a competent critic. Subsequent to this study she made use of her "special personal time" to experience subjectively practicing a difficult, long-forgotten composition, and then to play it successfully in reality from memory without having seen the written music for years.

In this same connection one may speculate upon the role of motor functioning in mental learning, since this violinist subjectively experienced the total process of playing the violin, studying the written music, and memorizing it, while lying supine and-inactive, and yet demonstrated the actual effects of reality practice.

A tempting experimental study based on these findings would be the exhibition of a form board to naive subjects and having them in special personal time, at a hallucinatory level, practice assembling it. The findings of this study warrant the assumption that, even as motor activity facilitates learning in everyday reality, subjective motor activity, as contrasted to objective, is an effective aid to memory and learning.

Another interesting, actually significant finding bears upon the validity of the experiential realities to the subjects, negates assumptions of retrospective falsification, and serves to confirm the findings of various competent experimenters that hypnosis cannot be used to induce antisocial behavior. This was the discovery in several instances that suggested hallucinatory activities were unexpectedly regarded as objectionable by the subjects. The reactions were essentially the same in all cases and can be illustrated by the following example.

The subject was instructed to experience herself in the role of a psychologist counseling a client relative to a problem involving epilepsy. Although willing to serve as a counselor, the experiential reality of the situation was so great that she could not tolerate the task of dealing with the problem because she felt that epilepsy was beyond the rightful scope of a psychologist and that any counseling she might offer would be unethical. Accordingly she referred her hallucinatory, client to a medical man and developed intense resentment and hostility toward the experimenter for calling upon her to violate, even at a subjective level, her personal code of ethics.

While much could be said about the implications of time distortion and the experimental findings reported here in relation to concepts of gestalt psychology, the molar psychology of Tolman, Hull's modern behaviorism, and Freudian psychology, this will be left to the special interests of the reader. Time and its relationships constitutes a significant element in all psychological functioning no matter from what school of thought it is viewed. Hence any study dealing with the element of time itself in psychological functioning must necessarily have important bearing upon every school of thought, and this concept of time distortion offers a new approach to many psychological problems.

A final item of special interest to this writer centers around the problem so pertinent in research in clinical psychology and psychotherapy-namely, the problem of how to create for a subject or a patient a situation in which to respond with valid subjective reality.

Certainly this study indicates the possibility of much more rigorous controlled research with time as aid rather than as barrier.

To conclude, this writer in all modesty-since the conception, plan, and organization of this study was entirely original with the senior author—can express the opinion that the experimental findings reported in this paper offer a wealth of highly significant ideas and concepts for extensive psychological research and clinical psychiatric application.

SUMMARY

The relation between experimental time and world time during hallucinated activity in hypnotized subjects was studied.

Various hallucinated activities were suggested and were carried out by the subjects, a record being made of their duration. In activities which did not involve a completed act a personal time interval was often suggested to the subject. The hallucination was terminated either by the subjects themselves or by the experimenter. In some instances the period of action was explored by injecting sound signals into the hallucination. In another group of tests the suggestion was given that a metronome, either real or hallucinated, would slow down. A brief study was made to determine the value of hallucinated review of previously learned material. An interesting attempt to improve motor function by hallucinated practice is reported.

The most important findings were that the investigator can control within limits the subject's sense of the passage of time, and that in a prolonged experimental time interval an appropriate amount of subjective experience, hallucinatory or otherwise, may take place. The suggested slowing of the metronome was accepted. Thus the findings of our initial report were confirmed. The sound signals often were apparent in the hallucination, their position in the subjective interval roughly corresponding to that in the world-time interval. Continuous sounds were definitely prolonged, as was to be expected. In one case the sound signals set up a conditioned stimulus in the hallucinated environment.

Inquiry was made into various aspects of the hallucinatory experiences. They were found to possess both realness and continuity. Time sense was strikingly altered. Thought seemed quite natural in distorted time. Subjects felt that their hallucinated activities in these experiments differed from nocturnal dreams. Subjects were unaware of their surroundings during their hallucinations.

The findings as a whole are analyzed.

Suggestions are given concerning the training of new subjects.

The experiments are discussed from a psychological and psychiatric point of view.

CONCLUSION

In view of these findings, the following statements are probably true:

1) Results reported in an earlier communication on time distortion in hypnosis (Cooper, 1948) can be duplicated in the majority of subjects. Time sense can be deliberately altered to a predetermined degree by hypnotic suggestion, and subjects can have an amount of subjective experience under these conditions that is more nearly commensurate with the subjective time involved than with the world time. This activity, while seeming to proceed at a natural rate as far as the subject is concerned, actually takes place with great rapidity.

2) Retrospective falsification does not enter into the subject's reports.

3) The continuity of these subjective experiences during distorted time is good.

4) Thought, under time distortion, while apparently proceeding at a normal rate from the subject's point of view, can take place with extreme rapidity relative to world time. Such thought may be superior, in certain respects to waking thought.

Clinical and Therapeutic Applications of Time Distortion

Milton H. Erickson

Written with L. Cooper. In *Time Distortion in Hypnosis*. Baltimore: Williams & Wilkins, 1954.

INTRODUCTION

The discovery or development of a new concept in science poses difficult questions concerning its definition and its eventual significances and applications. In the experimental work constituting the major part of this book the term "time distortion" has been used as offering a reasonably concise way of expressing a methodology for a study of time itself as one of the essential elements in the experience of human living. To so emphasize time as an integral part of human experience may be considered trite, but it is not trite to recognize time as an element fully as worthy of investigation as any other factor in human living. Yet such investigative studies have been seriously neglected. From recognition of this oversight and long interest in the experiential significance of time came the senior author's impetus for the foregoing experimental studies.

In sharing with him a small part of the experimental studies, this writer became interested in the question of the clinical and therapeutic applications of the experimental findings. The publication of the first experimental study (Cooper, 1948) suggested definite possibilities of new and better understandings of psychological functionings and consequently of different and more searching procedures and methodologies in dealing with psychological problems. Subsequent experimental studies and tentative applications of the findings to clinical work confirmed that first impression. In the second experimental study (Cooper and Erickson, 1950) these impressions have been discussed in the form of a general summary as follows:

> Foremost to this writer are the implications of time distortion in the field of psychotherapy. Certainly no one questions the importance of the subjective experiential life of the individual, nor the present unsatisfactory, laborious, time-consuming, and unscientific methods of studying it.
>
> What constitutes a subjective reality? Of what seemingly pertinent and irrelevant elements is it comprised? In what way is it integrated into the total life of the person? What self-expressive purposes does it serve for the personality? What determines its validity? How does it differ from a memory, a dream, a fantasy, and from retrospective falsification? In what way is it distorted by present methods of concurrent or retrospective reporting, and how much time does it require? All of these considerations are touched upon either directly or indirectly in this study, and each of them constitutes a significant problem in psychotherapy, to say nothing of psychology in general.

The girl who in an allotted 10 seconds subjectively experienced in voluminous detail a 30-minute automobile ride upon which a report could be made with "stills" of the scenes, demonstrated a challenging possibility of a new approach to the exploration of the experiential past of the individual.

The subject who found it impossible to demonstrate in the waking state her experiential behavior in picking flowers because it was under a "different" time limit and work limit, and yet weeks later in a trance state was able to demonstrate in actual accord with the previous findings, discloses the possibility of controlled studies of subjective realities.

Delusions and hallucinations have long constituted intriguing problems. They are subjective realities accepted by the person as objective realities. Yet one of our experimental subjects experienced dragging a basket of apples with such vividness that he expected the experimenter to note his forced respirations, which, similar to the basket, were only subjectively real. Nevertheless he recognized the total experience as entirely subjective but did so without it losing the experiential feeling of its objective reality. Experimental studies patterned from this and the other similar findings above might lead to a better understanding of pathological delusions and hallucinations.

Theories of learning and memory are constantly in need of revision with each new development in experimental studies in those fields. In this regard the findings on the subject who, in an allotted 10 seconds, took a long walk and developed a conditioned response reaction by being "jolted" by an interjected sound signal, pose definite problems for research on learning, memory, and conditioning.

Similar is the instance of the violinist who, in allotted 10-second periods, subjectively experienced playing various compositions with practice effects as attested by a competent critic. Subsequent to this study she made use of her "special personal time" to experience subjectively practicing a difficult, long-forgotten composition, and then played it successfully in reality from memory without having seen the written music for years.

In this same connection one may speculate upon the role of motor functioning in mental learning, since this violinist subjectively experienced the total process of playing the violin, studying the written music, and memorizing it while lying supine and inactive, and yet demonstrated the actual effects of reality practice.

A tempting experimental study based on these findings would be the exhibition of a form board to naive subjects and having them in special personal time, at an hallucinatory level, practice assembling it. The findings of this study warrant the assumption that, even as motor activity facilitates learning in everyday reality, subjective motor activity, as contrasted to objective, is an effective aid to memory and learning.

> Another interesting, actually significant finding bears upon the validity of the experiential realities to the subjects, negates assumptions of retrospective falsification, and serves to confirm the findings of various competent experimenters that hypnosis cannot be used to induce antisocial behavior. This was the discovery, in several instances, that suggested hallucinatory activities were unexpectedly regarded as objectionable by the subjects. The reactions were essentially the same in all cases and can be illustrated by the following example.
>
> The subject was instructed to experience herself in the role of a psychologist counseling a client relative to a problem involving epilepsy. Although willing to serve as a counselor, the experiential reality of the situation was so great that she could not tolerate the task of dealing with the problem because she felt that epilepsy was beyond the rightful scope of a psychologist and that any counseling she might offer would be unethical. Accordingly, she referred her hallucinatory client to a medical man and developed intense resentment and hostility toward the experimenter for calling upon her to violate, even at a subjective level, her personal code of ethics.
>
> While much could be said about the implications of time distortion and the experimental findings reported here in relation to concepts of gestalt psychology, the molar psychology of Tolman, Hull's modern behaviorism, and Freudian psychology, this will be left to the special interests of the reader. Time and its relationships constitutes a significant element in all psychological functioning no matter from what school of thought it is viewed. Hence any study dealing with the element of time itself in psychological functioning must necessarily have important bearing upon every school of thought, and this concept of time distortion offers a new approach to many psychological problems.
>
> A final item of special interest to this writer centers around the problem so pertinent in research in clinical psychology and psychotherapy-namely, the problem of how to create for a subject or a patient a situation in which to respond with valid subjective reality. Certainly this study indicates the possibility of much more rigorous controlled research with time as aid rather than as barrier.

Since the publication of the above, opportunities have arisen from time to time to utilize or to adapt various experimental findings in clinical and therapeutic work. However, it must be noted that experimental studies and clinical work belong to different categories of endeavor. In the former rigorous controls must be exercised, and the object is the determination of possibilities and probabilities. In clinical work the welfare of the patient transcends all other matters, and controls and scientific exactitudes of procedure must give way to the experiential needs of the patient in the therapeutic situation. Another type of measure of validity, different from the controlled scientific methodology of experimental procedure, holds in clinical work. Such a measure is constituted by the therapeutic results that can be definitely related to the procedure employed and which are understandably derived from it.

GENERAL CONSIDERATIONS OF CLINICAL APPLICATIONS

Since the clinical situation of psychotherapy is not a Procrustean bed, utilization of experimental findings and concepts must necessarily depend upon the patient's needs and desires and the attendant circumstances. It cannot be a matter of furthering special interests of the therapist. Hence any utilization must await the opportunities and occasions presented by the patient and not represent a planned procedure established out of context with the developing needs of the patient in therapy.

Furthermore the concept of time distortion does not constitute in itself a form of psychotherapy. Rather it offers a method by which access can be gained to the experiential life of the patient. Any therapy resulting derives from a separate process of reordering the significances and values of the patient's experiential subjective and objective realities.

The following case reports are those of patients who presented an opportunity to investigate the applicability of time distortion to psychotherapeutic problems. These reports are presented relatively briefly, and emphasis is placed upon the dynamics of the individual case, since the purpose of the reports is to demonstrate as clearly as possible the problem, the situation, and the circumstances which led to the utilization of time distortion, and the results obtained.

PATIENT A

The first case history illustrates an unwitting and unintentional spontaneous utilization of time distortion by a patient previous to Cooper's initial publication.

It is presented because it demonstrates not only the use of time distortion but how, in the ordinary course of psychotherapy, an opportunity can arise for the utilization of time distortion. Needless to say, at the time of this occurrence this writer was at a loss to understand what had happened, but it laid the foundation for a profound interest in Cooper's first publication four years later.

The patient, an artist in his early thirties, sought therapy primarily for marital problems and secondarily for personality difficulties. During therapy, despite his success in the field of portraits, landscapes, and still life painting, he felt extremely frustrated because he had not painted a circus picture. For more than ten years, even previous to his marriage, he had hopelessly desired to paint such a picture but had not even succeeded in making a preliminary sketch. He had not even been able to think sufficiently clearly on the subject to speculate on what figures or scenes he might wish to portray. The entire project remained a vague, undefined "circus picture."

Although his other problems were clarified during months of therapy, nothing was accomplished in this regard. Even profound somnambulistic hypnotic trances, with various techniques, elicited only the explanation, "I'm completely blocked mentally. I can't think any further than 'circus picture.'" He could not even sketch a possible

composition plan of vertical and horizontal lines, his usual method of working out preliminary sketches.

Since the patient wished further therapy in this connection, a deep trance was induced and he was given the following posthypnotic, suggestions:

1. Stretch a large canvas in the neighborhood of 24 x 40 inches. It may be larger or smaller—possibly a golden rectangle.

2. Secure a more than adequate new supply of paint tubes and pigments and set them up as if in preparation for painting.

3. Make out a daily hourly schedule for the next three months, blocking out hours that might be used for painting the circus picture (his usual procedure in planning a new painting).

He was then awakened and dismissed with an amnesia for trance events.

A few days later, with no realization of the posthypnotic nature of his performance, he reported that he had made a time schedule for the next two months. This schedule would permit him, if he worked hard, to finish his present commitments within two weeks. Then over the remaining period there would be blocks of time totaling 70 hours which he would reserve absolutely for an effort to paint a circus picture. No mention was made in relation to the other posthypnotic suggestions.

He was hypnotized deeply and instructed to fulfill his current commitments adequately. Then he was to set about this proposed project, working slowly, carefully, and painstakingly as he always did, without rushing or hurrying. In so doing the 70 allotted hours would pass with utter and incredible speed. Yet he would work satisfyingly and at a normal tempo. (The intended purpose of this instruction was to prevent him from feeling the burden of a long-continued task.)

All of this instruction was emphatically and repetitiously given to insure adequate understanding.

Two days later a highly excited telephone call was received from him, asking for an immediate interview.

His story was as follows: While completing a current picture, he ceased work to eat his lunch of sandwiches in the studio. While so doing he decided to stretch a new canvas, thinking vaguely that he might use it for the projected picture.

This done, he picked up the remainder of his sandwich and found it inexplicably dry. Puzzled by this, he chanced to look at the stretched canvas and was utterly amazed to find a freshly completed oil painting of a circus scene. With intense curiosity he examined it carefully, feeling exceedingly pleased and satisfied with it. Suddenly he saw his signature

in the corner (which he ordinarily appended ritualistically only when he had given his final approval to his work) and noted at the same time that the style of painting was his own. Immediately he had rushed to the telephone, observing on the way that the clock gave the hour as 6:00 P.M. All the more bewildered, he had telephoned, saying, "Something's happened. Can I see you right away?" To this account he added, "What happened? What happened?"

Since he had brought the picture with him, he was questioned about it. The performing dog in it was really a neighbor's; the equestrienne was his recently acquired second wife; the clown was himself; and the Ferris wheel was one his present wife had recently described in a reminiscence. Yet the painting as a circus picture was more than satisfying to him as a person and as a critical artist. (At art exhibitions in various states critics have all been most favorable in their comments.)

He was much puzzled by his replies to the questioning and kept reiterating, "It's the circus picture I've always wanted, but it's got nothing to do with any ideas I ever had about a circus picture. It's mine; it's a circus picture; it's what I want. But what happened?"

He was hypnotized and asked to explain.

> When I had the canvas stretched like you told me to, I knew I had plenty of time. So I worked on it as slowly and as carefully as I could. I painted just the way I always do-slowly. And I had trouble, too. I knew the clown's coat had to be blue and the ribbon and the Ferris wheel also. They had to be the same shade of blue but a different blue. I used different pigments for each one, and it was an awful slow job mixing those different pigment combinations to get the same shade of color. And I had trouble with the horse's mane. I wanted to work out an entirely new technique for that, and I finally succeeded. [The critics also commented favorably on that item of technique.] But I didn't have to hurry because I had plenty of time. And then when I had it finished,
>
> I studied it a long time, making sure that it was all right, and when I was finally sure, I signed it. Then I picked up my sandwich and woke up. I didn't remember a thing, and when I saw the picture I got puzzled and scared. I even examined the studio doors—they were still locked on the inside. So I knew that I had better see you in a hurry. But it is a good picture. Be sure you help me to know that I really painted it.

While he now knows he painted it, his general understanding of the entire matter is sketchy and vague, but his satisfaction is unchanged. A year later he commented on the "curious fact" that in daylight the three shades of blue are identical but that under different lighting effects they are dissimilar. From this he had "deduced" that he "must have used different pigments."
Therapy was terminated a few sessions after the completion of the picture.

Comment

Regardless of the dynamics involved, the hypnotic suggestions given, and the purposes served for the patient, one fundamental fact remains. This is that a task conceived of as requiring, on the basis of long experience, a total of about 70 hours, was accomplished in six with no known preliminary preparation, at a totally unexpected time and in a fashion alien to established patterns of behavior and work. The parallelism between this report and many of the experimental findings reported in the first part of this book is at once obvious and pertinent.

PATIENT B

This next case report is decidedly different. It is an example of the intentional therapeutic use of time distortion as a consequence of a failure to secure results by other methods. And since therapy was the desired goal, there was no opportunity to utilize the clinical situation to demonstrate time distortion *per se*. Rather its existence as a reality in the situation was assumed, and all efforts were directed to the securing of therapeutic results as a direct outcome of its utilization.

The patient was a 30-year-old twice-married woman who was known to have suffered from recurrent episodes of hysterical amnesia characterized by essentially complete personal disorientation. These attacks dated from two years prior to her second marriage six years ago. Since it had been a hasty wartime marriage, her second husband knew practically nothing about her past except that she was a widow with two children and that she had recurrent "sick spells when she didn't know nothing."

She was first seen in consultation while hospitalized with amnesia. She gave the date as 1934 and described herself as a woman but could give no other information. She did not recognize her name, her husband, or her children. She complained of a severe headache, and her appearance and behavior corroborated this complaint.

She made, as was usual for her, a sudden spontaneous recovery after three weeks in the hospital and left hurriedly in a state of terror upon discovering where she was.

She was seen at home the next day. She was fully oriented but still frightened. She explained that many times in the past she had suddenly awakened in a hospital after being unconscious for days at a time or even weeks. However, she was uncooperative about further questioning or therapy.

She was seen again five months later. During that time there had been a number of brief amnesic periods during which she had been cared for at home by constant supervision. Now she was again amnesic, and the only information that could be elicited was that she was a woman and the year was 1934. She was hospitalized and heavily sedated for a week. She then made her usual sudden spontaneous recovery, but this time she was cooperative about therapy.

She was interviewed daily for the next three months from two to four hours each day. Only a scanty outline history of her present marriage could be obtained. As for her previous life experiences, she knew only that she had been widowed, but not the year, although she knew the birth dates of her children. Nothing more of apparent significance was elicited. Mention of the date 1934 was without any apparent meaning to her. She expressed doubts about the correctness of her first name. This lack of knowledge of her past was most frightening to her, and every inquiry caused her intense anxiety.

Concerning her amnesic states, she regarded them as periods of unconsciousness. She described them most unsatisfactorily. Typical of her accounts is the following: "When I woke up in the hospital, the last thing I remembered was walking down the street when a truck came along." Or, it could have been going to the store or reading a newspaper.

During those first three months every possible effort was made to secure some understanding of her problem. Since she proved to be an excellent subject, every hypnotic technique known to the writer was employed, to no avail. While she could be regressed in age, such regression was limited to the relatively normal happy periods of the past eight years. Indeed, every effort to reconstruct her past by whatever technique was restricted to some limited period of the recent past. Automatic writing and drawing, crystal gazing, dream activity, mirror writing, free association, random utterances (i.e., every fifth, eighth, or tenth word that comes to mind), depersonalization, disorientation, identification with others, dissociation techniques, and other methods were futile. It was obvious that she was trying to cooperate, but only relatively meaningless material of the recent past was secured.

Additionally during this time she developed frequent amnesic states of one to three days' duration. During them she always gave the date as 1934. While she could be hypnotized deeply in these states, and hypnotic phenomena elicited, these were restricted and limited in character to various aspects of the actual office situation. Thus she did not recognize the writer but did regard him as a possibly friendly stranger. She viewed the wall calendar as "some kind of a joke," since it did not read 1934. She could hallucinate readily and would count the books in an hallucinatory bookcase. She would write simple sentences upon request, but did not seem to understand what was meant when efforts were made to have her write her name, geographical location, or age. Nothing that impinged upon her personal life seemed to be comprehended. However, to a colleague experienced in hypnosis but unacquainted with her, she was obviously in a trance. She would awaken from these trances in the amnesic state.

These amnesic periods usually terminated after a night's sleep, or if more than a day in duration, responded to heavy sedation.

On one occasion, in the writer's presence, she chanced to see through the window a Borden's milk truck, and immediately she developed a three-day amnesia. Several days after her recovery, during an interview, she happened to see on the writer's desk, purposely placed there, a small calendar advertising Borden's milk. Another three-day amnesia occurred. Later she was asked to copy a weekend sales advertisement. Upon

reaching the item of Borden's milk, a third three-day amnesia ensued. Still later, while discussing recipes, Borden's milk was mentioned by the writer with a similar result. Finally she was asked what a male hog was called and what a bear slept in. She gave the correct answers. She was then asked, with careful emphasis upon the key words, "What would happen if you put a boar in a den?" Her reply was simply, "I guess the bear would eat him."

However, the amnesic states were frequent and were apparently caused by a variety of other stimuli not recognized by the writer.

Every effort was made to secure some measure by which the amnesias could be interrupted or aborted. Finally a very simple measure was found. Since she could be regressed to a previous age within the eight-year limit, and since she always gave the date as "sometime in 1934" when amnesic, the regression technique in reverse was employed. Thus she would be hypnotized and in a systematic, repetitious fashion be told, "Yes, it is 1934, and the seconds and the minutes are passing one by one, and as the seconds and the minutes pass, so do the hours, and with the passage of the hours, so do the days pass. As the days pass, so do the weeks. The weeks come and go and the months pass and 1935 is coming closer and 1934 is passing, passing. And after 1935 will come 1936, which will pass, and then it will be 1937," etc., until the current time was reached. Frequent need to utilize this technique rapidly reduced the initial period of 30 minutes to less than five in bringing her out of her amnesic state. On two occasions, when she wandered away from home and was picked up amnesic by the police, her memory was promptly restored by this technique.

A laborious, futile effort was made, following this success, to regress her from 1934 to 1933 or earlier. Then an effort was made, after getting her to accept the argument that there were years antedating 1934, to induce her to forget 1934 and to experience the date as 1930, with the hope of building up from that date. This and numerous variations of the general idea failed.

After three months' failure to make recognizable progress with her it was decided to employ time distortion.

In the guise of sharing personal satisfactions in past professional experimental work, several prolonged sessions with her were devoted to presenting the general concepts and experimental procedures of time distortion, all as something of only intellectual interest to her. In so doing it was hoped to avoid any measures of defense against this therapeutic approach.

This was done in both the waking and the hypnotic states. When she seemed to have a good comprehension of world, solar, clock, special, experiential, and allotted time, time distortion, and time distortion experiments, the suggestion was offered that she might like to engage in an experiment comparable to those that had been read and explained to her. She agreed readily and seemed to be under the impression that the project was essentially a mere continuation of the already published study.

The next day she was hypnotized deeply and instructed as follows:[1]

> You have many times taken a trip in a car and enjoyed it immensely. The car was moving very rapidly. You saw this sight, you saw that scene, you said this, you said that, all in an ordinary way. The car moved fast, but you were sitting quietly, just going along. You could not stop the car, nor did you want to. The telephone poles were so many feet apart and they came along one by one and you saw them pass. You saw the fields and they passed by, large fields, small fields, and you could only wait quietly to see what would be in the next field, and to see whether the next house would be brick or frame. And all the time the car went along and you sat quietly, you saw, you thought, all in your own way, at your own speed, just as it happened, and the car just kept going. You did not need to pay attention to the car, *just to what next would happen*, a field, a house, *a horse or whatever was next*."
>
> "However, this experiment will not be a car ride. I have just used it to explain more fully to you. I could have described going through the cooking of a dinner—peeling potatoes, washing carrots, putting on pork chops—*anything that you could have done*."
>
> "Now I'm going to give you much more time than you need to do this experiment. I will give you 20 seconds world time. But in your special time that 20 seconds will be just as long as you need to complete your work. It can be a minute, a day, a week, a month, or even years. And you will take all the time you need."
>
> "I will not tell you yet what your experiment or task is. As soon as you nod your head to show that you are ready, I will start the stopwatch and give you the signal now, and very rapidly I will name the task and you will start at the beginning of it, the very beginning, and go right through to the end, no matter how far away it is in time. Ready? All right, listen carefully for the click of the watch, my signal, and the name of the task. *Now—from Childhood to Now—remember*!" [The Now was repeated as literally a double signal.]"

Her response was a tremendous startle reaction, a gasp, a marked physical slumping in her chair and a frozen facial expression.

Twenty seconds later she was told, "Stop," and was asked, "Through?"

"Yes."

"Will you tell me if I awaken you?" "Yes."

For several hours there was a tremendous outpouring of her past traumatic memories. These were related in a most remarkable fashion. She detailed them as if they were actually in the course of happening, or as if they were items of the very recent past, and at

the same time, in a dissociated fashion, she offered comments and interpolated remarks bearing upon much later events. For example, she began her account with:

> "My dress is pink. It's my birthday. I'm sitting in a high chair. I'm going to eat my cake. My daddy is going to kiss me. He falled down. That's what happened. My father died of heart failure. I was three years old. Pink dress. When Deborah [her daughter] wanted a pink birthday dress, I forgot everything and I went to the hospital. I couldn't think. My head ached. . . .I'm going on a train ride. Mummie is taking me. It's fun. See the pretty trees. There's cows, too. Mummie is coughing. She's sick. Her handkerchief is all red. [Pulmonary hemorrhage.] I'm scared. My mother is so sick. And every time Elaine [her second daughter] had a nose bleed, I got sick. . . . I'm so tired and thirsty-he keeps doing it—he's going to kill me—I wish somebody would come." [This was a long story of being tied hand and foot to a bed for three days and repeatedly raped by a man named Borden.]

Another account was that of her delivery in 1934 of her stillborn child resulting from the rape, and her vivid report of the delivery scene and her grief over it. "That's when everything in me died. I couldn't stand to remember."

Three more instances that may be cited are her first husband's infidelity and the finding of a love letter from his paramour in his effects, and her present husband's receipt of a letter from a former fiancée, with a consequent amnesia resulting for her; the suicide of one of the girls in the maternity home during her own stay there by hanging from a chandelier, and her own daughter of similar age tying crepe paper to a chandelier as a Christmas decoration; and the inexplicable death of her third child while lying in bed one night, and reading a newspaper account of a similar instance. All of these were vividly described in the present tense and then related to actual amnesic episodes.

There were many more comparable traumatic experiences recalled and discussed, all in chronological order. This required many hours before she could complete her review of her past. Various of the events could be verified, some appeared to be hysterical fantasies of a morbid character, and yet later some of these were found to be true.

Her therapeutic response to this catharsis was decidedly good. However, there were several more brief amnesic episodes, but each time she recovered promptly and was able to define the precipitating stimulus and to relate it to either an incompletely discussed trauma or to one that had been overlooked. In each instance the precipitating stimulus lost its effect upon her. For example, upon moving to a new location, she readily purchased her milk from the Borden truck that traveled that street.

Shortly after all this her husband deserted her. She responded by divorcing him, securing employment, and supporting her children adequately. Her employers thought highly of her.

Therapy was discontinued upon her gaining employment, except for brief casual visits at long intervals.

In final appraisal, two years after termination of therapy, she was still an hysterical personality type, but well controlled and functioning at an adequate personal, social, and economic level.

Comment

What happened during that eventful 20 seconds after months of futile effort, and how it happened, can be speculated upon best in terms of the experimental findings reported in the first part of this book. That the previous work with the patient quite probably laid the foundation for the final outcome does not militate against the significance of what occurred in 20 seconds time.

Her narrative of what happened, extended over many hours, was given largely in the present tense. Yet at the same time it was given with interpolated comments and explanations relating long-past events of her life with those of the recent past. This indicates that the narrative was not a simple initial revivification of the past. Rather it strongly suggests that in those 20 seconds she had achieved a sufficiently comprehensive recollection of her life history to be able to see it in meaningful perspective. Then, in her narrative, couched in the terms in which she had reacquired her memories, she communicated it to the writer for his understanding and at the same time achieved for herself an effective catharsis of her experiential past.

Before utilization of time distortion, therapy was a clinical failure. Twenty seconds of time distortion, whatever that may mean clinically, resulted in a therapeutic success of a known two years' duration.

PATIENT C

This case report concerns a relatively circumscribed emotional problem for which the concept of time distortion was employed as an expeditious and experimental measure.

The patient, a 25-year-old student working his way through college, was primarily interested in the field of entertainment. His voice was fair and he accompanied himself on a guitar. Because of his promise as a singer, a night club gave him regular weekend employment. Unfortunately, as the weeks went by, his performance showed no improvement, and he was notified that he would be replaced at the first opportunity. This had caused him much discouragement, anxiety, and depression, and he sought therapy because of his hopeless attitude.

His history disclosed nothing of immediate significance except that his studies and his regular weekday employment on a late shift, in addition to the weekend engagement, gave him practically no time for practice.

Further inquiry disclosed that his late shift was characterized by spurts of activity followed by intervals of idleness.

This fact suggested a possibility for utilizing time distortion. Accordingly the question of hypnosis was raised with him, and he dispiritedly expressed his willingness to try anything. He proved to be a good hypnotic subject and was easily trained in hypnotic phenomena.

This accomplished, he was systematically instructed, under hypnosis, in Cooper's experiments on time distortion until his understanding of the general concepts was good. The suggestion was offered that he might participate in a time distortion experiment. He was disinterested in the idea but did consent reluctantly. He preferred that attention be given to his problem.

Accordingly, on a Monday, while in a profound trance, he was given a series of posthypnotic suggestions. These were that he was to utilize, from time to time, each night the idle periods at work to develop brief 10- to 30-second trances. During these trances, at an hallucinatory level, he would have adequate special personal time to practice extensively both his singing and his playing. Since the trances would be brief in clock time, and since his practicing would be hallucinatory in character, his fellow-workers would not note more than that he appeared momentarily self-absorbed.

He was awakened with a total amnesia for the trance instructions and given an appointment for the next Monday.

He reported excitedly at that interview, "I've got a new lease on life. Saturday was the best night I have ever had. Sunday night I did so well that the boss said that if I kept on that way, I could be sure of my job. I don't understand it because I didn't get a chance all week to practice. But Sunday I got out my tape recorder and made a new recording. Then I played it and some of my old recordings for comparison. Sunday's sounded as if I had had a lot of practice. I was amazed to find out how much I had improved. I must have unconsciously ironed out some emotional kink that was interfering."

Hypnotized, he explained that he had averaged at least three long, as well as several brief, practice sessions per night. During the long sessions he went through his repertoire, and the brief sessions were used for the practice of individual selections. Each time everything seemed to proceed at a normal tempo. Additionally, he frequently made an hallucinatory tape recording which he "played back" so that he could listen to his practicing and thus note errors for correction. At no time had any of his associates seemed to notice his periodically preoccupied state. He expressed his intention of continuing with this method of practice and supplementing it with ordinary practice.

At the present time, many months later, he still has all of his jobs and his weekend stipend has been greatly increased. He has enlarged his repertoire, and he practices at every opportunity in the ordinary state and in posthypnotic trances in time distortion.

He is still unaware of his trance activities but is greatly amazed at the rapidity with which he learns new selections.

To date he has made no effort to apply this special learning in any other way. Nor has such a suggestion been offered to him, since the excellent therapeutic result might possibly be jeopardized by other experimental efforts.

Comment

This case report is essentially a parallel of some of the experimental findings reported by Cooper. While the validity of this report rests upon the bare facts of the patient's statements and his continued employment at an increased stipend, there can be no question that the concept of time distortion served a significant personality purpose for the patient. Additionally, of particular note is the fact that the patient elaborated the suggestions given him by including an hallucinatory tape recorder to further still more the hallucinatory practice sessions, and that he has continued to utilize time distortion in learning new selections.

PATIENT D

The manner in which this patient sought therapy was both challenging and baffling. Her seemingly impossible demand was met by the utilization of time distortion, which resulted in amazing and surprisingly rapid therapeutic results.

She was a 19-year-old girl employed in a dental office, and she suffered from a severe reaction to the sight of blood. Usually she fainted, although occasionally she became only nauseated and greatly distressed. Otherwise she was a competent and willing employee and genuinely interested in dental work. She was directly referred for therapy by her employer, who expressed a hope to retain her services and at the same time a fear that her behavior of the past few months precluded any such hope.

She arrived at the office accompanied by a chaperone. She seated herself and smoothed her dress down with exaggerated modesty and was utterly brief and final in her statements. She declared that she had come for therapy, that this was to be accomplished in a single interview, and that hypnosis was to be employed.

The protest that she was demanding a miracle was disregarded by her. She merely reiterated her demand.

When asked for her history, she replied, "The doctor [her employer] has already told you over the phone. All the time I've worked for him, I've fainted every time I saw blood, and I hate being picked up off the floor over and over again. I'm going to lose my job and I want to work in a dental office. That's my ambition. That's all you need to know. Now, I want to be cured. I want you to hypnotize me right away and cure me." It was as if she had indicated an aching tooth and was demanding an extraction.

A deep somnambulistic trance was induced with remarkable ease. Asked if she were ready for therapy, she shook her head negatively and asked that "things" be "changed." This cryptic request led to an inquiry about the chaperone's presence. She asked that the chaperone be dismissed "tactfully."

When this was done, she hastily and with great urgency declared, "I'm scared—I don't know why— "I'm afraid to think *and I won't think*. You have got to hypnotize me some more or I'll wake up—I just can't stay asleep. Just keep me asleep and *don't let me wake up*. You have got to help me, *but don't let me know about it until it's all over, and do it fast or I'll wake up and faint. I don't want to know anything and I don't want you or anybody else to find out what's wrong*. So don't try to find out and don't let me wake up." Much of this was repeated with emphasis.

She was assured that her wishes would be met to the fullest extent. The suggestion was offered that first of all it might be well to have her experience, as a means of keeping her hypnotized and as a measure of giving her satisfaction, the various common phenomena of the hypnotic trance. She agreed readily as if being given a reprieve, but admonished the writer not to forget the problem of therapy afterward.

For 50 minutes she enjoyed thoroughly experiencing a great variety of the common hypnotic phenomena. Care was exercised constantly neither to impinge upon her personal life in inducing the hypnotic manifestations nor to seek any understanding of her as a person.

She was then told, while still in the trance, that there remained a couple more phenomena which she could enjoy. One of these was related to time and would really center around a stopwatch, which was exhibited to her.

With every effort to be instructive, she was reminded of the rapidity with which time passed when she was pleased, how slowly when bored, the endlessness of a few seconds' wait for an intensely regarded outcome of a matter in doubt, the rapidity with which a mere word could cause to flash through the mind the contents of a well-liked book or the events of a long, happy trip and the tremendous rapidity and momentum of thought and feelings.

Against this background a detailed elaboration was presented of the concept of distorted, personal, special, or experiential time as contrasted to clock time. Extensive discussion was also offered of the "normal tempo" of distorted or experiential time.

When she seemed to understand, the explanation was offered that this hypnotic phenomenon could be initiated for her by giving simple instructions which she could easily accept fully. These instructions would be followed by the starting signal of "Now," at which time the stopwatch would be started. Then, when the phenomenon had been completed, she would be told to stop. This explanation was repeated until she understood fully.

Then with compelling, progressive, rapid, emphatic, insistent intensity she was told, "Begin at the beginning, go all the way through in normal experiential tempo with a tremendous rush of force, skipping nothing, including everything, and reach a full complete understanding of everything about *Blood-Now*."

She reacted to the word "blood" by a violent start, trembled briefly, became physically rigid, and clenched her fists and jaw. She appeared to be in acute physical distress but too rigidly involved physically and mentally to break into disruptive actions.

Twenty seconds later, at the command "Stop," she relaxed, slumped in the chair, and breathed hard.

Immediately she was 'told emphatically, "You now know, you understand, you no longer need to fear. You don't even need to remember when you are awake, but your unconscious now knows, and will continue to know and to understand correctly, and thus give to you that ease you want."

She was asked if she wished to awaken or to think things through. Her reply was, "I've done my thinking. Wake me up."

Her waking remarks were, "I'm all tired out. I feel simply washed up. Where is Miss X [the chaperone]? What's been going on—did you put me in a trance—did she see me?"

The reply was made that she had been hypnotized and given an opportunity to learn hypnotic phenomena, but that Miss X had not been a witness. She asked that Miss X be summoned and some unimportant demonstration be given to show Miss X what hypnosis was.

When this had been done, she remarked, "I suppose I owe you a fee, but I don't even know why. But I am going to make you wait for it. I don't know why."

She was told to return in one month's time. She replied, "I suppose I will, but there is no reason to do so," and thereupon took her departure.

Late the next day her employer telephoned, stating, "Whatever you did, worked. She has assisted all day in comfort, handling extracted teeth, washing out bloody trays, and even picking up bloody teeth and examining them. I haven't said a word about you nor has she and I don't think it wise."

Three weeks later part of the fee was received. A week later she came in to say, "I don't know why you want to see me. There is no reason. I've had to get another job. My boss is going into the Army. So I've got another job. It's with Dr. Y [a dentist who does extractions]. I like being a dental assistant."

A few days later a telephone call was received from her. She inquired about the balance of the bill and expressed regret for having overlooked it. Asked about her work, she

declared that it was wonderful and that she would place a check in the mail immediately, as, indeed, she did. Her good adjustment is known to have continued for more than a year.

Comment

To discuss this report without emphasizing the obvious is difficult. One can readily state that it demonstrates that sometimes brief psychotherapy can be remarkably effective; that the dictum that the unconscious, if therapy is to be achieved, must be always made conscious warrants serious doubt; and that the concept of time distortion lends itself in a remarkable way to clinical therapeutic work.

What the patient's problem was and the nature of its causes remain unknown, even to her conscious mind. Equally probable is that therapy by other methods, given more cooperation, could have led to a similar therapeutic result. However, the fact remains that, whatever her problem was and how the therapy was achieved, the concept of time distortion proved applicable and effective under adverse conditions in meeting adequately the patient's needs.

PATIENT E

The following case is reported for two reasons. It illustrates a problem comparable to the preceding case history in that, despite much previous therapy, the entire therapeutic result was determined by the handling of a single session. Secondly, the crucial situation was one in which time distortion could have been used most advantageously but was not, since it antedated Cooper's experimental work. Viewed in retrospect, however in terms of what happened and the final result, the utilization of time distortion could easily have resolved the ominous difficulties that developed.

Two young women in their mid-twenties had been intimate friends since early childhood. Now they were roommates and engaged in the same occupation. Each had influenced the other in the choice of work. Both were members of a minority group and had grown up in a community rife with prejudice. Both encountered prejudice in their daily work. Each confided in the other, and they regularly exchanged sympathy and encouragement. Their identification with each other was remarkably strong, and their relationship was definitely sisterly in type. Their adjustment within their own group was good, but they were both regarded as decidedly neurotic and they themselves recognized their neurotic patterns of behavior. Each encouraged the other to seek psychotherapy but neither had the courage to do so for herself.

Their neuroses deepened, and one night Kay complained that all day she had felt strange and different. Peg tried to comfort her but found her peculiarly unapproachable. The next morning Kay was even more disturbed, and on the way to work her erratic behavior attracted the attention of the police. When hospitalized she manifested an acutely catatonic state.

For about a month Peg brooded over Kay's condition, wondering obsessionally if she should "let myself go like Kay did." Her work performance failed greatly, and she spent much time staring into space.

Finally, and reluctantly, she decided to seek therapy. Four psychiatrists were consulted, two of whom stated that their schedule was too full. The other two declared that they did not have the training requisite for her problem. She was then referred to the writer. Inquiry of the other psychiatrists disclosed that they felt that she was an "incipient, if not an actual catatonic," and not amenable to therapy at the time.

Hypnotherapy was employed from the beginning, but progress was slow, uncertain, and difficult. Frequently she appeared on the verge of an acute psychosis. Repeatedly during interviews, both in the waking and the trance states, she would ponder the idea of "giving up" and "letting myself go just the way Kay did."

One evening she entered the office for her usual appointment wearing a completely new outfit, including even hat, shoes, and handbag. Most seriously and in a frightened manner she declared, "I don't know what I'm doing. I can't afford these clothes. Either I'm going to improve or I'm having a last fling before they lock me up. Maybe my unconscious knows."

With this remark she closed her eyes and developed a deep hypnotic trance. She was asked why she had purchased the new clothes. She answered, "I don't know. Either I'm going to get well or I'm going to get worse. Wake me up."

She aroused with an apparent amnesia for her trance state. Immediately she asked, "Instead of working, can't we have a little casual conversation?" However, after a few commonplace remarks she declared suddenly that she had just remembered that she had dreamed the previous night. This dream, she knew, was tremendously important, but she could not recall its content. Perhaps a little reflection would enable her to remember it.

After a couple of minutes of thoughtful silence she leaped to her geed and screamed, "No, no I won't remember any more. I won't. I won't It's too horrible. I'm going to forget it so that I can never remember the rest of it. It's too horrible. I'd go crazy if I remembered it."

The, speaking to herself, she proceeded to utter a whole series of auto-suggestions, patterned after the writer's technique of suggestions, to induce an amnesia. She concluded then with a self-satisfied remark, "I've just forgotten something. I don't know what is was even about, but I do know that I can't even think of what it might be. It's completely forgotten."

In a subdued, frightened way she continued. "I know I've done something I shouldn't have done, but I don't know. It was wrong, but I'm glad I did it, awfully glad. But now I will have to give up therapy because there is no hope for me, and I'm glad. Good night!"

With difficulty she was persuaded to remain at least long enough for a social visit, but she kept declaring, “It’s no use.”

However, she was finally induced to review superficially and disinterestedly some of the work of previous sessions, but was adamant in her refusal to permit further hypnosis.

Finally she was persuaded to allow the writer to try and find out what she had done that was wrong and which had made everything “all over” for her. She agreed reluctantly, but again stipulated that hypnosis was not to be employed.

A whole series of speculations was offered to her, among which, in random order, were included, dreaming, remembering a dream, and forgetting a dream. She listened attentively and thoughtfully but discarded every possibility named.

She then announced her intention of leaving at once and going to visit Kay, “because I’m going to do something horrible when I get to her ward.”

The plea was offered that she stay a little longer to please the writer. She yielded reluctantly but began pacing the office. She smiled to herself, pirouetted, waved her arms, fiddled, and now and then stared abstractedly into space. Her attention could be secured fairly readily, although only briefly.

At last, after much persuasive effort, she consented to be hypnotized but declared that she would terminate the trance and walk out of the office, never to return, if there were any hint at therapy or even investigation of her ideas.

A number of trances were induced and utilized to elicit demonstrations of the common hypnotic phenomena in an impersonal manner.

When an effort was made to induce crystal gazing, she protested that that measure had been used therapeutically with her. She was reassured by having her hallucinate a rosebush and count the roses on it.

However, any attempt at depersonalization, disorientation, or regression elicited prompt protest and treats of waking and leaving.

More than four futile hours were spent in laborious efforts to gain control of the situation. In retrospect the concept of time distortion could have been readily and easily utilized. With the first development of her adverse reaction there could have been made a shift from the therapeutic situation to a simple experimental situation involving distorted time. Then in all probability her behavior would have paralleled that of Patient B or E.

However, after this extensive effort with her, a solution of the situation was finally reached by means of a simple, fortunate stratagem.

She was told, “Since you are terminating therapy and I shall not see you again, I would like to ask a parting favor. I hope you will grant it. It is this. You entered the office wearing a new outfit and I was glad to see you. Now I would like to hypnotize you and send you out of the office to enter it again as you did earlier, so that once more I can have the pleasant feeling I had when I first saw you tonight. Will you do this?”

She agreed and a deep trance was induced. She was instructed, “Leave the office, walk up the hall a short distance, turn, and then *come down the hall and enter my office in exactly the way you did upon arriving, feeling and believing as you enter that you have just arrived, and give me the same initial greeting*.”

In her willingness to grant this parting favor she was so attentive to the actual wording of the instructions that she failed to perceive their significant implications.

She obeyed the instructions exactly and thus reentered the office regressed in time to the moment of her original arrival. Thereby an amnesia had been effected for everything that had already occurred in the office.

In this new psychological setting it became relatively easy to guide a second course of developments.

By techniques of dissociation, depersonalization, disorientation, and crystal gazing, the patient was enabled to achieve adequate insight into and understanding of both the dream and the uncooperative, disturbed behavior related to it.

Thereafter the course of therapy was favorable and rapid, and it was soon terminated as successful. More than eight years have verified this judgment.

Comment

Perhaps technically this case report, like that of Patient A, may be regarded as not belonging properly to this series. However, it illustrates, and all the more clearly since it is in retrospect, how the concept of time distortion, had it been available, could have been applicable and effective in an extremely difficult therapeutic situation. In its absence hours of futile anxiety, which certainly did not benefit the patient, had to elapse until a fortunate stratagem of psychological maneuvering met the patient’s needs. Otherwise the probable outcome would have been regrettable.

Furthermore this case presentation illustrates the constant need, in every field of endeavor, to review the past in terms of newer understandings and thus to achieve a better comprehension of both the old and the new.

PATIENT F

This final case report concerns a difficult psychiatric problem in which therapeutic progress was exceedingly slow and difficult until resort was had to the utilization of time distortion.

The patient, in his mid-twenties, complained of a variety of symptoms. He suffered from overwhelming obsessional fears of homosexuality; he had frequent disabling headaches; he was extremely fearful and shy; he loved from day to day without any interests; he was both agoraphobic and claustrophobic; and he was afraid to look at women because they became hideous creatures in some inexplicable way that caused him to be afraid to look at them.

These symptoms, of more than six months' duration, had developed rapidly some 18 months after he had completed his military service, but he could not attribute them to any particular set of circumstances nor to any particular time. They had merely developed with such distressing rapidity that he was not able to remember their onset not the order in which they appeared.

The personal history he gave disclosed little of recognizable significance, nor was he at all interested in discussing it. His concern was a repetitious recounting of his present condition.

However, it was learned that his military history was creditable and that he had had active combat experience. Upon discharge from the Army he had systematically visited numerous relatives in the East and then had come to Arizona for employment.

Shortly thereafter his father and stepmother had moved to Arizona because of his father's health. While he did not live with them, he visited them weekly until shortly before entering therapy, and he supported them willingly. His relationship with them both had always been and still was good.

His mother had died "when I was just a little boy. It was on my tenth birthday. She was awful good to us kids. There were eleven of us. She dies suddenly, I guess it was her heart. We were awful poor and it was a really tough struggle. We were glad when Dad married Mom. This got easier then."

Further extensive questioning elicited one other item of possible significance. This was that shortly prior to the onset of this symptoms, contrary to his usual habit, he had slept poorly and had had most disturbing dreams, none of which he had remembered subsequently.

Then one morning on his way to work he saw a pretty girl, but a close look disclosed her to have the hideous appearance of a "rotting corpse." This terrified him. Further down the street he was another girl approaching, and as they met she too assumed the appearance of a "rotting corpse." Doubts of his sanity came to his mind, and these were reinforced by the discovery that every female he met became transformed into a similar

revolting sight. When he finally reached the large factory room where he worked with a score of other men, he felt protected and most grateful to them, but drawn to them emotionally in a "horrible, sentimental way."

Thereafter journeying back and forth and working became nightmare experiences for him.

On payday he had to stand in line in a small office to receive his check from a young female clerk. He became oppressed by the small size of the room and felt hopelessly trapped. Following this he was unable to sleep in his room unless the windows were open and the door slightly ajar, and repeatedly during the night he would awaken to see if all were well.

He sought therapy because he felt himself on the verge of insanity, with suicide the only other possible alternative.

Therapeutic interviews for many weeks yielded little more than a compulsive, repetitious recounting of material already related. He was averse to hypnotherapy and insisted that if he talked long enough, he would succeed in "talking it out."

Finally, since his funds were being exhausted, he was persuaded to permit hypnosis as a possible stimulant to more rapid progress. However, he emphasized that actual therapy must be limited to the waking state. Accordingly it was agreed that the hypnosis would be employed simply to give him access to unconscious material which could then be discussed in the waking state.

He proved to be a good subject and, after intensive training to insure a good hypnotic performance, his permission was asked for a therapeutic investigation. This was refused, and he insisted anew on only waking therapy.

Accordingly he was told that an experiment requiring 10 to 20 seconds' time could be done that would undoubtedly enable him to get at the core of his difficulties. Reassured by the brevity of the time required, he consented readily.

He was systematically taught a working knowledge of time distortion in much the same fashion as has been described above.

When this had been completed, he was given the following instructions:

> With this stopwatch I will give you an allotted world time of 20 seconds. In your own special experiential time, those 20 seconds will cover hours, days, weeks, months, even years of your experiential life. When I say "Now," you will begin the experiment. When I say "Stop," you will be finished. During that 20 seconds of world time you will sit quietly, neither speaking nor moving, but mentally, in your unconscious, you will do the experiment, taking all the experiential time you

need. This you will do thoroughly, carefully. As soon as I give you the starting signal, I will name the experiment and you will do it completely. Are you ready?

"Now—Go through all the causes of your problem. *Now*."

"Stop."

Immediately he awakened, sighed deeply, wiped the perspiration from his face and stated, "It was my mother. She always told me to trust her. I was so mad when she died and I hated her."

He paused, and then went on to explain, very much as Patient B did but with much less tendency to vivify so intensely. He employed tenses in a comparable fashion and interpolated explanations similarly.

A summary of his utterances is as follows:

I was a little boy sitting in her lap. I cam home from school and I fell and bit my tongue and she told me to trust her. That was her way of comforting. I suppose, but I didn't understand. The cat scratched me [rubbing his hand]. Always she said "trust me." She promised me a birthday party when I grew up. I waited and waited—hundreds of days. I can feel that waiting right now. It was so long. I waited for her to tuck me in bed—she is good. I waiter for her to get me a penny for candy—I waited and waited. Always she said "Trust me." It all happened right here in this room, but I thought I was back in Pennsylvania. I had to run home from school because I played too long and I was late. And always, always, always, I heard her say, "Always trust mother, just trust Mother, you can always trust Mother." She is just saying it to me over and over and over all the years.

I have just been growing up from a little boy. Everything that happened to me that made mother say "Trust me" has just been happening right here.

There are so many of them. I can tell you them if I should, I don't need to because they all led to the same thing. [He was assured that other details could be given later.]

I was 10 years old that day. Mother promised me a special birthday dinner and cake. We were too poor to have those things. I wanted it so bad. She dept telling me all day, "Trust Mother to make your cake, the best cake you will ever have in all your life." She is going in the kitchen, she stopped, I saw her get pale. She said her arm and shoulder hurt and she went to bed and I sat and watched her die. The last thing she said was "Trust me." I was mad at her—she promised me and she always told me to trust her and I did and I didn't have my birthday. I hated her— I was sad, too. I didn't know how to feel and I was scared. But I forgot all that. I just remembered it here.

> And then Dad and Mom came to Arizona. I visited them regular. Then one day he told me confidentially that he had cancer and that the doctors said he had only a month left to live. [Actually the father lived nearly a year.] I was feeling bad about this. I heard him tell it to me just the way he did then. Then later Mom said, "This is the tenth birthday of our marriage," and I froze up still and I just now heard her say it again just like she did then. Then I was going to bed and trying to sleep, but I kept waking up because I kept seeing dead bodies. I hated them. They were my mother. And every one of them kept saying "Trust me." And I tried to run to my Dad and climb into his lap and I wanted him to love me and comfort me and put his arms around me. And I could not find him anywhere and everywhere I looked, I saw Mother dead and saying "Trust me."
>
> And the next day everything began. The girls on the street, my crazy ideas.
>
> That's how my problem started. Now it's over with.

The patient was right. Therapy was complete except for a few more interview. During these he reviewed various incidents of the past and discussed his confused thinking and emotions as a child and his consequent development of intense guilt reactions.

A year has passed. He is engaged to be married and is happy and well adjusted.

Comment

One can only speculate on how long a time therapy by other methods would have required. Equally well one can wonder how time distortion, in 20 seconds, could effect a removal of such massive repressions and activate into seemingly current reality so great a wealth of experimental life.

Undoubtedly the preceding efforts at therapy and the established rapport constituted a significant and essential foundation for the therapeutic results obtained. It does not seem reasonable to this writer that in this kind of a problem time distortion could be used as an initial procedure. But the results do indicate that time distortion has definite clinical and therapeutic applications.

GENERAL SUMMARY

Perhaps the best way to summarize these clinical studies is to refer the reader to the conclusions at the end of the experimental section of this book.[2] In so doing the parallelism between the experimental findings and the clinical findings is easily recognized.

Study of the concept of time distortion by controlled experimental research led to findings of definite psychological interest and significance. The same concept was utilized independently in the totally different field of clinical and therapeutic problems. It yielded results confirmatory and supplementary of the experimental findings. The

therapeutic results obtained indicate the validity of the concept of time distortion and its applicability to psychopathological problems.

There remains now the need for further and more extensive and varied study of time distortion both as an experimental psychological problem, and as a useful concept applicable to clinical and therapeutic work.

---

[1]These instructions are probably much too elaborate, but a first experimental therapeutic effort with a new methodology is not an occasion for economy. They are presented rather fully in order to demonstrate the effort at comprehensiveness.

Further Considerations of Time Distortion: Subjective Time Condensation as Distinct from Time Expansion

Milton H. Erickson and Elizabeth M. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, October 1958, 1, 83-89. Published simultaneously as an additional section in the second edition of *Time Distortion in Hypnosis* by Linn F. Cooper and M. H. Erickson, published by The Williams and Wilkins Company, Baltimore (first edition, 1954).

Shortly after the publication of the first edition of this book one of the authors of this new section (E.M.E.) noted a definite oversight in the development and explication of the concept of time distortion and its clinical applications. This new section is intended to correct that omission and to clarify, from a slightly different angle, the concept of time distortion and other aspects of its clinical application.

In both the experimental and the clinical sections of this book the concept of time distortion has been developed unilaterally in relationship to the "lengthening" or "expansion" of subjective time. The converse manifestation-that is, the "shortening," "contraction," or "condensation" of subjective time-has received no direct recognition or elaboration, except for brief mention in discussions to establish contrast values. However, the implications to be derived from, and the deductions warranted by, the experimental and the clinical sections of this book make apparent that time distortion as an experiential phenomenon may be either in the nature of subjective "time expansion" or its converse, "time condensation."

Though not then recognized as such, the first experimentally and clinically significant instance of hypnotic time condensation known to these writers occurred some years previous to the initial work basic to the first edition of this book. The situation was that of a young woman trained as a hypnotic subject for the delivery of her first child. No suggestions of any sort had been given her concerning her perception of time except that she would "have a good time" and would "enjoy having her baby."

Nevertheless, spontaneously she experienced the following subjective phenomena:

1. The 20-mile automobile ride to the hospital seemed to be remarkably rapid, despite her repeated checkings of the speedometer, which always disclosed a speed within established limits.
2. The elevator ascent to the maternity floor seemed to be unduly rapid and in marked contrast to the definite slowness of subsequent rides in that elevator.
3. The delivery room preparation of the patient seemed barely to begin before it was completed.

4. Nurses seemingly dashed in and out of the hospital room, orderlies appeared to run rapidly up and down the corridor, and everybody apparently spoke with the utmost rapidity. She expressed mild wonderment at their “hurried” behavior.
5. The obstetrician “darted in and out” of the room, “hastily” checking the progress of her labor, and he seemed scarcely to complete one examination before beginning the next.
6. The minute hand of the bedside clock appeared to move with the speed of a second hand, an item of bewilderment on which she commented at the time.
7. Finally, she was transferred to the delivery room cart and was “raced” down the corridor to the delivery room, where the minute hand on the wall clock was also “moving with the speed of a second hand.”
8. Once in the delivery room the transfer to the delivery table, the draping of her body, and the actual birth of the baby seemed to occur with almost bewildering rapidity.

Actually the labor lasted a total of three hours and 10 minutes and had been remarkably easy and unhurried. Detailed inquiries to the mother subsequent to delivery, supplemented by various pertinent comments she had made during labor, served to furnish an adequate account of the greatly increased subjective tempo of all the activities comprising her total experience. All of this, she explained, had “interested” her “mildly,” but she had been much more interested in the arrival of her baby. The interpretation offered at that time of her subjective experience was the simple jocular statement that she “obviously just couldn't wait for the baby.”

Cooper’s development of the concept of time distortion, however, makes apparent the fact that the patient, in her eagerness to achieve motherhood, spontaneously employed the process of subjective time condensation, thereby experientially hastening a desired goal.

The above case report is a strikingly illustrative example of spontaneous experiential condensation of subjective time. However, this phenomenon is one of common experience in everyday living. We all readily recognize how pleasures vanish on fleeting wings, but to date it has been primarily the poet who has best described time values, as witness: “Time travels in divers paces with divers persons. I'll tell you who Time ambles withal, who Time trots withal, who Time gallops withal, and who he stands still withal.” [Shakespeare, As You Like It, Act III, Sc. 2, lines 328 ff.]

A common general recognition is easily given to time condensation in daily living. The vacation is so much shorter than the calendar time, the happy visit of hours’ duration seems to be of only a few minutes’ length—indeed, too many pleasures seem to be much too brief. Unfortunately, in the very intensity of our desire to continue to enjoy we subjectively shorten time; and conversely, in our unwillingness to suffer we subjectively lengthen time, and thus pain and distress travel on leaden feet.

These spontaneous, untutored learnings from everyday experiences suggest the importance of a continued and even more extensive study of time distortion in both of its aspects of subjective expansion and condensation.

In our experience, as well as the experience of various colleagues, the ready reversal of the usual or ordinary learnings of subjective time distortions seems to be limited primarily to learnings achieved in relation to hypnosis. In this regard a wealth of observations has been made on hypnotic subjects in both experimental and clinical situations.

To cite an example, a dental patient who had an extensive knowledge of hypnosis and who was definitely interested in subjective time expansion sought hypnotic training for dental purposes. The results achieved did not derive from the actual hypnotic instructions given but were expressive of the patient's own wishes for subjective experiences. Dental anaesthesia and comfort were achieved by a process of dissociation and regression, by which she subjectively became a "little girl again and played all afternoon on the lawn." As for the dental experience itself, as she remembered experiencing it subjectively, she adjusted herself in the dental chair, relaxed, opened her mouth, and was astonished to hear the dentist say, "And that will be all today." She surreptitiously checked her watch with his clock and then another clock before she could believe that an hour had elapsed. Yet at the same time she was aware of the prolonged, dissociative, regressive, subjective experience she had had as a child for an entire afternoon.

Thus within the framework of a single total experience both subjective time expansion and time condensation were achieved to further entirely separate but simultaneous experiences, that is, simultaneous as nearly as the writers can judge.

Another subject, untrained in time distortion, was employed repeatedly to demonstrate hypnotic phenomena at the close of an hour long lecture. After the first few occasions the subject developed a trance state at the beginning of the lecture which persisted until the demonstration was concluded. By chance it was discovered that thereafter the subject inevitably misjudged the lapse of time by approximately the duration of the lecture. After repeated observation of this manifestation inquiry elicited the significant explanation from the subject, "Oh, I just stopped the clock. I didn't want to wait all that time while you lectured." By this she meant that she did not wish to experience the long wait for the close of the lecture. Instead she had arrested subjectively the passage of time and thereby reduced it to a momentary duration. Or, as she expressed it in her own words, "You see, that way you start the lecture, I go into a trance and stop the clock, and right away the lecture is over and it is time for the demonstration. That way I don't have to wait." In other words she had subjectively arrested the passage of time and thereby had reduced the duration of the lecture to a seeming moment.

That report is but one of many similar accounts that could be cited. One of us (M.H.E.) has repeatedly encountered over a period of years, while assisting in conducting postgraduate seminars on hypnosis, volunteer subjects, themselves physicians, dentists, or psychologists, who have spontaneously developed time condensation. Furthermore they have done this without previous training in hypnosis or in time distortion.

Usually the situation in which this manifestation developed was one wherein the teaching needs of the lecture period required the repeated withdrawal of the instructor's attention from the volunteer subject.

One such subject, in a post-trance review of his hypnotic activities in an effort to develop a more adequate understanding of hypnotic phenomena, inquired at length about the nature and genesis of his apparently altered visual perception of the lecture room clock. He explained that during his trance state he had been distracted and fascinated by his discovery of a repeated sporadic movement of the minute hand of that clock. This hand, he explained, did not consistently move slowly and regularly. Some of the time it did—specifically, during those periods when the instructor kept him busy at various tasks. When left to his own devices because the instructor's attention was directed to the classroom, he noted that the minute hand "would stand still for a while, then jerk ahead for maybe five minutes, pause, and then perhaps jerk ahead for another 15 minutes. Once it just slid around a full 30 minutes in about three seconds' time. That was when you were busy using the other subject [a second volunteer]. It annoyed me when you kept demanding my attention when I wanted to watch that clock." Inquiry disclosed that his awareness of the passage of time had greatly decreased. In other words he, too, had "stopped the clock."

Another example of the experiential values of time condensation relates to the experience of a dentist who employed hypnosis extensively in his practice. Unfortunately, in the individuality of his personal technique in maintaining a trance state he conditioned his patients to a continuing succession of verbalizations. Even more unfortunately, as he became absorbed in the intricacies of his work on the patient, he would find himself unable to verbalize. The result was that his patients would arouse from the trance state, to the mutual distress of both dentist and patient. One of the writers (E.M.E.), on the basis of her own personal experience, suggested that he employ time condensation by teaching it to his patients so that they might abbreviate the time between his verbalizations and thus become unaware of his silences. The results for that dentist were excellent.

Two further instances of the clinical use of time condensation in the therapy of individual patients can be cited. The first of these is the report by one of us (M. H.E.) given before the Arkansas Medical Society in May 1958 on "Hypnosis in Painful Terminal Illness" and accepted for publication in 1959 by The American Journal of Clinical Hypnosis. In this report an account is given of the teaching of time condensation, in association with other psychological measures, to a professional man in the last stages of painful terminal carcinomatous disease. The clinical results obtained in this patient definitely indicated a highly significant relief of the patient's distress, a part of which was directly attributable to time condensation. Particularly for this patient did time condensation appear to preclude variously a subjective awareness, memory, and anticipation of pain. The usefulness in this one case suggests the possibility of its utilization as a clinical measure of reducing subjective awareness of physical distress and pain.

As a final illustration of time distortion involving both subjective time condensation and time expansion in a complementary relationship, a clinical history from the practice of

one of us (M.H.E.) is cited. In this report an account is given of the experimental-clinical therapeutic procedure employed in the alleviation of a symptomatic manifestation.

The patient, a 50-year-old socialite, was referred by her family physician for hypnotherapy. For many years she had suffered a yearly average of 45 severe incapacitating migrainous headaches, for which there had been found no organic basis. She had often been hospitalized for these attacks because of severe dehydration and uncontrollable vomiting, and the attacks lasted from not less than three hours to as long as three weeks.

Although the patient was desirous of therapy, she was incomprehensibly demanding, dictatorial, and actually uncooperative as far as psychotherapeutic exploration was concerned. She wanted all therapy to be accomplished, very definitely so, within four visits at intervals of two weeks. Hypnosis and any hypnotic procedures considered valuable by the therapist were to be employed, with the exception of any psychological investigative procedures. The entire situation was to be so handled that she was not to have any seriously incapacitating attacks—that is, attacks of over three hours duration—in the six-weeks period of her therapy.

However, it was also her demand that, since she had these headaches for many years with great regularity, she wanted them to continue, but in such fashion that they would serve to meet her "hidden personality needs" but without interfering with her as a functioning personality. (The patient was intelligent, college-bred, well-informed, happily married, and a devoted grandmother.) She suggested that the character of the headaches might be changed but not the frequency. However, this was but a suggestion, she declared, and she was content to rest this responsibility upon the therapist.

In reply to her the demand was made that the therapist required as a special consideration that she report yearly to him as a form of insurance of her therapy. After careful thought, she agreed to do so for two years providing no fee was charged, but thereafter the therapist would secure any information from her family physician.

Despite her attitude toward therapy in directing it, restricting procedures, and establishing limits, she was readily accepted as a patient, since she presented an excellent opportunity for a combined experimental and clinical approach. When informed of this type of acceptance, she agreed readily.

The actual approach to her problem, in addition to being oriented to her demands, was based upon a combined experimental-clinical procedure utilizing in sequence subjectively condensed and expanded experiential time, employing the one to enhance the other. She proved to be an excellent subject, developing a profound somnambulistic trance within 10 minutes.

The first instruction given to her was that she was to accept no suggestion that was contrary to her wishes and to resist effectively any attempt to violate any of her instructions. Next she was told to execute fully all of those instructions given her in

actual accord with her expressed desires. In this manner her full, responsive acquiescence was secured in relationship to both her resistances and her actual cooperation with possible therapeutic gains.

The therapeutic plan devised for her was relatively simple. The first procedure after the induction of a deep trance was to instruct her fully in the concepts of time expansion and time condensation. Then she was told that she was, without fail, to have a relatively severe migraine attack of not more than three hours' duration sometime within the next week. The severity of this attack and its termination within three hours were imperative for adequate therapeutic results.

The following week she was to have another and even more severe attack. It would differ, however, from the headache of the preceding week in that, while it would last in subjective or experiential time slightly more than three hours, it would last in solar time as measured by a stopwatch not more than five minutes. Both of these headaches were to develop with marked suddenness, and she was to go to bed immediately and await their termination. The patient was then awakened with an amnesia for her trance experiences and informed that she was to return in two weeks. Meanwhile she was not to be disturbed or distressed by any headaches she might have.

When the patient was seen two weeks later, she developed a trance readily upon entering the office. She reported that she had obeyed instructions fully and had experienced two headaches. The first persisted two hours and 50 minutes, and the second almost five minutes. Nevertheless the second headache seemed to be much longer than the first, and she had disbelieved her stopwatch until she had checked the actual clock time.

The first headache had developed at 10 A.M. and had terminated at 10 minutes of one o'clock. The other had begun sharply at 10 o'clock, and she had seized her stopwatch for some unknown reason and had proceeded to lie down on her bed. After what had seemed to be many hours, the headache had terminated as suddenly as it had begun. Her stopwatch gave the duration as exactly four minutes and 55 seconds. She felt this to be an error, since she was certain that the time must be somewhere near mid-afternoon. However, checking with the clocks in the house corrected this misapprehension.

With this account completed, the next procedure was to outline the course of her therapy for the next two weeks. To insure her full cooperation instead of her wary acquiescence she was instructed that she was first to scrutinize them carefully for their legitimacy and then to answer fully a number of questions. In this way she was led into affirming that 10 o'clock in the morning was a "good time to have a headache"; that Monday morning was the preferable day, but that any day of the week could be suitable if other matters so indicated; that on occasion it might be feasible to have headaches on successive days and thus "to meet personality needs" for a two-week period instead of "meeting them" on a weekly basis of one headache per week. It was also agreed that she would have to consider the feasibility of having a "spontaneous, unplanned" headache at rare intervals throughout the year. These however would probably be less than three solar hours in length. To all of this the patient agreed. Thereupon she was instructed to have headaches

of less than five minutes each beginning at 10 o'clock on the next two Monday mornings. Again she was awakened with an amnesia and dismissed.

Upon her next visit the patient demanded an explanation of the events of the preceding two weeks. She explained that she had had two social engagements which she had canceled because of a premonition of a headache. In both instances her premonition had been correct. Both headaches were remarkable in her experience. Both were so severe that she had become disoriented in time. Both made her feel that several hours had passed in agonizing pain, but a stopwatch she had felt impelled to take to bed with her disclosed the headaches to be only a couple of minutes in duration.

She was answered by the statement that she was undergoing a combined experimental-clinical hypnotherapy that was developing adequately and that no further explanation could be offered as yet. She accepted this statement after some brief thought and then developed of her own accord a deep trance state. Immediately she was given adequate commendation for the excellence of her cooperation, but no further explanation was offered and no inquiries were made of her.

Further therapeutic work centered around teaching her a more adequate appreciation of subjective time values. This was done by having her, still in the trance state, determine with a stopwatch the actual length of time she could hold her breath. In this way it became possible to give her an effective subjective appreciation of the unendurable length of 60 seconds, to say nothing of 90 seconds.

Against this background of stopwatch experience she was given hypnotic suggestions to the effect that henceforth, whenever her "personality needs" so indicated, she could develop a headache. This headache could develop at any convenient time on any convenient day and would last a "long, long 60 whole seconds" or even an "unendurably long, painfully long, 90 seconds." It would quite probably be excruciatingly painful. When it was certain that the patient understood her instructions, she was dismissed.

She returned in two weeks to declare it was her last visit, since she expected therapy to be concluded. Thereupon she developed a profound somnambulistic trance. She was immediately told that the therapist wished to review with her the proceedings of the previous interviews and the resulting events. She replied, "That is all so unnecessary. I remember perfectly everything in my unconscious mind. I understand that I approve and I will cooperate fully. Is there anything new you wish to tell me?"

She was reminded that it was possible that on rare occasions she might develop an "unexpected, unplanned, completely spontaneous headache."

She replied that she remembered and that if there were nothing more to be done, she wished to terminate the interview without delay. Upon the therapist's assent, she roused from the trance, thanked the therapist, and stated that a check would be sent in three months' time, at which time she would send also a preliminary report.

The reports received in the next two years and from her physician since then have all disclosed that the patient benefited extensively. She has on the average about three "unexpected headaches" a year, lasting from two to four hours. At no time has she required hospitalization, as had been the case previously.

However, once a week, with ritualistic care, usually at 10 o'clock on a Monday morning, she enters her bedroom, lies down on the bed, and has a headache, which she describes as "lasting for hours but the stopwatch always shows it only lasts from 50 to 80 seconds. It just seems for hours. And then I'm all over every bit of it for another week. Sometimes I even have those headaches on two successive days, and then I'm free for two weeks. Sometimes I even forget to have one and nothing happens."

CASE SUMMARY AND GENERAL COMMENT

This last case history illustrates a number of important considerations. It demonstrates effectively both the value of the experimental psychological approach in psychotherapy as contrasted to traditional methods, and the efficacy of an alleviation of a symptomatic manifestation when adequate allowance and provision is made for the unknown personality structure and its resistances to therapy. Also, it discloses clinical and experimental possibilities in the varied utilization of two distinct aspects of subjective time distortion.

However, of greater significance for the purposes of this book, this case history in conjunction with the material preceding it demonstrates the importance experimentally, clinically, and experientially of subjective time distortion whether as time expansion or as time condensation.

Clinical and Experimental Trance: Hypnotic Training and Time Required for their Development

Milton H. Erickson

Unpublished discussion, circa 1960.

My primary interest in this roundtable discussion today arises from a certain unhappy conclusion that has been forced upon me repeatedly after reading reports of hypnotic experiments, discussing the problems of hypnotic experimentation with various workers interested in the field, witnessing the hypnotic techniques employed by various students of the subject, and after recalling the innumerable errors, oversights, and serious mistakes committed by myself in the course of my own work. That unhappy conclusion, briefly stated, is that the whole field of hypnotic research is still so undeveloped that there is very little general understanding either of how to hypnotize a subject satisfactorily for experimental purposes, or of how to elicit the hypnotic phenomena which are to be studied after the subject has been satisfactorily hypnotized. From all that I have gathered, except in a few carefully made studies the general tendency is to carry on experimental work in hypnosis by employing a type of trance that is suitable primarily for the purpose of clinical demonstrations intended to give a general comprehensive survey of the types of behavior that may be elicited in the trance state, but actually unsuitable for the detailed experimental investigation of a specific form of behavior. In support of this one need only to recall the contradictory, unsatisfactory, and unreliable results usually obtained in specific studies of hypnotic manifestations.

The reason for such a confusion in experimental results is the typical utilization of a clinically satisfactory trance in experimental situations. The induction of a clinically satisfactory trance leads directly to the development of a peculiar psychic state of passive responsiveness in which the subject automatically accepts and acts upon any suggestion given as a purely responsive form of behavior. This type of hypnotic response I regard as satisfactory for clinical work only. A further and much more difficult step lies in the utilization of the subject's passive responsiveness to secure a spontaneous development of a pattern of behavior merely initiated by the suggestions given; I regard this type of response as experimentally satisfactory.

To state this more explicitly, in the clinically satisfactory trance the subjects perform as instructed in accord with their understandings of what the hypnotist wants. Thus the hypnotist not only suggests the behavior but also, though perhaps only indirectly, governs and controls the course and the extent of its development, thereby eliciting behavioral responses oriented primarily about the hypnotist. In the experimentally satisfactory trance the entire orientation of hypnotic responses is totally different. Suggestions given are accepted passively but are utilized only as initiating stimuli for the desired pattern of behavior, the development of which then occurs independently of the hypnotist and is in entire accord with the subjects' general reaction trends and their understanding of the

behavior suggested. Thus their responses are oriented not about the hypnotist but about the behavior as a thing complete in itself, thereby rendering the behavior itself the primary issue and not the behavior situation.

To illustrate these various points material may be cited from various experiments. In one instance an unpleasant artificial complex was suggested to a subject, who responded to it with every clinical evidence of having accepted it fully. However, when tested by a modified Luria technique for objective experimental evidence of the acceptance of the complex, the findings indicated that the complex simply had not been accepted and that it had not been a valid psychic experience. Investigation disclosed that, in giving the suggested complex, the subject had unwittingly been forced by the hypnotist's instructions to mail an unfortunate letter around which the complex centered in the "*mailbox on the street corner*," when the mailbox habitually used by the subject and the only one actually available to him in the suggested experience was located in the middle of the block. By thus limiting and restricting the subject to a performance of what the hypnotist wanted done and thereby precluding the subject's own natural, self-determined development of the suggestions given, there resulted only a clinically satisfactory acceptance of the complex, but an acceptance not experimentally demonstrable. Correction of the error to a mailing of the letter in the "*regular*" mailbox permitted an acceptance of the complex experimentally demonstrable through disturbances on the word-association test, involuntary motor responses, and respiratory changes. This is not an isolated instance, but it is a finding that has been made many times not only by myself but by others working on complex implantation.

Another type of example concerns the processes involved in inducing the reliving of an actual past experience. In one instance, later verified as to its accuracy, the subject was reliving his experience of driving a team of horses along the road. Quite unaccountably he suddenly stopped the team, and no explanation could be obtained except that he was "waiting." Impatience with the delay led to the giving of repeated, insistent suggestions that he drive on, but without effect. Indirect suggestions that the horses had started again were perceived by the subject not as hypnotic suggestions but as an impatient starting up by the horses themselves, and were responded to by a jerking on the imaginary reins and a shouting of "Whoa." Extensive inquiry finally disclosed the delay to be occasioned by a flock of geese impeding traffic, and not until the last one was safely out of the way would the subject proceed, regardless of the insistence of the hypnotist's suggestions. Thus the role of the hypnotist was limited strictly to the initiation of the process of reliving, and once started it continued in accord with the *actual experiential patterns of response individual to the subject*. Even when the hypnotist succeeded in intruding into the situation by his attempt to direct and control the course of developments, this was reacted to in a way appropriate only to the immediate psychic situation of the subject. This was an experimentally satisfactory trance.

Still another example may be cited to illustrate the integrity of the subject's own spontaneous development of the suggestions given in the experimentally satisfactory trance. In this instance the subject was known to be planning to attend for a second time a movie in which he was greatly interested. Accordingly hypnotic suggestions were given

to the effect that he was actually doing so in the company of the hypnotist and that he was describing the movie fully as he watched it. After this process had been initiated and a sufficient account of the movie had been obtained, repeated attempts were made to interrupt his performance. The subject, however, announced firmly his intention not only of sitting through the entire show but of attending the second show also, and all suggestions to the contrary were rejected until resort was made to the not uncommon experience of having the film break and the show interrupted. Suggestions to this effect permitted the initiation of another behavioral process entirely in accord with the subject's experiential past and leading to the desired goal. An essentially identical experience occurred on another occasion with a different subject, and the same type of behavior has been obtained from many subjects and in relation to a great variety of hypnotic manifestations. Yet in all of these subjects it was possible at any time to elicit the same type of behavior but at a purely responsive level, subject to the control and direction of the hypnotist as is typical of the clinically satisfactory trance but lacking in that peculiar quality of subjective, experiential validity that obtains in the experimentally satisfactory trance.

Now the points I have raised so far serve to emphasize that *hypnosis can be employed to elicit purely responsive behavior*, which apparently constitutes a remarkable and vivid portrayal of memories, experiences, and understandings in a fashion adequate to permit a general comprehensive survey of the various forms of hypnotic behavior, or that it may be employed to initiate by suggestion spontaneously developed forms of behavior comparable to those evoked by outer realities. It is my belief that the former type of hypnotic behavior serves best to demonstrate clinical possibilities, while the latter type offers an opportunity for the experimental investigation of specific forms of behavior.

However, if I have given the impression that the hypnotic trance in a given subject is always one or the other of these two forms, I wish to correct that misapprehension immediately. Because of the individual peculiarities of subjects one always finds admixtures of the types of hypnotic responses I have characterized. In a total of approximately 500 individual subjects I have not found one who was simon-pure in either regard, but it is my experience that the majority of subjects can be trained to develop the more experimentally satisfactory trances.

Now that I have presented some views upon what constitutes a satisfactory experimental trance, I might summarize my remarks by an attempt at a definition of that trance state: *An adequate experimental trance state is one in which the passive responsiveness of the subject is utilized only to control and direct the selection of the general type of behavior desired, with the entire course of the development of the behavior once initiated dependent upon the individual reaction patterns of the subject*.

The next consideration for discussion concerns the problem of the proper technique for experimental hypnotic work. This includes not only the technique of trance induction but the techniques of suggestion requisite after the trance state has been induced. However, I have nothing to add to the general understanding of how to induce a trance except to stress the importance of making full provision for all individual differences and

peculiarities of the subject and the highly personal character of the hypnotic relationship. I also want to emphasize the absolute importance of the element of time itself in securing hypnotic phenomena. This consideration has been sadly neglected despite the general recognition of the fact that time itself constitutes an absolute function of all forms of behavior and that the more complicated the form of behavior, the more significant is the time element. Hence I will limit my discussion to a consideration of this item.

To present this point I will give material illustrative of the general attitude and the common practices prevalent in hypnotic work which ignore the importance of the time element, and which consequently lead to a misdirection, misinterpretation, and an inadequacy of experimental work. This general attitude and the attendant practices derive from an unrecognized tendency to look upon hypnosis as a miracle producer, a tendency that probably arises from the startling phenomenal character of hypnotic manifestations. Because of this tendency we find many experimental investigations based upon techniques better adapted to the evocation of miracles than to the eliciting of hypnotic manifestations. Because of the oversight or neglect of the element of time, there is a marked confusion of the significance of the suggestions given with the processes of response and the actual behavior invoked. To illustrate, we find quantitative studies made of hypnotic phenomena by controlling the suggestions given by use of a certain phonograph record as if such a measure could control the nature and extent of the development of the response processes so aroused in different subjects; we find studies of amnesia accomplished by means of a simple direct command to forget chosen material followed by proper testing for evidence of amnesia; we find studies on dissociation based on the assignment of two tasks followed by a strict injunction that they are to be performed simultaneously but independently of one another; we find experiments on regression conducted by the simple measure of telling a 30-year-old subject that he is now 10 years old and promptly administering an intelligence test to secure evidence of the regression; we find experiments on hypnotic anaesthesia performed by direct suggestion of it and a direct testing for it; in brief we find, despite our knowledge that behavior constitutes an end-product of a long process of complicated reactions, that in hypnotic work the assumption is made repeatedly that the process of hearing and understanding instructions is identical with the process of the development of the behavior the instructions are supposed to elicit.

Another type of illustration which typifies an observation I have made repeatedly is the general belief that the induction of a sound hypnotic trance requires only a relatively brief period of minutes. Thus one worker, representative of many I know, assured me most earnestly that it was never necessary, even with naive subjects, to spend more than 15 to 20 minutes in inducing profound trances and that the average length of time for him was five to 10 minutes. Also he assured me, as have many others, that once the subject was hypnotized, the induction of any specific type of complicated behavior was simply a matter of giving appropriate suggestions. While I am ready to concede that trances can be induced and experiments conducted by such techniques, I doubt if the trances are ever more than the type I have described as clinically satisfactory only; the experimental results are therefore nothing more than evidence of passive responsiveness oriented about the suggestions given.

Now the question arises, what is the proper length of time that should be spent in inducing an experimentally satisfactory trance or in eliciting hypnotic behavior adequate for experimental investigation? No definitive answer can be given, not only because of individual differences between subjects but also because of differences within the subject in relation to various types of behavior. Hence the only safe procedure is to give suggestions in such fashion and sufficiently slowly that subjects have an opportunity not only to respond in a passively responsive fashion in accord with the hypnotist's suggestions, but also an opportunity to respond in accord with their own understandings of the behavior desired and to develop their responses in accord with their own reaction patterns. Only the latter type of behavior is to be accepted as evidence of an experimentally satisfactory trance. This implies the need for extensive experience to enable the scientific investigator to discriminate between the types of the behavioral responses obtained, but I know of no easier way until sufficient experimental work has been done to discriminate more satisfactorily between clinical and experimentally satisfactory trances.

Returning to the question of the actual length of time required, I can speak only from my own experience, which is supported by that of certain other workers, chiefly psychiatrists, interested in establishing in their subjects valid experiential processes by hypnotic techniques. My finding has been that on the average a total of three to eight hours, usually in interrupted sittings, should be spent in training a good unsophisticated subject to develop a sound hypnotic trance before there can be any experimentally valid attempt to elicit the various forms of hypnotic behavior. Once the subject has been trained adequately to develop a satisfactory trance, a period of at least 20 minutes should be spent in inducing each new trance intended for experimental work, although this period can gradually be shortened to five or 10 minutes.

Next is the question of how much time is required to elicit any specific form of behavior after a sound trance has been induced. For example, when it is desired to develop an amnesia for a series of nonsense syllables just learned, it is necessary to give the subject a period of 20 to 30 minutes and even longer to permit the development of an easily demonstrable amnesia, as shown by a relearning of the amnesic material in the waking state. Or, if it is desired to have the hypnotized subject develop a psychic blindness, a period of 20 to 30 minutes must elapse after the suggestion has been given before any attempt should be made to secure and test that behavior. That period of waiting is best spent in casual conversation, unrelated activities, with an occasional reiteration of the suggestion that sooner or later the subject will experience the desired effect. Even the giving of a complicated, attention-compelling task to subjects to keep them busy will not militate against the development of the desired behavior. The essential consideration seems to be the provision of a sufficient period of time to permit the development of a mental set conducive to the behavior. Unless this period of time is allowed, the subject's response, while in accord with the suggestions given, will be marked to the critical observer by inhibitions, denials, avoidances, and blockings not in keeping with a valid experiential response. The following example will serve to clarify this point.

Recently I suggested hypnotic blindness for two persons in the room. After a 20-minute wait I gave the same suggestions to two other persons and then proceeded to test the responses of all four subjects. The original two subjects demonstrated an entirely satisfactory blindness, but for the second two the psychic blindness was marked by avoidances, inhibitions, conflict reactions, and blockings which persisted for half an hour. After this time the psychic blindness for the second group became satisfactory. When we realize the importance of time in the evolution of behavior in the ordinary life situation, its importance in hypnotic behavior can be more fully appreciated.

I will close with the statement that I believe hypnotic experimentation constitutes one of the richest fields for research; it warrants every bit of time given to it; and, that as one's experience grows, the amount of time required for specific investigative procedures diminishes.

Laboratory and Clinical Hypnosis: The Same or Different Phenomena?

Milton H. Erickson

Reprinted with permission from The American Journal of Clinical Hypnosis, January 1967, 9, 166-170.

In late 1924 and in the spring of 1925 two similar isolated but most interesting events occurred. Subjects H and W, who had worked extensively as hypnotic subjects for the author but who were unknown to each other, were both on University of Wisconsin athletic teams. In the fall of 1924, at practice for a coming meet, Subject H, during practice jumping, caught his tongue between his teeth and cut through completely one side of his tongue except for a narrow marginal edge. He was rushed to the hospital for surgical care. Upon being told that his tongue would require suturing, that he would be placed on a liquid diet, and that he would be disqualified for the coming athletic competition the next weekend, his reaction was most obstreperous. He rejected all medical help and advice and promptly sought out the author for hypnotic aid. He could not talk understandably because of the swelling of his tongue; he had to write an account of his mishap; and the author was then too naive about medical problems and too eager to experiment to exercise reasonable caution in a medical situation.

Within four hours H was free of swelling, pain, and handicap. He was not seen again for three weeks. Then he came rushing into the laboratory at an hour he knew the author would be there. He explained:

> You remember that bitten tongue of mine about three weeks ago? First you hypnotized me and removed the pain. After I awakened from the trance, I did a lot of studying here in the lab, and you kept looking at my tongue every little while until the swelling went down and I could talk normally. Well, something else happened. On the way to my room [rooming house] from the lab that evening I developed an amnesia for the whole thing, and the memory of it just came back to me this afternoon, so I thought I had better tell you. It was a Saturday, three weeks ago, and the fraternity was having a special steak dinner that Sunday. I remember eating my share, but there was no pain or trouble with my tongue. At the next practice meet with the team some of the fellows asked me how my mouth was, and I didn't know what they were talking about, so I just said it was as big as usual. Then this afternoon I asked several of the fellows in my rooming house if they know about my biting my tongue. They didn't, and wouldn't believe me about it. They just said that there was never anything wrong with my mouth except that I used it too much. Then I went to Dr. S. [the physician who took care of injuries for the Athletic Department] and he said he was "still too disgusted" with me to talk to me. I asked him if I had bitten my tongue. He just looked me up and down and said, " You not only bit it, but you acted like a damn fool when I

> wanted to give you proper medical attention and put you in the infirmary. But I suppose you thought you could get better medical treatment by going downtown for it. I should have kicked you off the team." To this the patient added, "But I did all right in the meet that weekend—one first place and one third place."

Since his interest was psychology (he later became a professor of psychology) a discussion ensued of all that had really occurred hypnotically. There finally resulted his spontaneous observation:

> What you did for me is exactly like what we have done in the laboratory except that it is different. In the laboratory I accept suggestions and carry them out thoroughly. I've experienced anaesthesia before. It was just as good as the anaesthesia you produced in my tongue. But laboratory anaesthesia, no matter how real, belongs to the laboratory. It is a part of a scientific study. What you did for me was just as real as any hypnotic anesthesia I ever had in the lab. But it was mine, all mine—not even you could have a part in it—it was mine. Maybe I can say it this way. I am a student. I am a member of the student body. The physical identity is the same. The meanings are different. Lab hypnosis and personal hypnosis may give you similar results. But they are different to the person.

Concerning his amnesia he could offer no explanation, but he did suggest that he might find out if he were to be hypnotized and questioned. This was done and the simple answer received was, "I just didn't want the memory of biting my tongue to enter m head during the meet. After that it wasn't important. But this afternoon I was studying on memory processes so I just quit having an amnesia."

The author and H discussed all of this material but without reaching any definite conclusions.

The next spring Subject W sprained his ankle during athletic practice and came to the author that evening hobbling on crutches prescribed by the athletic department physician after an examination had disclosed "only a severe sprain."

He gave an account of his accident, the coming athletic contest, his present severe pain, and then he asked if all the hypnotic work he had done in the laboratory could be employed to meet his present personal needs.

As with H, the problem was accepted, a hypnotic trance was induced, removal of pain and pain reactions was effected, and then regression was induced to effect a reestablishment of physical relationships as much as possible as they were before his accident. A final measure employed was temporary time displacement so that he could think about his sprained ankle as if it had occurred a year or so previously.

W (who later became a physician) won a place in two contests in the racing meet that weekend, and on the succeeding Sunday sought out the author because the temporary

time displacement had been spontaneously corrected. He was given a full recollection of events, and his resulting discussion, less extensive than that of H, was essentially identical in significance. The pertinent points were:

> "The anaesthesia of the sprain was as perfect as anything I ever did in the lab but I still have the anaesthesia for pain. That putting of the accident into the past messed up the thinking of my teammates, but I was completely clear in my own mind and I wasn't troubled about their confusion about a sprained ankle I knew I had had a year or so ago. As I look over all the hypnosis you did for my ankle, it's just as good and real as any of the lab experiments. But it is different in a peculiar way. Hypnosis in the lab belonged to you, to me, to the psychology department to science. The hypnosis for my sprain, all of the hypnosis you used for the pain, in some way belonged just to me. The best way I can put it is to say: Just like the ankle sprain was all mine, so was the hypnosis. That, too, was all mine. Lab hypnosis and personal hypnosis can give the same results, but they are different in their personal meanings. Do you suppose these new ideas of mine will interfere with the work you have planned for me in the lab? I'd sure hate to miss it." (In no way did his new understandings interfere with his work as a subject.)

Quite contrary to the above accounts is another kind of finding. Over the years many excellent laboratory subjects who demonstrated the phenomena of hypnosis exceedingly well and who withstood seemingly searching tests were found to be either unwilling, actually unable, or perhaps only partially able to use hypnosis when it involved personal needs. For example, one college student used in the laboratory to demonstrate anaesthesia could undergo obviously painful test measures with no evidence that there was any pain experienced. Yet when this same subject suffered an accidental and actually minor injury requiring three sutures, in no way could hypnosis be induced to lessen the distress of his injury. Some nurses who have proved to be excellent demonstration subjects have been found to be completely unresponsive to hypnosis when suffering from even minor as well as major physical discomforts. For example, a nurse who satisfied a group of physicians that she could develop a profound anaesthesia was unable to develop an anaesthesia when she suffered a fall and bruised herself, even though medical examination of her injury pronounced it to be painful but not serious in any way. In other instances excellent demonstration subjects at times of their own need have not been able to develop more that light trances. Apparently this question of personal needs is on that is interpreted by individuals in their own way.

Another experimental subject, a music lover, was being used to test the possibility of hallucinated experience forming a part of a condition response complex. Once of the things she did in this experiment was to hallucinate the rendition of her favorite musical compositions. However, this subject always demanded payment for laboratory work in a remarkable manner. For all participation in any kind of experimentation she insisted that payment had to be made by letting her hallucinate some music while the author was busy at some other experiment and thus not sharing anything more that time and space with her. She explained that music hallucinated for experimental purposes was identical with

the music she hallucinated for herself. There was only a personal significance which she did not want to share and could not explain.

In the years since then occasionally the author has encountered or dealt with persons who have had both laboratory hypnotic experience and medical or dental hypnotic experience. Of these, the more thoughtful have explained that laboratory hypnosis is one order of phenomena, that hypnosis involving significant physical needs of the self is another order of phenomena. An information nurse told the author:

> You taught me a hypnotic saddle block at the medical society meeting the only time I was ever hypnotized. Later I got married and went to live in an isolated rural community. Neither a doctor nor a nurse was available when I went into labor about three weeks earlier than I expected to. I took the saddle block you taught me and changed it into mine. I'm sure your saddle block would have worked, but it was my baby, my first one, so I made the saddle block my own. My husband was away, caught by a forest fire, and the only person to help me was a newly married girl. But I was trained in obstetrics so I had no worries. The saddle block was just the same as yours, and then all at once it became different. It was personal. What that means maybe you can understand.

This nurse had been used as one of a volunteer demonstration group for the medical society. It was by mere chance that she was again met. Following her initial remarks she was questioned rather extensively. She was asked to describe more fully what had happened during the birth of her first child. She explained,

> Being an obstetrical nurse, I knew I should have an episiotomy, but I knew that was impossible. But I remembered what you said about relaxation in your lecture so I relaxed my perineum. I don't really know how I did this, but I just relaxed it, but I kept all the feeling of movement because I knew I should know when the baby was born and when the placenta was passed. My friend helped me with the things that I couldn't do myself. When my husband got home three days later, he was very much surprised and had to go to get a doctor, since the telephone lines were still down. The doctor said everything was all right.
>
> Since then I have had four more children. The next two I had in the hospital under "proper medical observation." The following two I had at home with a doctor in attendance. I have never had any medication or any anaesthesia for childbirth. The hospital doctor was very displeased because he did not like the way I developed my own saddle block. Neither did the general practitioner serving my community approve of my use of hypnosis. All doctors agree, however, that my pelvis is entirely normal. I don't know how to explain to you how I changed the saddle block you taught me into *my saddle block*, which I used for all five of my children. I would like to have you suggest a saddle block to me now, with me wide awake from the waist up, so I can discuss it with you, and after we have discussed it I will change it into *my saddle block*.

Her wishes were met. Her explanations can be summarized by the simple statement that:

> They are both the same and yet they are different. The saddle block that I just produced seems to be a reliving of my saddle blocks during childbirth. The saddle block you induced, while it removed all feeling from the waist down just like mine did, seemed to be totally different but just as effective. I really wish I could give you more information. It just seemed to be a real experiencing of the saddle block you gave me in front of the doctors. In fact, I looked around almost expecting to see them.

Another finding, much more rare, has been encountered by this author and confirmed unexpectedly by several colleagues. It is that some persons who responded well to hypnosis directed toward their personal needs could not enter into the hypnotic state for either experimental or demonstration purposes. Yet they could do so readily for questioning about their possible personal needs, even in the presence of other, even lay, persons. Yet laborious effort and seemingly full cooperation on the person's part would not result in trance development. Also, after securing permission from such persons, a trance induced to inquire about personal needs would terminate when a shift was made toward experimental work. Yet these same persons would cooperate in experimental work in the waking state.

The above instances have been cited because of the clarity with which the hypnotic subjects (patients) gave their accounts. There have been, relatively speaking, many occasions on which there appeared to be a marked conflict between laboratory hypnotic findings and those encountered clinically. For example careful, well-controlled laboratory experiments may find hypnotic anaesthesia to be questionable and even of a most dubious character. Yet the clinician reports instances in which hypnoanaesthesia was successfully employed without any medication. Hence there arise the questions: Was the laboratory experiment on hypnoanaesthesia a reliable test of hypnotic anaesthesia, and was the surgical patient merely complaisantly cooperative? Are hypnotic subjects merely self-deluded in both laboratory and clinical (including even major surgery) settings? Can there be a reliable comparison of laboratory findings with clinical findings? Are they of the same order of phenomena? Dies not the frequent contradiction between laboratory and clinical hypnotic findings imply other significant factors as signified by the above accounts? In what way can definitive laboratory experiments on hypnosis and clinical utilization of hypnosis be tested on the same scientific basis, or is this impossible with the present state of understandings? What are the determining factors in each procedure so far as the person involved is concerned? Should not personality factors and personal motivation be regarded as vital to both laboratory and clinical studies. Are laboratory hypnotic states and clinical hypnotic states *sometimes* identical, perhaps differing only in the subjects' recognition of them? These are only a few of the questions that need to be answered, if such answering can be achieved.

Most thought-provoking in relation to the findings reported above, as well as to the controversy about the use of hypnosis for antisocial purposes, are the informative and

outstanding reports on human behavior published by Milgram (1963, 1964, 1965). These are studies that should be read most thoughtfully by whomever undertakes either laboratory or clinical hypnosis, since they are indicative of the stresses a person in the waking state will endure and thereby, by inference, indicating that situations, motivations, obedience, and personality factors are highly significant in human behavior and response in a manner not yet understood in the waking state of a subject, much less in hypnotic states or other states of altered awareness.

Explorations in Hypnosis Research

Milton H. Erickson

Presented at the Seventh Annual University of Kansas Institute for Research in Clinical Psychology in Hypnosis and Clinical Psychology, May, 1960, at Lawrence, Kansas.

I would like to present two concepts of different types of thinking: unconscious or subconscious thinking and conscious thinking. If I were to ask you to look at my watch and to continue seeing it right there, you would all know immediately, not being in a trance state, that I lowered my watch. In hypnotic response you would see the watch but it would be the psychical watch, and since I told you that you would see it right there, you would continue to see it right there and not in the moved position. You would substitute immediately the visual memory of that watch because there is an interchangeable use of reality stimuli and remembered experiences, visual memories, auditory memories, kinesthetic memories, etc. It is out of the use of these understandings, learnings, and memories in the mind that hypnotic subjects develop their behavior. In this state of special awareness, or special consciousness, the operator (the hypnotist) plays a role in communicating ideas to the subjects, of orienting the subjects in that unique, individual hypnotic situation which each particular subject finds himself.

The subjects need not necessarily accept anything the operator suggests. The subjects tend to respond in accord with patterns unique to each. In the hypnotic state the subjects are willing to accept ideas; to accept any idea that is offered. The subjects then take a second step: They examine the idea for its inherent value to themselves. That is one of the reasons for the time lag in hypnotic behavior. Time is needed for the examination of ideas, thoughts, and understandings. It is a very careful examination. That is why you have literalness in your subjects' understandings when you ask them this or that particular question. After having examined those ideas, there is the tendency to respond.

The subjects accept those ideas in terms of their own frames of reference and a lifetime of experiential learning. These experiential learnings may be unusual and quite unexpected. For example, there was a veteran who had leapt downstairs, fallen on the floor, picked himself up, and then walked back and forth to college every day for a week. Finally he came in to the Veterans Administration hospital to be examined because his foot was very swollen and because it made a noise when he walked. I happened to be the consultant on duty, and when I heard him walk across the floor, I winced. The X-ray showed a comminuted fracture of all the bones in the ankle. When I showed this veteran the X-ray, he said, "But I thought broken bones hurt." That's what he honestly thought. He had an hysterical anaesthesia extending almost up to the knee, with anaesthesia for deep pressure and vibration. How did he ever acquire such an anaesthesia except through some kind of experience, through some kind of learning? Our unawareness of stimulations, and our unawareness of pressure on muscles are body learnings which come from actual experience.

Let me illustrate another type of body learning. The postman hands a box to the college student. He takes it to his room and opens it—homemade fudge. He eats it and enjoys it. Two weeks later he is sitting, studying, and happens to look out the window and sees the postman coming down the street. Immediately he starts drooling, not because the postman looks appetizing, but because in a one trial learning situation (and a stimulation that did not lead to complete satisfaction until quite some time later, when he had unwrapped that unknown package) there was a linking of the postman's uniform with the salivation process. I stress this example because the laboratory learning of conditioned responses usually involves so many repetitions of stimuli before you finally achieve the desired conditioned response. Here a particular situation set up a conditioned response so that the very next time the student saw that postman, he drooled. Laboratory learning is suggestive, but far from identical with, the learning which real life experience makes possible.

If I were to ask any of you to elevate your blood pressure, how would you do it? If I were to ask you to change the rhythm or tempo of your smooth muscle function, or to alter the circulation of your blood in anyone part of your body, you would wonder how to do it. Yet your body has considerable experience in vascular dilation and contraction. When I was a medical school student, I clearly remember when our class would enter the lecture room of a certain professor. There would be a generally happy mood, and then the professor would snarl and say: "There will be a written examination!" My classmates would divide into two groups: (a) the diuretic group, and (b) the peristaltic group. There would be an almost instantaneous alteration of circulation and smooth muscle activity throughout the entire body, involving physiological, psychological, and neurological functioning. These alterations derived from the real-life experiences each one of us had had, time and again, in the past whenever we suddenly experienced altered patterns of body behavior, physiological behavior, somatic conditions, etc.

Let me cite still another instance of human behavior change. A little three-month-old baby boy is taken to a pediatrician. The baby doesn't pay much attention to the pediatrician clad in white. While at the pediatrician's he gets stabbed with a needle. Three months later, when the baby returns to the pediatrician's examination room, he begins to yell immediately. How did the baby get conditioned to understand all of that behavior, to alter all his physiological behavior? What kind of a memory does a three-month-old baby have of being stabbed in the bottom with a needle?

Throughout life there are various conditions of learning for individuals that involve their total functioning as organic creatures, where blood circulation, neural and muscle behavior, and other organ systems participate most actively. Whenever you set up the right kind of stimuli, you can elicit some of these experientially conditioned behaviors. It is possible to use hypnosis as a method by which you can secure patients' complete attention. It is then possible to focus their attention and to create a state of receptivity by such stimulation so that they function in accordance with those relevant past learnings.

I would like to stress that to be in a trance state does not mean that individuals are unconscious or that they cannot function with their conscious mind. I can think of a

parallel with the sleep state. A man may wake up in the morning with the realization that he has not completed a dream. He is aware that he is in bed, but would like to go back to complete the dream. He proceeds to do so, knowing that he is dreaming, that he is completing the dream of a delightful plane ride or a pleasant picnic with a dual awareness of operating in two spheres. I recall a physician who underwent surgery and who felt very sorry for the surgeon because the surgeon didn't believe in hypnosis. The physician-patient wondered if the surgeon were distressed or worried, if the surgeon was beginning to come around to some belief in hypnosis as an anaesthetic agent. He also wondered about the nurses who were watching the operation. Simultaneously this physician-patient was on a "fishing trip" in Canyon Lake, delighted to find how well the fish were biting, and pulling them out of Canyon Lake one after another—all the while enjoying a delightful fishing trip. This physician-patient functioned with a dual awareness: He was aware he was in the operating room where he had an hypnotic anaesthesia which was necessary for his own surgery, and at the same time he was also participating in a fishing trip. When the tray of instruments fell on the floor, there was a "simultaneous" jump of a big fish out of the water, accompanied by a big splash and noise as the fish fell back in. The physician-patient wondered whether he was merely reinterpreting the stimulation of the fallen tray and translating into the jumping of the big fish even while the event was happening. He demonstrated excellent dual functioning at two different levels of psychological awareness.

I regard hypnotic techniques as essentially no more than a means of asking your subjects (or patients) to pay attention to you so that you can offer them some idea which can initiate them into an activation of their own capacities to behave. The best way to illustrate this point is by way of a clinical example. Barbara was a 14-year-old girl who had been failing in her adjustments at school and had developed serious behavior manifestations. She said her feet were too big, so she was not going to go to school, church, or out of the house. She was not going to talk to anybody. Her mother, who was my patient and a good hypnotic subject, consulted me about her daughter's problem. The mother described how Barbara's behavior had been going on this way for two long weeks, that Barbara had been secluding herself in the home, not talking, and was most unresponsive. I told the mother I would make a house call, and that she was to go along with whatever I said. She was not to discuss the visit beforehand with her daughter.

When I arrived at the home, I took out my stethoscope and said to the mother, "I think that the first thing I ought to do is examine your chest. So will you please take off your blouse and bra, but call your daughter in here to act as a chaparone and have her bring a towel." The girl of course could not refuse to come in; she had to come in to act as a chaparone. That was the first thing that I got the girl to do for me. It seemed to be so innocent, so appropriate, so right, but I was getting a response from her. I carefully examined the mother's chest, all the while with Barbara standing there beside the bed in her bare feet, with a sullen look on her face. Finally I got up from where I had been sitting, stepped backward, and brought my heel forcefully down on Barbara's toes so that she let out a yell of pain. I turned to her, seemingly very irate, and said: "If you had only grown those damn feet big enough for a man to see, you wouldn't get them stepped on." *If you could grow those damn feet big enough for a man to see, they wouldn't get stepped*

on. Barbara looked at me, first in a frightened way, and then all of a sudden the smuggest smile I ever saw came over her face. She turned and walked out of the room. On the way out she said, "Mother, can I go to the show?" Barbara went to the show that day, she went to Sunday school the next day, and returned to school the next Monday. It was the end of her symptomotology.

What had I done? I had asked Barbara to respond. I also made her respond by stepping on her toes. I did it in a totally unexpected way. Then I took the idea that her feet were so big, that she was ashamed to be seen in public, and in a horribly impolite fashion I convinced her that I honestly felt that her feet were very small, and that she was remiss in not having grown them larger. Could I have ever told Barbara that her feet were of normal size, of a good size by just pointing it out to her, by measuring her feet, by showing her that she had feet no larger than her classmates? Barbara needed therapy, she needed to stop secluding herself. It was to get Barbara in some way from within herself to make response-behavior that would be corrective of her situation and her condition that I proceeded as I did. *Hypnosis is essentially that sort of concept, i.e., a way to offer stimuli of various kinds that will enable patients in response to those stimuli to utilize their own experiential learning*. I helped Barbara reorient to the size of her feet rather than to ideas about the size of her feet. Hypnosis facilitates exceedingly effective learnings that would be impossible otherwise except by prolonged effort and therapy.

HYPNOTIC ANAESTHESIA

Let me give you another example. A little three-year-old girl had to have an adenoidectomy, and hypnosis was used. After the adenoids were taken out, the doctor said, "Now, you're such a nice little girl and that didn't hurt at all, did it?" The little girl looked at him and said, "Your pupid [stupid]. It did too hurt but I didn't mind it." I questioned this little girl about her hypnotic experience, as I have a number of other children. They do not all necessarily say that. Some say that they didn't feel anything at all. What took place? In some way that three-year-old girl altered her perception of pain and made it less meaningful for herself. She restructured it in some fashion just as the businessman with purely imaginary worries restructures those worries into a gastric ulcer. How does the businessman create this ulcer out of his body learnings, his experiential conditioning, etc.? The research approach in hypnosis ought to seek out the means by which hypnosis facilitates the utilization of body learnings, tissue learnings, physiological learnings. What were the learnings, understandings, and the body conditionings that the three-year-old girl had achieved that resulted in her statement, "I didn't mind it."

I think that cancer pain is a very severe pain experience. If you can get your patients' attention in some way so that they can be induced to use their learnings, you can abolish the pain. It doesn't matter whether you keep them awake, or keep them asleep, or keep them in a state of dual awareness. In some way you need to communicate to patients the desirability of doing something about their pain, just as the businessman does something about his worries and converts them into a painful ulcer with tissue destruction. Before I begin to induce hypnosis in cancer patients, I explain to them that pain isn't a simple, pure thing. There is hard pain, there is soft pain, burning pain, cold pain, stabbing,

cutting, heavy pain. I think of all the possible adjectives that I can to describe the pain so that my patient will listen to me. Then I point out to the patient, "You know, pain in some part of your body doesn't hurt you half as much as it does in another part of your body. " I know from psychiatric practice that people can displace sensations. I also know that patients with cancer pain are worried about the metastases in their body, in their liver, in their spine. The pain that they have in their trunk is the thing that they know or believe is going to kill them, and they know that I know it. Thus sometimes I tell the cancer patient, "Suppose you had all that body pain right here in your left hand. You are not going to worry about that. It isn't going to hurt half as much as the pain in your body." I get them to "displace" a share of that pain into their hand. I don't know what the mechanism of displacement is, but I do know that human beings make use of that mechanism. I know that cancer patients can suddenly find that they have pain in their left hand which they don't mind, and the pain in their body is considerably decreased.

Is anaesthesia a state of unconsciousness? I don't know, but I don't think so. I think at times that anaesthesia is primarily a matter of amnesia. I know that I can teach a cancer patient, "It's all right for you to have pain, but why have pain for very long?" And why ever remember pain?" To one patient I explained, "You know, pain for you is made up of three things: anticipation of pain to come, memory of pain you have experienced, and the current experience of pain. Let's just not remember the past pain. Let's have an amnesia for past pain and for future pain." I call it "amnesia for future pain," an unawareness that pain can be anticipated. Then you have cut down the pain complex by one-third. Similarly you can shorten it by time distortion; by applying time distortion to the particular current pain, and reduce it greatly.

There is another mechanism that you can employ by hypnosis, and that is a reinterpretation of pain. The illustration I give to cancer patients is: Suppose you were alone in a house, 10 miles from any other habitation, and that you are absolutely alone. You are sitting with your back next to a curtain and you are reading a tremendously exciting suspense story. In that suspense story a hand came through the curtain and stabbed the victim in the neck. Just at that moment, as you read that line, a tiny little bug steps off your collar onto your neck, and as a result you hit the ceiling, not because that little bug tramped so hard on you but because of the general psychological situation. There had taken place a reinterpretation of the stimulus, a magnification and intensification of a minor stimulus." And so I ask my patients, "This short, cutting, stabbing, blinding pain of yours, could you make that into a dull, heavy pain?" In the hypnotic state subjects are open to ideas. *They like to examine ideas in terms of their memories, their learnings, their conditionings and all of the various experiential learnings of life*. They take your suggestion and translate that into their own body learnings. There was a cancer patient who had transformed the sharp stabbing, blinding pain into dull, heavy pain, and I then suggested that he take the dull, heavy pain and transform that into a feeling of relaxation and weakness. In other words his attention was redirected again, but this time into heaviness, weakness, and relaxation. I think that a great deal of research remains to be done on the matter of pain, on its transformations into nonpain or decreased pain situations, so that we can better offer suggestions and frames of reference which patients can utilize in terms of their own body experiences.

In the control of cancer pain I teach my patients to listen carefully to my words and to follow my train of suggestions closely. I can direct their attention to the shoes on their feet, the glasses on their face, the collar around their neck, and the way their hand is on their thigh, or to sounds outside the room, etc. As they follow my train of suggestions, it is not long before they forget about the shoes on their feet and the cloth around their neck, etc. In their effort to constantly redirect their attention from one idea to another, there is a more rapid slipping away of earlier suggestions. I explain to the cancer patient: "While you're thinking about this or that particular happy thing, you won't have enough energy left over with which to feel the pain of your cancer, because all of your energy is going to go into this matter of thinking over all the nice things that you ought to say to your wife, your grandchildren, or something of that sort." I get their attention focused.

What does focusing of attention mean? I know that you can get certain types of physical behavior and certain types of psychological behavior after you have induced the hypnotic state, *which is a state of special awareness and special responsiveness*. Cancer patients have much activity going on within them. But you know that they also have a lifetime of body learnings that are available within them for therapeutic application.

CATALEPSY

Then there is the phenomenon of catalepsy which also occurs within the patient. Did you ever try to hold yourself completely still in the ordinary state of conscious awareness? Soon your nose, your ear, or some other part of you begins to itch, especially if you know that you should not move. The urge to move becomes stronger and stronger and more and more fatiguing. How can the hypnotic subject maintain a state of rigidity with utter comfort and satisfaction and ease? The catatonic can do it. I have posed a catatonic patient against a wall with lights to outline his shadow, and drawn the outline of his shadow on the wall even though he was standing on one foot, with one arm out in one direction and the other arm in another, his head bent. That was 8 A.M. in the morning. At 12 noon I had someone else go out and outline the shadow; at 4:00 P.M. a third person went out to pencil mark around the shadow. There was practically no shift from the hour of 8 A.M. until 4 in the afternoon. How could he do it? Certainly there are significant differences between the catatonic patient and the normal person in the appreciation of fatigue. I have posed a cataleptic hypnotic subject, but of course have not presumed to do it for as long as a patient for many reasons, not the least of which is that I like to have my subjects remain my friends. I have posed them for an hour without any particular distress. I believe catalepsy is a phenomenon that is at the frontiers of our understanding of body learning. We ought to experiment with, test, and examine what constitutes it. I can recognize it in the way that I can recognize a number of other hypnotic phenomena, but I do not know what it is.

RAPPORT AND DISSOCIATION

Let us now consider the phenomenon of rapport. An obstetrical patient comes into the delivery ward: She hears her physician, she hears the nursing personnel, but she doesn't

hear the screams of other women in labor. She doesn't even know that there are other women in labor. I hadn't specifically told her that either. There has occurred a redirection of her attention, and we say that she is in rapport with, and is responding to, only a certain number of persons, events, and things. What is this narrowing of the field of awareness, the narrowing and shrinking of the field of consciousness? Can you deliberately shrink the field of conscious awareness so that it excludes the pain of an injured foot, the pain of a badly burned foot? One way anaesthesia can be developed in a case with burned feet is to ask patients to forget their feet and then lose their sense of body continuity. I have inflicted painful stimuli upon a foot after such a thought had been accepted without the subjects reporting stress, because they had forgotten their feet. Why shouldn't they feel the painful stimuli on their feet, even though they had forgotten their feet? They were naive subjects and they didn't know that I was going to pinch their feet or inflict pain or distress on them, but they had forgotten their feet. What does that actually mean? What is an amnesia? What is dissociation?

My daughter had said that under no circumstances would she ever, ever, permit anaesthesia. I know my daughter's interest in hypnosis and her interest in psychology, but she was only a grade-school child at the time. I had promised her that I would not offer her any suggestions regarding anaesthesia. Once, in a medical setting where I was demonstrating hypnosis, I asked my daughter to see herself sitting "over there" on the other side of the room. She was very interested in hallucinating herself "over there." Then I asked her to feel herself on the other side of the room, really to feel herself sitting there, to experience herself sitting over there. Then one of the doctors, over to one side, came up and pinched her very thoroughly, tested her for pain. He was very certain that my daughter, experiencing herself" "over there," did not show any pain reactions. The dissociation, the hallucination of herself" "over there," was quite complete. How could she be pinched "over here" when she was "over there"? How could she feel pain "over here" when she was "over there." We have the analog of this experience in another type of behavior. I haven't been able to recall the names of my psychology friends of many years past because I am no so busy in psychiatry and hypnosis. I had a delightful ride from Kansas City last night. My driver was working for his doctorate degree in psychology. After talking with him for a while, I began to call to mind name after name of psychologists that I had known back in 1929 and 1930, with vivid recollection. Why? I had never met this graduate student who was driving me before that evening, but he was a psychologist, and I knew that he was studying for his doctorate degree. It was a relaxed, friendly social situation in which conversation came easily. It brought back to me memories of a time when I was much closer to his present age. There was an awareness on my part that I was going to address a meeting where there would be many psychologists in attendance. These many factors provided a setting which facilitated the coming forth of all those forgotten memories. This was not hypnosis. However, if I wanted somebody to call forth memories of past events, past experiences, and past learning, I know that I could suggest to him that he be back in Worcester State Hospital talking to Dave Shakow or Paul Huston or somebody like that, and that he could begin to recall the names of the patients who had been on the ward when he had been there, and we would find a similar facilitation of recall.

My daughter "over there" could associate to the feelings that she would have "over there." She wouldn't have any feelings "over here." I later let her find out about anaesthesia. She said that she was very interested in this because she did not think that it was right for someone to suggest to another person, "Now, you can't feel anything." That was the first time I really understood why she objected to anaesthesia, even though she was quite willing to learn many other possible hypnotic responses.

It is difficult to tell somebody who is sitting in a chair in the middle of a room, "Now just feel yourself to be sitting in a chair behind me." No one can really do that in the waking state. In hypnosis, however, individuals are more open to ideas, and they more readily consent to examine them. If I were sitting in a chair behind the speaker, I would be facing in the opposite direction from that in which I am facing now. What would I see? I would be seeing an audience. The individual would permit himself to build up association by association until his thoughts would become more and more filled with an understanding of what an audience looks like, how it behaves. Soon it would become more and more possible to construct with these memories a feeling and image of yourself sitting in a chair behind someone and seeing that someone's back and then sitting in that chair. The individual would be able to take all of those past learnings and fit them together, and then he would feel himself in the chair behind me, looking at the audience.

In the ordinary state of conscious awareness, however, we are constantly orienting ourselves to the concrete reality around us. We do this as a matter of biological preservation. None of you would forget that there are people to the right and to the left of you, behind you and in front of you, in this audience. You remain well aware of these facts, and from moment to moment you reinforce this orientation to reality. In the hypnotic state subjects take one look at the hypnotic situation and they have established their orientation. They do not need to keep returning, verifying and reverifying their reality situation. They know the situation, and they are aware that, should any change in that reality orientation occur, they would be able to make the modifications. Thus they are perfectly willing to make these adaptations when the occasion arises, but they do not have to keep verifying that they are in this particular room, that there are lights in the ceiling, etc.

HYPNOTIC AMNESIA

What is hypnotic amnesia? I know that there are amnesias which occur in hypnosis. I also know that every hypnotic phenomenon can be found in everyday life, but only in a minor and disconnected way, and only at certain times. My favorite way of inducing amnesia is by a rather simple technique. When the patient with whom I know I am going to use an amnesia comes into my office I may say: "You know, it was very pleasant driving to the office. Today is such a nice day in Phoenix. Where there many cars on North Central Avenue?" Perfectly casual conversation. The patient answers, and then, in response to a posthypnotic cue she develops a trance, and we proceed with the therapeutic work. However, on this occasion I want her to have an amnesia, so when she awakens I say, "How was the traffic on the corner of Camelback and North Central?" I'm right back into the conversation that preceded the therapeutic I interview. I have thus

reestablished and made dominant the trend of thought that I preceded the therapy. In other words I have gone clear around and back to the beginning of the interview, until the patient walks out of the office, thinking about the traffic and the nice day in Phoenix and the number of cars on Camelback and North Central roads, and proceeds about her business with a total amnesia of the therapeutic work. Why shouldn't she have a total amnesia? By a simple asking of questions, casual thoughts have been used to emphasize a train of thought, a train of association in her mind, to bypass the conscious memories of the therapeutic interview.

A patient comes to you about a migraine headache. You sense that the patient is going to be very resistant about hypnosis and about therapy in general. You inquire sympathetically about the migraine headache. In one such interview I learned that there was a history of right-sided migraine headaches that had been going on for II years-always right-sided migraine headaches. I asked, "Is the headache present at this moment?" The patient said that it was. Then I asked, in absolute earnestness, "Will you please describe—you say it's an 11-year-old migraine headache—will you please describe . . . you did say 11 years, will you please describe the exact sensation you have right there," and I pointed to a place at the left side of her head. The patient wondered what I meant and why I pointed to this specific spot. As she tried to answer that question, I interposed, "Will you compare it with the same feeling on this side, and do you notice that you're beginning to have a pain over there similar to this one?" The patient began to examine that, for she had had plenty of experience with pain. Pain is something that you experience, pain is something that you remember, pain is something that you learn, and you can have it in all parts of your body. Pain is a learned experience. I just asked her to learn about pain "right there."

She accepted that idea and started to examine this area for pain, and she discovered pain. *I call this a hypnotic technique. I have offered a suggestion, and the subject accepted it*. She then made use of memories of pain and learnings about pain, and when I suggested to her that the pain was growing, the patient. I discovered that the pain was growing, and suddenly she had a left-sided migraine headache. What happened to the right-sided migraine headache? I had not asked it to disappear; I had not offered any therapeutic suggestion. On the contrary, I offered the suggestion that she have a left-sided migraine headache all at once, and she obliged me. However, she relinquished the right-sided headache. Now, if I can give her a left-sided headache, then I ought to be able to take it away. She has had 11 years of right-sided migraine headaches only, and suddenly she lost that for a left-sided migraine. It should be much easier to deal with a migraine of such recent occurrence acquired under these particular circumstances.

Hypnosis is a state of awareness in which you offer communication with understandings and ideas to a patient and then you let them use those ideas and understandings in accord with their own unique repertory of body learnings, their physiological learnings. Once you get them started, they can then proceed to utilize a wealth of other experiences. I do not know how that patient got rid of a migraine headache that she had on the right side repeatedly over a period of 11 years, but she did lose it right there in the office. She proceeded to develop a left-sided migraine headache, which I was able to hypnotically

suggest away. The left-sided migraine, as the right-sided one, was willingly given up by some utilization of body learnings. I don't know what they were. I don't know if she dissociated from her headache, or whether she just displaced the headache, or reinterpreted the headache, or just forgot the headache, or whether she suppressed the pain impulse that gave her a perception of headache. I know only that I presented ideas intended to stimulate the patient to behave in accord with actual body learnings over a long period of time.

ISOLATION (DISSOCIATION)

What are the implications of the hypnotic experiences which I call "isolation phenomena"? For example, instructing a patient to forget his foot, and then painfully stimulating the foot without disturbance to the patient. I use an isolation technique with highly resistant subjects who generally want to go into a trance. I tell a patient, "You know, in hypnosis you can really be so objective that you can look upon yourself, think about yourself in a nonsubjective fashion, with tremendous objectivity. Now take your hand, look at it, it's a nice hand. I wonder whose it is? That is an interesting hand, I wonder whose it is? Is that little finger going to move?" You and your patient look at that hand, and there is no sense of ownership, no sense of personal identity with that hand. You have just isolated it in an objective fashion. You're both looking at that hand. Not so long ago, when I was doing that with a patient, I reached over and squeezed on the phalanx in order to get joint pain. My subject watched what I did and said, "You know, that ought to hurt that hand." I have personally experienced polio, and I know something about the things that can happen to a person who has had polio. You can forget your body, you can lose your awareness of the various parts of your body. You can lose it to such an extent that you have to open your eyes to see if you are looking at the sheet or looking at the ceiling, because you really don't know whether you are lying on your back or on your stomach. You don't know where your feet are. You remember that you have feet, you remember that you have hands, but you don't remember what the feelings are like when your hands are closed and when they are open.

With subjects in an hypnotic trance you can bring about an isolation of the hand so that they can regard that hand as someone else's. You can cover up the hand and you can manipulate it. These subjects are very surprised when they find that the hand position is changed, because they didn't see it change its position. They didn't feel it change its position, nor do they feel pain. I have discovered that in working with polio patients who have forgotten physical movements you can do a great deal for them by asking them to remember their kinesthetic memories. I explain that word "kinesthetic" to the child and to the young adult so that they understand it. I tell them that if they can remember the taste of something and if they can remember the smell of something, then they can remember the feel of a movement. Thus with some of those patients who still have muscles, even though these muscles are inadequate, incompetent to use, you can get them to remember kinesthetic memories and kinesthetic images, so that they actually do It. In hand levitation, for example, sometimes your subjects will respond to you very adequately when told to lift their hand higher and higher, and the hand is lifting, is lifting, lifting. At other times when you say, "Your right hand is lifting way up in the air," you sit there and

you watch that hand remaining exactly where it was. Finally you tell these patients, "Take your left hand and put it on top of your right hand." They put it on top of their right hand, and because they have substituted an actual arm movement for kinesthetic memories, the right arm begins to lift. Joint sensation and kinesthetic memories are as valid as any other kinds of memories. You can substitute them and modify them. I think there is need for a great deal of research on the characteristics of these different types of learnings and memories, the conditions for change, and the way in which they undergo spontaneous alterations during life.

REGRESSION

How valid is regression as a phenomenon? How far can you regress? I recall a paper that was submitted to me as editor of *The American Journal of Clinical Hypnosis* in which a doctor used regression with a nine-year-old boy suffering from overwhelming acrophobia. He couldn't ride in a car in a high place, on a hill, or a mountain. He would cower on the floor of the car and sob. It was an agonizing experience for him to go to any high place. The physician regressed this nine-year-old boy and explained very carefully that he could go "way back" until the very beginning of his fear of high places. The doctor wrote that he did not know how far back the boy was going to go, so he told him, "And take your voice along with you, your nine-year-old voice with you, so that you can tell me." The patient said, "I am three months old and I am riding in a plane." (This was done in the presence of the mother.) "I am awful scared being way up high here." The mother shook her head vigorously in denial: "That's all wrong, all wrong." The boy came out of the trance state and showed no signs of fear. He seemed perfectly willing to go look out of a window which he had previously shunned, and to look down and things of that sort. The mother took the doctor aside and said, "He didn't go in a plane, he's never been in a plane."

It was a week or so later that the mother returned anxiously to the doctor's office and said, "You know, I'm completely mistaken about that. I took him on a trip just that once when he was three months old. I checked with my husband. He did ride in a plane at that time. I didn't want to take him, but I had to take him," showing some of her own reasons for forgetting the incident. How do you take the boy's voice and nine-year-old vocabulary back with him when he is regressed to the age of three months? How do you recover a memory of that sort, when the mother had forgotten it and the father had almost forgotten about it? How did that three-month-old infant know that he was three months old, and how did the nine-year-old boy take back with him a voice that could identify the age of that baby? Perhaps to the unconscious mind the primary problem is the intrinsic meaning of the idea or the communication which has been received, and then use is made of such capabilities and potentialities as are available to respond to and interpret this communication. I think age regression—whether partial, selective, or whatever aspect you focus on—can be investigated.

I know that everyone is capable of having perfectly wonderful dreams. I personally enjoy dreaming about things when I was a boy at home on the farm, about how nice it was in the early spring to feel the bare ground on your bare feet. Now and then I can have a very

pleasing dream experience that enables me to answer a lot of questions or to give some understanding to my patients or to my little children about what farm life was really like, particularly my children. Sometimes it opens up for me the possibility of empathizing with my patients in terms of feelings, thoughts, memories, relating to their age by a dream memory, a dream revivification or perhaps a dream regression. How much of regression is revivification and how much of revivification is regression I am not able to answer at this time.

In summary, I earnestly believe that the different kinds of behavior that you can elicit in the trance state are at least as worthy of investigation as are the learning and the forgetting of nonsense syllables, the recognition of negative afterimages, and similar samplings of behavior which have been considered valuable for the exploration of the principles of human behavior. I do not think that hypnosis should be or can be investigated as a total phenomenon (whatever is implied by that global term). I think that hypnosis can best be investigated by a careful searching of the great varieties of human behavior which can be modified or changed or influenced by the hypnotic state. Learning, forgetting, sleeping, dreaming are but a few of the areas in which research on hypnosis needs to be done. I think research should focus on the various manifestations of hypnosis rather than a total hypnotic state. As for research on hypnotic techniques, one should never forget that these are only a means of attracting the subject's attention, and we should not lose sight of the purpose of these techniques because of fascination with the variations which can be employed.

DISCUSSION

Dr. Henry Guze: Many years ago a paper by Dr. Erickson dealt with the post-hypnotic state. In view of what he said about hypnosis in his presentation, I would appreciate some clarification on what he considers to be the posthypnotic state.

Suppose he has treated a patient for pain in the manner that he has described. Does this patient go away and return to a posthypnotic trance to relieve pain at a later date? Is this another hypnotic state? If the pain is not experienced, are we to assume that the pain is not responded to? Is this patient constantly living in something of an hallucinatory state? The patient has perhaps put his body on the other side of the room, indulging in behavior which might, under a little pressure, be regarded as topological.

Dr. Erickson has stressed the verbal aspects in introducing ideas, concepts, attitudes, particularly that kind of attitude or idea, as it might be called, which creates a kind of refocusing of concentration of a certain kind. What about the patients who cannot speak? Can we hypnotize a deaf mute? Can we make a person who cannot speak go into a so-called hypnotic trance? I have been very interested in the problem of nonverbal communication. I would add, also, that I have maintained for some time the conviction that there is a continuity in terms of hypnotic phenomena phylogenetic ally from the lower animals up to man. If there are such things as hypnotic phenomena, it is quite reasonable that there should be such a continuity. Investigation of what we might call

comparative hypnosis might reveal that many behaviors of other animal forms might be explained on the basis of an hypnotic like state.

What is the relationship, if any, in terms of continuity? It is difficult for me to conceive that animals, if they do go into a hypnotic state, are able to go off into the realm of hallucinatory experience or imagery, which seems to be a basic constituent of hypnosis stressed in the presentation of Dr. Erickson. Finally, to what extent do you consider the hypnotic state and the psychotic state to be psychodynamically similar, related, or identical? Your emphasis on hallucinatory experiences, dissociation, and the like make me wonder about your thinking on this issue.

Dr. M. Erickson: Let me deal first with the matter as to whether the hypnotic state is similar or identical to the psychotic state. I think that hypnotic behavior is a normal, controlled, directed behavior useful to the individual. On the basis of my knowledge of psychiatry, psychotic behavior is disturbed, uncontrolled, and misdirected behavior which the individual has limited ability to change, modify, or understand. It is in some ways a misuse of a capacity to behave. A pansy in a tomato bed is a weed, just as a tomato in a pansy bed is a weed. A tomato in a tomato patch is a very desirable thing, as is a pansy in a pansy bed. In psychosis there is the wrong behavior, in the wrong place, usually at the wrong time. In hypnosis you have the right behavior, in the right place, doing the right thing, at the right time.

Now about this matter of the hallucinatory state of hypnosis. I do not like this formulation, unless Dr. Guze is ready to describe all memories as manifestations of hallucinations. I wonder how many of you ever had chilblains and then forgot about them for years and years. Then circumstances bring you back to Wisconsin in mid-winter and you are suddenly amazed to discover that even without getting cold, you've got a very good tissue memory of chilblains. Or is it tissue memory? I don't know exactly what it is. But your feet do itch frightfully. Why? You study it for a while, you're amused by it, and then you forget about it.

In my experience I have known people who never went into hypnosis, but who went to a movie because they had a severe headache, forgot their headache during the course of an interesting movie which had involved them, and perhaps didn't remember the headache until the next day. I don't know where the headache went in the movie situation, but I do know that they lost it sometime during the viewing of that movie, and that they did not necessarily have to have another headache to make up for it. I don't know what becomes of that headache that gets lost in the middle of a suspense movie, or a toothache that disappears on the way to the dentist, but it does disappear. There are many such things that disappear and are not accounted for.

In carrying out a posthypnotic act there is most likely a revival of the original trance, perhaps for a moment, perhaps for longer. It then passes on, just as you can have thoughts come into your mind that tense your muscles or alter your blood pressure, your blood circulation, and then the thought is succeeded by other thoughts with or without other physiological alterations throughout one's body. It's been a passing experience. The

thought may have brought about an unpleasant memory, recalled an unpleasant set to the muscles, but then these disappear and may remain away indefinitely. There is no basis for considering that the original trance has to continue indefinitely for the posthypnotic suggestion to remain effective.

Can you hypnotize a deaf mute? That question came up in Caracas, at the maternity hospital in Venezuela. I was there lecturing to the staff, and one of the psychologists was very interested about the application of hypnosis. He found out that my Spanish vocabulary was limited to a fluent use of *si, manana*, and *hasta la vista*. They asked me if I could induce hypnosis in someone who could not speak English. I felt that was not only feasible, but also not too difficult. One of the physicians went into the maternity ward and spoke to one of the patients. He told her that, "The North American doctor is interested in obstetrics and is interested in you." This was all that was told to her.

The woman came in, sat down, and looked me over. I looked her over. After a few moments I reached over, took hold of her hand, and elevated it up in the air. I looked at it there, then let loose of her hand. I looked at my hand, pinched the back of my hand, and grimaced. Then I pinched the back of her hand, and she grimaced. I pinched hers hard enough that she was justified in grimacing. Then I lifted my hand, stroked the back of it, and smiled and looked happy. I pinched the back of my hand and looked happy and as surprised as I knew how. She looked at me with a puzzled look on her face. I took her hand, brushed it, and gave the happiest look that I could give her, then pinched the back of her hand again. She looked very surprised, and said in Spanish, "It doesn't hurt." Communication can be verbal, but it is also quite obvious that there is a great deal of nonverbal communication. Communication can be an angry look, a lovely look—all kinds of looks and all kinds of gestures.

Dr. Fritz Heider mayor may not recall a conversation which I had with him many years ago about how deaf mutes swear in sign language. It is a very charming sign language, beautiful swearing, and it is meaningful, too. I think that you can hypnotize a deaf mute. I have asked blind people, blind from birth, to go into a trance and to hallucinate visually. The ideas which they have of what eyesight is, and how one would employ visual memory, are quite interesting and tend to be a composite of description of tactual, pressure, and kinesthetic memories.

Dr. Roy Dorcus: Dr. Erickson is a master of his art and he has given us a wonderful description of how he therapeutically creates in the individual the things that he wishes to bring about with respect to changes in behavior that the individual needs. I don't think that his discussion was primarily oriented to how these matters are related to the induction process, or really as to what hypnosis, itself was.

He raised the question about catalepsy, how far this could be extended. I might indicate that in one instance we kept an individual in a cataleptic position for approximately 13 weeks. This was done for surgical purposes. The individual maintained this position, of course, during sleep. It was necessary because of a skin transplant, in which the transplant was made from the abdomen to the wrist and then from the wrist to the jaw.

There were some real counter indications against placing the arm in a plaster cast for this length of time. It was not necessary to use this method because of the effectiveness of the hypnotic catalepsy. I do have a question with regard to Dr. Erickson's report of the case of a child with fears of height. I believe that this is closely related to another report presented to this Institute about the young woman who needed dental work. Even though the recalled memory made possible therapeutic management of the dental situation, there was found to be complete fabrication with regard to causality of the so-called memory of the traumatic situation. I have some serious doubts about this physician's report about the three-month-old child as to how this three-month-old child would know whether he was up in an airplane or on the ground and whether, by having the child report that he went back to this traumatic experience, that we are justified in concluding that this "recalled memory" was related to the particular problem which was being experienced. This is not to question whether the nine-year-old did not experience therapeutic relief, but it is my impression that it is very likely that you have had some projections and possibly some fabrication in this particular situation.

I can also affirm that it is possible to hypnotize deaf mutes. I had a patient referred for a particular reason. She happened to be a Czechoslovak who couldn't speak English, but the woman could read sign language from her daughter. I made one very foolish mistake in working with this woman because I started out with a visual technique, transmitting the signs through the daughter who could speak with her mother. I could not speak with her. I got her eyes closed and, of course, lost communication with her. At that point I had to take a hold of her eyelids and open them up until we could give her some signals again, and go back and start over.

I am in basic agreement with Dr. Erickson with regard to his general tenet-that is, the less stress and strain put on the subject (or patient) with regard to projecting himself into situations in which you wish to bring about some changes of behavior, (the better). If you can specify the situations for your patients, if you know something about their own background, then it is much easier to bring about the changes in behavior. If you happen to use some situation that is unfavorable for them-for example, in the situation where you might ask an individual to project himself into a very relaxed situation on the beach, you will find that occasionally you run into an individual who, because of sensitivity to sunlight, won't tolerate this sort of a projection. So if you either allow them to select the situation that is going to be appropriate for them, or if you can suggest one that is appropriate for them, the chances of getting the behavior one desires are greatly multiplied.

Dr. T. Sarbin: I would like to accent Dr. Dorcus' doubts about the case of the person reporting a memory of being in an airplane at the age of three months. This is so reminiscent of the Bridey Murphy phenomenon which, as you all remember, created such a stir a few years ago. It is the sort of thing that is very easy to induce in most subjects. In fact it is not difficult to have a hypnotized person report an experience during fetal life. We have to be very skeptical in accepting such reports as valid, even though such reports may be very important in therapeutic analysis.

I am very much interested and I approve heartily of Dr. Erickson's beginning analysis of hypnosis as an attention phenomenon, and some of his illustrations would seem to indicate that hypnosis is a matter of redeploying attention from one stimulus object to another. Redeployment of attention is a concept that is employed to account for changes in behavior in other social psychological situations than hypnosis, e.g., faith healing, conversion reactions, pain-free birth, etc. But when Dr. Erickson moves from attention concepts into a definition of hypnosis as behavior *within the person* that has to do with an altered state of awareness, then I have some questions.

Awareness is a term that is in common parlance. But when we introduce a definition of one unknown, e.g., "hypnosis," we don't want to use a word the referents for which are also unknown, or a word that has multiple referents. Ordinarily when you ask a patient, "What is awareness?" the subject uses the word "conscious" or its opposite, "unconscious." About 1941 Dr. James G. Miller wrote logical analysis of the multiple meanings attached to the word "consciousness." His study yielded, I believe, 17 major meanings and a number of subsidiary meanings. The same analysis could be applied to the term "awareness." Changes in "awareness," or changes of some kind that have to do with inner dynamics, as it were, are something that can only be inferred *from conduct*. The therapist, the hypnotist, and the analyst are limited to observations of conduct, to things that the patient says or does. They are free, of course, to take the sayings or doings and reconstruct them in any way that they wish. If we go back to the 18th century, we find that the sayings or doings were interpreted as a mysterious force, as animal magnetism. In the mid-19th century, the sayings or doings of the patient which came about as the result of hypnotic induction procedures were interpreted as disorders of the central nervous system. More recently these sayings and doings have been interpreted as learning phenomena. The ultimate test of what usefulness our inferences have about the behaviors that we call hypnosis can only be realized through observation and experiment.

Dr. Erickson was generous in his comment that such things as the analysis of the learning and forgetting of nonsense syllables have a place, but it seems to me that there was hidden in these remarks a criticism of such kinds of research, that this type of research would not really get us into the inner life of the person, which is the core of hypnosis.

Dr. Erickson's report presented us with a number of clinical anecdotes. The techniques that he uses in his clinical practice are imaginative, original, and I'm sure influence the patient in the direction of removal of symptoms, perhaps toward a change in character structure, or whatever the goals of the therapeutic endeavor are. But we must always bear in mind that individuals change their conduct in a number of settings. The settings certainly can be analyzed the same way that hypnotic influence can be analyzed. Dr. Watkins made the point in his report that we have to analyze variations contributed by the therapist, by the subject, by the interaction, etc. The procedures that we use in basic experimental I design are no different. Whenever controlled experimentation has been done, I invariably we find that the kinds of change, the kinds of influence that are produced under hypnotic conditions, can also be produced under nonhypnotic conditions.

My theme is that we are not moving forward if we look upon hypnosis as some kind of force or process that goes on exclusively within the individual, a force or process that demands explanatory concepts that are different from explanatory concepts that we use for the analysis of everyday behavior. In this respect I would urge the next generation of scientists to focus on the special social relations between hypnotist and client that influence action.

Dr. M. Erickson: When that three-month-old baby was taken to see a pediatrician, he did not know that the adult was a pediatrician. The baby did not even have a concept of a medical office, but that three-month-old baby was able to, and did, receive certain sensory impressions, visual impressions of whiteness, visual impressions of the pediatrician's shape and manner, as well as the cutaneous sensory impression of the hypodermic needle. Three months later, six months later, when the baby was taken back to the pediatrician's office, he was still unable to identify the pediatrician by name, or give the color of white, or recognize the hypodermic needle, but he was able to, and did, show a conditioned response of fear, anxiety, and distress. He can keep right on with that learning. I think the boy did have a plane ride at the age of three months, that perhaps, as he was carried up the ramp into the plane, he had the visual impression of a distance which was disturbing, and only later on put a name to this experience. I mentioned that he took the nine-year-old voice along with him in that regression, which meant that he took his nine-year-old understanding of height. He named the plane. I don't know where he got the memory of the plane, but it was verified that he had a plane ride. Most people have had the experience of seeing a strange, unfamiliar object and wondered and wondered what it was. And then one, two, or more years later it will suddenly dawn on them what it was that they had seen and didn't recognize at the time.

I would like to respond to Dr. Sarbin's comments about an altered state of awareness. If I wanted Dr. Sarbin to say a large number of very pleasant things, I think I would introduce him into a setting where there was soft music and flowers and sufficient other attractions which would induce in him the desire to say a number of nice soft words. However, if I introduced him into a situation where I was tormenting a dog, I expect I could induce him to say a great many unpleasant things. You alter a person's state of awareness by the conditions associated with, and the character of, the stimulation which you offer along with the inner behavior of potentials in that person. I do not think that I am in error to give the general term "state of awareness" to the memories, ideas, and emotions characterizing a person at a given time, nor do I consider this a "mystical appellation." I also do not feel that it is mocking the learning and forgetting experiments using nonsense syllables to say that just-as-serious scientific attention should be given to the study of hypnotic learning, hypnotic forgetting, and other hypnotic manifestations.

Dr. T. X. Barber: I was impressed with Dr. Erickson's statements concerning the technique of hypnosis. He said that it consists basically in asking the subject to pay attention. I can generally agree with this, and I believe most of the other people on the panel would also generally agree with it. Of course the problem remains, what do we mean by attention? In a general way this is probably the essential element of the hypnotic

induction. Dr. Erickson emphasized this many times, but then shifted over into something different.

It seemed to me that half of Dr. Erickson's presentation was from the position of a natural scientist, psychologist, and psychiatrist trying to understand what hypnosis is; the other half of the time the presentation seemed to be from the position of someone of many years ago who really thought hypnosis was a mysterious, magical thing.

Dr. Erickson's main point seemed to be that what we're doing is trying to get the patient to use previous learnings. He put this in various ways, but always saying the same thing—experiential learning, bodily learning, conditioning processes. It was my impression that he was affirming that we have learned many things in our life, most likely due to some kind of conditioning process. The learning is present; the problem is, how are we going to bring it out? We do that by hypnosis: First we get the subject's attention, then (according to Dr. Erickson) the subject goes into a trance, and when he is in a trance, magic-like things happen. It is implied that a kind of mysterious thing happens because of trance. An example was a case of amnesia that Dr. Erickson presented. Before therapy began the therapist was talking about the traffic on the street; then, immediately after termination of the hypnotic therapy session, the therapist begins talking once more about the traffic on the street, and supposedly because the patient had been in trance, she immediately had an amnesia for all that went on during the "trance." She didn't remember anything else, supposedly because the therapist had reoriented her and he was again speaking to her in the same way he spoke to her originally (before the hypnotic induction). Why does the patient have the amnesia? The answer given by Dr. Erickson was that she was in a trance and the therapist reoriented her thought processes.

Let's ask a simple question: How do we get a person not to remember what has occurred during trance by simply talking to her again about what we were talking about before trance? The answer, as I believe Dr. Erickson said, was "I don't know." I would also say, "I don't know," but I would also say that it is not simply because we have indirectly given her a suggestion for amnesia. This is not magic nor are we back in the 18th century.

There is something more in this, and this is what I believe is happening. In all the studies of hypnotic amnesia that I have done, I have always found that the subject *in some very purposive, deliberate way* wants to do what I tell him. He wants to comply. This might be on an unconscious level, if you want to use that term. This is quite obvious, and we can pick it out all the time. If he is not a good, motivated, hypnotic subject, then he is not going to show amnesia.

Suppose we tell the subject, "You won't remember something," or perhaps we suggest amnesia in another way. For instance, we may start talking about something that was occurring before the hypnotic induction and thus give the subject the indirect suggestion that he should not remember. What happens then? Suppose he says, "I don't remember what occurred," which shows amnesia. Then we ask him, "Why don't you remember?" What will the subject say? I wonder if Dr. Erickson has ever questioned the subjects. It appeared that Dr. Erickson just took the amnesia for granted. He starts talking about the

traffic again, and the subject "doesn't remember." Did Dr. Erickson ask her, "Why don't you remember—what's happened?"

Every time I have asked my subjects that, they all say something like this, and I'll try to quote them: "I don't remember because. . . well, I can't." "Why can't you?" "There is a block there." But if you really get around it another way and have somebody else question the subject, the answer comes out, something like this: "I don't remember even though I know I can remember ... but I can't let myself remember. I could remember if I tried ... but I won't try." Why is the subject not remembering? The subject is not remembering because in some way he is *not letting* himself verbalize what occurred; he is not letting himself remember. What does that mean? What he is doing is something like the following: "I will think about certain things, but I will not let myself think about certain other things." A good hypnotic subject, when he gets his cue that he is not to remember, will not let himself verbalize these things to himself. They are there, he can remember all right. All that he has to do is just let himself verbalize, but he doesn't let himself do it. Amnesia takes purpose, effort, striving; it is a deliberate kind of thing. It is not something that just happens magically just by giving the stimulus. I am bothered by Dr. Erickson's formulations because I get the impression that there is magic being attributed here that does not promote scientific understanding or investigation.

Let me cite a second example. Dr. Erickson reported about an age regression back to three months. Both Dr. Sarbin and Dr. Dorcus commented on this. This might very well be. Nobody can absolutely say that we cannot remember or that it is impossible to remember what occurred at three months of age. It might be possible even though I don't think that it is at all probable. That, however, is not the question here. The question is that a subject was reporting this, and the report was taken so uncritically and so readily accepted without asking a whole series of questions. First of all let us suppose this boy actually took the plane ride at three months of age. How do we know that this was not discussed at some later time, that it didn't come up in some way later? How do we know that at four, six, or more years of age the subject did not hear that at three months old he took this plane ride. Dr. Erickson did not report if these questions were asked. He seemed so ready to accept this report at face value that he gave the impression that there was magic at work. There is the connotation of a real mystery here that I just cannot accept. The evidence from psychoanalysis has been critically reviewed so that we have reasonable doubt about the historical accuracy of reported memories.

I believe that Dr. Erickson was on the right track when he was talking in terms of attention. This is a word that we can use, although it is quite hazy. I believe that he was on the right track when he was talking about conditioning, learning, and how we have learned many more things than we utilize. But I believe he goes off in some way when he is ready to uncritically accept evidence about age regression.

It was said that a hypnotic subject was made cataleptic. All that means is that the subject kept his body rigid and he sat there for one hour. Should we do research on this? The implication was that this was an amazing phenomenon. Motivate a person, or pay him some money; pay him enough to sit there for an hour. If he is motivated, he will do it.

That is all the research we need to do on that. It is not amazing or mysterious if somebody can sit still for an hour. The only research we need to do on "cataleosy" is to show that it can readily be duplicated by a motivated person, and hypnotic subjects are usually very motivated.

Dr. M. Erickson: I believe that the hypnotic subject can do in a trance state the same sort of things he can do in the waking state. I might introduce someone to a dozen other people. At the end of that time, by virtue of having directed this person's attention first to Mr. Jones then to Mr. Green, to Mr. Brown, etc., and after I had finished the 15th or 16th introduction, I could ask him, "Tell me, what was the name of the first man, the second man, the third, the fourth, the fifth?" We would readily appreciate how rapidly a person can forget something, especially when his attention is constantly redirected. There would be no problem to prove that this person had really forgotten the names. Even when we have people who are strongly motivated to remember the names which have just been presented to them, we find that they forget easily. I don't think that this forgetting is a function of mesmerism or magic. I think it is ordinary normal behavior.

I believe that the hypnotic subject can, in the trance state, do something besides please Dr. Barber. I think he can use his own behavior for his own purposes, and do it in his own way. He doesn't lose his capacity to behave to please himself. I think he can also do things to please Dr. Barber as well as do things to displease Dr. Barber.

As for this Bridey Murphy mystical thing, I said that I think you can condition a three-month-old baby and that you can condition him in various sensory modalities. Later an interpretation can be placed upon that conditioned response. I also said that the boy took his nine-year-old voice into the situation with him. Is that magic? I don't know what else was taken along, but I looked upon it as a partial regression, and I don't think that this was a matter of gullibility. All we know is that these were the things done and that certain therapeutic results were obtained. I think that the therapeutic result was a valid occurrence, a valid experience for the boy. What is the explanation? Let us not call the explanation Bridey Murphy. Let's not call it any names at all. It is more productive scientifically to wonder what the processes are that constituted that experience. I fully recognize that you and I cannot apply the most useful concepts nor give the right terms as yet. We haven't examined the items of behavior most meaningfully, perhaps not defined these items of behavior in the most useful language.

Dr. Andre Weitzenhoffer: I feel that I must concur with the previous discussant and express my doubts as to the likelihood of a three-month-old child being capable of a conception of distance which the reported paper seems to have implied. Even if the infant had a conception of distance, I would question how he would come to fear distance unless he had been dropped. It is possible that he had been dropped by his father. I remember hearing about a father regularly lifting his child up and then letting him fall saying, "He's got to learn the hard way that he can't trust people." These are assumptions. I am only raising this question. I do not mean to question the validity of the reported regression as a regression, or its therapeutic value. I do want to raise this

question about whether the three-months-old baby could have this memory of depth and height and somehow could have learned to fear this.

The comments of Dr. Barber and Dr. Sarbin lead me to make the following points. It is true that we can find individuals whom we thought were actually "hypnotized" (but who said they were not), who could produce the phenomena which have been produced in hypnotized individuals (at least by the best of our criteria). But it is to the point that we can also find individuals who, under the ordinary conditions of not being hypnotized, cannot produce certain phenomena, but when they are "hypnotized," are able to produce these phenomena. I do not mean anything transcendental, nor do I mean anything magical. You can take an individual and show that he cannot produce a certain type of hallucination. Then you hypnotize him by means of some ritual (I don't care what method you use), and then show that under these conditions the individual can produce hallucinations. I think then we do have a basis for saying there is a state which we can call "hypnosis. " It seems to me that it is not enough to say that we can find nonhypnotized individuals who can produce the same phenomenon that these people who are hypnotized can produce. I am sure we can. I don't believe that under any condition we can produce phenomena which transcend the potentialities of the individual. We all have our potentialities. We can't go beyond this. I do think, however, that under normal conditions many individuals cannot make use of all their potentialities. In a sense I agree with Dr. Erickson that most individuals have potentialities that are not being actualized but which, under hypnosis, come closer to actualization.

Dr. Orne has been doing a lot of work with simulators. I know he has been concerned with these same problems, but from a different angle. He has asked himself the question: Is there some one single test which can be given to two groups of individuals (one group composed of good hypnotic subjects, and the other a group with simulators, i.e., people who have been instructed to simulate, to pretend, people who have been instructed to simulate to do their best, to behave like a hypnotized person), and which only non simulators can pass? He says that if he can find such a test, and if he can find that individuals can pass it only if they have been hypnotized by means of a ritual, then he will be in a position to say that we can speak of hypnosis as a state, as a condition.

Dr. Henry Guze: I, too, cannot accept the validity of a three-month-old memory of that kind. However, we should maintain an awareness of very early affects in development which in some way may leave some kind of state that later may be associated with an experience. We should not neglect the aspect of imprinting from animal behavior, and also the data which we have gathered on early deprivation states, both in human beings and in the lower animals. As a comparative psychologist I have done work on very early deprivation, preweaning nursing deprivation in mammals, and we have definitely and distinctly demonstrated permanent effects, permanent changes. It is very difficult to draw the analogy, but I think that we should keep an open mind about the possibility.

The second point which Dr. Weitzenhoffer so very aptly brought forth is the problem of equivalent behavior. We are missing a very vital problem by forgetting that we can very often, in many states, elicit the same phenomenon by different means. For example, sugar

and saccharine are both sweet, but this does not mean that because they both give us very similar sensations of sweetness that therefore the two chemical compounds are the same. Similarly we can find types of behavior, all along the various biological levels, which appear to be the same type of behavior on the surface but which are elicited really by different means. Therefore I don't think that we invalidate hypnotic phenomena by the fact that certain hypnotic phenomena may appear in some people during the waking state. I would be extremely cautious about this.

Expectancy and Minimal Sensory Cues in Hypnosis

Milton H. Erickson

Incomplete report written in the 1960s.

The significance and effectiveness of minimal cues in eliciting and altering responsive behavior is frequently overlooked, even disregarded, in hypnotic work, not to mention other forms of endeavor employing interpersonal communication. As a measure of impressing this upon medical students and candidates for doctoral degrees in clinical psychology, the following teaching procedure was devised and carried out over a period of years, with succeeding classes divided into small groups, each handled in a separate fashion.

Well-trained somnambulistic subjects capable of manifesting readily all of the usual phenomena of deep hypnosis were employed. At every opportunity new subjects were employed; they were kept unaware if possible of the work to be done; and whenever they were used with different groups, the actual group task was varied if possible. Subject sophistication as to the nature of the work done was found to occur frequently, but this was early discovered to be an additional valuable experimental finding and also an experimental control. It was not, however, deliberately employed.

Pairs of study groups were formed composed of one to six students each. At first an effort was made to select homogenous groups, but this was found to be most uncertain, a fact that proved experimentally advantageous.

The experimental procedure was relatively simple. The subject, in a profound hypnotic trance, was told that he was to be a teaching subject for students. He was to develop a trance state slowly in response to whatever induction technique was employed, taking from five to 10 minutes before he entered the somnambulistic state. This he would manifest to the students by some specified cue such as a deep sigh, of which the students would be apprised in their preliminary instruction. Then, and not until then, would the students offer suggestions for specific phenomena. These suggestions were to be "listened to attentively and understandingly." They were "to be executed in exact, precise accord, and only in accord with their actual, their real meaning as given." Their response was "to be made unquestioningly," that "nothing more, nothing less than that actually expected" was to mark their responses to the suggestions given to them, that they were to respond adequately and well to the "real, the exact meaning of the suggestions as you hear them."

To summarize-and it is necessary to summarize at this point to keep the nature and purposes of the experimental study in mind:

Somnambulistic subjects were told to accept "in their exact, their precise meaning" suggestions for specific hypnotic phenomena offered to them by students. They were earnestly instructed to respond with behavior that was no more and no less than the *actually expected responses*, and they were to listen attentively, well, and understandingly to the suggestions given.

The instructions to the students were given separately to each of the various groups. These instructions followed the same general pattern, but their content varied from group to group. For example Group A was told emphatically that Subject X was a remarkably fine somnambulistic subject and could develop all of the phenomena of the deep trance with the one exception of anaesthesia. A casual explanation was offered of individual variation of subjects, and it was pointed out to them that some subjects who seemingly could not develop certain phenomena would do so with the right operator.

Group B was given the same instruction about Subject X but told that, despite adequate ability in all other regards, X could not develop auditory hallucinations. Group C was told that Subject X could do anything except visual hallucinations, and Group D was instructed that Subject X could manifest everything except posthypnotic amnesia.

Each group was given the same total list of phenomena to elicit and the same set of token suggestions by which specific phenomena could be elicited. For example, in securing anaesthesia of the hands, the pattern of suggestions followed a noticing of the feeling in the hand, its warmth, its weight, its beginning feeling of coolness, of coldness, of slowly developing numbness, of final absence of feeling.

For visual hallucinations the pattern of suggestion included feeling oneself staring into distance, of vision getting blurred and indistinct, of fogginess and haziness developing, of finally seeing nothing but a meaningless haze in which would develop lines and shadows and curves and shadings and blurred forms that would become more and more clear and visible until they saw some chosen visual hallucination removed from the experimental situation such as a movie, a wedding party, etc.

For each of the deep hypnotic phenomena comparable sets of detailed, rather amateurish sets of instructions were made up and presented to each student group for careful study and use during this work with the subject.

Basic Psychological Problems in Hypnotic Research

Milton H. Erickson

Reprinted with permission from G. Estabrooks (Ed.), *Hypnosis: Current Problems*. New York: Harper & Row, 1962, 207-223.

Research in hypnosis and the presentation of ideas about hypnosis too frequently parallel the arguments that the seven blind men offered about the elephant. They argued first with much intensity and finally they did research. One got hold of the tusk and another of the tail, another felt the flank, another, the ear; the fifth examined the trunk, etc. Then, after each had done his complete examination of his particular part of the elephant, their arguments became intensified.

So it is with hypnosis. Everybody has a particular point of view, and it is necessarily a limited point of view, just as mine is. I am going to ask a critical question, therefore, of my colleagues: Why should anyone assume that hypnosis is of necessity a matter of distorting reality? Certainly such a forthright assumption is far beyond the call of any scientific duty. One could equally well and perhaps more rightly and informatively say that hypnosis is a state of readiness to utilize learnings. Why should it be viewed as a distortion of reality instead of some kind of readiness to use abilities normally? It has also been said that "Hypnosis is an alteration in perception," as if this were an abnormal process, an indictment of hypnosis. But is it not a part of our learning experience in life, and does it make hypnosis a distortion of reality?

I have been credited with using hypnosis to maintain the "strength of the ego" in deep hypnosis. The ego, so far as I know, is a helpful and convenient concept, but that is all that it is. "Ego" is a verbalization to permit better communication of abstractions employed in conceptualizing. Then to speak of "strength" as a reality attribute of an abstraction serves only to lead scientific thinking further afield.

It is also stated that hypnosis is a state where one person takes responsibility for another. I think that is on a par with the supposedly explicit and specific statements that hypnosis involves an interpersonal relationship in which one person, the operator, restructures the perceptions and conceptions of another person, the subject. Let us examine this statement to see if it is equally applicable in other fields. Anaesthesiology is a relationship wherein one person takes the responsibility for another. Education involves an interpersonal relationship in which one person, the teacher, restructures the perceptions and conceptions of another, the student. Eating involves an interpersonal relationship in which one person, the waitress, restructures the perceptions and conceptions of another person, the diner. In other words these presumably specific scientific statements intended to describe hypnosis are so generally applicable as to be descriptive of the teacher, the lover, the bus driver, and so on. One does not describe hypnosis scientifically by offering with an air of profundity vague generalities that can be paraphrased in a wealth of ways.

Science is the method by which we endeavor to achieve more and more explicit and specific understandings of phenomena, expressed in terms applicable to the phenomena themselves and not to other unrelated things.

The question has often been raised of universal hypnotizability and its bearing upon health and sickness. It is almost universal for us to be born with two feet and two hands, but what bearing does it have upon the question of health or sickness? So far as I know, hypnosis as a form of human behavior has been in existence since the beginning of the human race. Then why should hypnosis necessarily be singled out from the entire variety of human behaviors and designated as something that is highly specific or even slightly specific in relationship to mental health or mental sickness, emotional health or emotional sickness? Yet there is much thinking along that line because so many people believe unthinkingly that hypnosis is an abnormal state. Furthermore we may ask, Are not the manifestations that are developed in the hypnotic trance the behaviors learned in an ordinary waking state? One could parallel this type of thinking by the statement that the circulation of the blood is highly specific to mental, emotional, and physical health, and that such circulation varies according to sleeping, waking, and activity states. All of this is true, but it neither discloses nor constitutes any specific understanding of health or of blood circulation until it is refined in relationship to highly specific items of special reference.

In illustration of some points I wish to make I will cite the instance of a paralyzed man bedridden for 15 years. I saw him when he was in his 80s. He had pneumonia, was dying, and was delirious. The thing that astonished me was what that man was doing in his delirium. His history was this. His mother had been a very religious woman who compelled her children, from the age of four, to listen to her give a daily prolonged reading of the Bible. Year after year, every day, this was done without fail so that she repeatedly read through the Bible. Before his mother died this man had had six years of that daily listening to the Bible. His reaction to her death and to that Bible reading had been one of utter bitterness and resentment. At his mother's death he was placed in a foster home where there was no Bible reading, no church attendance, and no going to Sunday school.

He grew to manhood with these foster-home attitudes, married, never allowed his wife or children to go to church, and declared the Bible and all religion to be unacceptable. In his early 70's he suffered the paralyzing cerebrovascular accident that rendered him permanently bedridden. Then he developed pneumonia, became delirious, and in that delirious state he *recited the Bible*, chapter by chapter, hour after hour. Using a Bible to check his recitation, I found that he was reciting it correctly. To everybody's knowledge in the community he had not even looked at a Bible since the age of 10 years. I encounter people in the psychology laboratory and in the field of psychiatry and medicine who say in all seriousness, "Hypermnesia and those regressive phenomena attributed to hypnotic subjects are dubious, questionable, open to question," and they work out all manner of experiments to prove that hypermnesia and regressive phenomena are impossibilities and, what is worse, they believe their inadequate findings. That dying old man proved that regression to childhood memories is an actual phenomenon. Yet there are any number of

attitudes taken to disprove the legitimacy of hypnotic experiments and the concepts that one deals with in hypnosis despite their occurrence in the ordinary course of human events. If that aged, sick, delirious, brain-damaged man could recover childhood memories, is it not reasonable to assume that comparable behavior can be achieved by the young and healthy?

Another example I wish to cite is that of a hysterical patient who sat in a wheelchair for nine years, presumably totally unable to walk—"paralyzed." Once her child, who was on the other side of the room when the housekeeper went out, started the electric motor that ran the wringer on the washing machine and got his hand caught in the wringer. The patient, who was in a wheelchair on the far side of the room, jumped up, rushed across the room, rescued the child, and never thereafter showed any ability to walk. Of course hysteria can be called a functional thing: yet that hysterical paralysis was sufficiently real to govern most significantly that woman's life. What did that woman say about this rescuing of her child? She said she did not do it, she did not and could not get up out of her chair, that the child had just looked at the washer. Nevertheless the occurrence had been observed in its entirety. That woman was not deliberately or even unconsciously lying. Two orders or categories of behavior were manifested, one which occurred in reality and another which constituted a reality of understanding for her. Yet research workers will propose methods of study to determine the "validity" of such behavior despite its actual occurrence and overlook the far more important need to devise methods and procedures to elicit such manifestations for study as such. So often the experimenter blindly construes experimental negative results to signify nonexistence of phenomena instead of incompetency of procedure.

Somewhat comparable is the case of Jimmy. For 30 years he had been a deteriorated patient in a state hospital, sitting around on a bench, drooling, untidy, filthy, just about as "deteriorated" as a patient can be. His record disclosed his condition to have been at a constant low level since admission. He was simply and obviously an old, hopelessly deteriorated schizophrenic patient. Then one day a fire broke out in the hospital, and the attendants in that ward became frightened and panicky. Jimmy got up, walked over to the first attendant, said, "Listen, you take your keys and go to that end of the hall and you stand by the door." He went to the other attendant and he said, "Now you get all the patients and you march them over there." Then to the second attendant Jimmy said, "Give me your keys," and Jimmy himself systematically searched each room thoroughly, and when he had made certain that there was no frightened patient concealed in any part of the room, he locked the door and moved on to the next room. This done, he left the ward, locking the door behind him so that no patients could run back into the ward. He then walked over to make certain that the two attendants had marched all the patients outside and were handling them adequately out in the yard. This done, he said, "Here are the keys," and lapsed into his old "deteriorated schizophrenic self" again, a seemingly total loss. Now this instance may be quite different from that of the hysterical patient-or is it different? When you produce in hypnosis tremendous alterations in the subject's behavior, is it not possible that processes comparable to those which sometimes occur under ordinary or pathological conditions are set into action in a limited, but controlled and instructive fashion?

Another thing I want to mention is the matter of conditioning. Everybody knows that you can get conditioned responses in the psychology laboratory. You ring a bell, you flash a light, do this and that. You do it a sufficient number of times and you can get a conditioned response that governs the subject, and you can do a number of things in relation to that conditioned response. I think of Ann, who walked into a dentist's office when she was eight years old. She was a frightened little girl, and she was squalling and yelling because her parents were the type of people whose children would cry when they went to see the dentist. The dentist believed in the wet-towel method of handling crying children. He slapped her face with a wet towel, picked her up and put her in the chair, slapped her face again, and told her, "Shut up and be a good girl." So she was! At age 21 Ann walked into another dental office and said to the receptionist, "I want to talk to the dentist. Tell him I'll be out in the hallway." The receptionist told the dentist about it as he went out in the hallway where Ann was standing fearfully. "You won't slap me, will you?" she asked pitifully. Ann was a college graduate, an intelligent girl, but such was her uncontrollable fear that she had to make absolutely certain that she would not be slapped. It was impossible for her to believe otherwise at first, and the dentist had much work teaching Ann that brutality was not a part of dentistry. Ann had never been to a dentist since that childhood experience—she had been thoroughly conditioned in one single experience. The dentist had to be most laborious in his deconditioning of the girl, who now wears complete dentures as a result of that original experience.

Why should not one assume that if such a massive thing can happen in one little instance of everyday life, massive phenomena comparable in intensity and effectiveness can be secured by hypnosis in a directed and controlled fashion? Why not assume that the same forces that condition people in ordinary life can be as effective in hypnosis? The people are the same, they still possess their innate abilities, and we all know that a single starry-eyed look can initiate generations of events. Why assume that hypnosis negates the possibility of sudden effective conditioning?

I recall a little girl about seven years old to whom in jest, pointing to the empty air, I said, "You know, that's an awfully nice doggie there. He's black, isn't he?" And the little girl stepped over and petted the dog. She fed him cake. She had a delightful time playing with that dog, and I had a delightful time following up the results of that simple jest, because the little girl was so very pleased with that dog. When visitors would come, she would ask them, "Please walk around the dog. He's sleeping in the hallway." For many months she played extensively with the hallucinatory dog.

The girl is now grown up, a mother of children, and she hopes that every one of her children will have as nice a dog as she had when she was a little girl, though she recognizes that it was some kind of visual image or hallucination, but nevertheless a very real experience and memory, and a good and happy one. She found that dog as real to her in ordinary, everyday, waking life as are the figures in a nighttime dream during physiological sleep, and such dreams can be decidedly vivid and happy. And what about the imaginary playmates that children have? I knew a little girl who had a playmate named Booboo. Full respect had to be accorded Booboo in every possible way. I have

encountered many people who have had imaginary playmates that were a normal part of their lives as children. Comparably, why should not one expect a subject in the hypnotic state to manifest the same sort of normal behavior with similar realism? Why should not the highly intelligent child grown older experience again a past reality as competently as when a child? Why assume that visual images are willful confabulations in adults and experiential realities spontaneously developed in children? Scientific study of such possibilities is needed, not dogmatic negation.

There is the matter of a phantom limb discussed in Dr. Wright's chapter. You can encounter people in ordinary, everyday life who will discuss their phantom limb as a reality. The reality of the phantom limb as an experiential phenomenon cannot be questioned. From whence comes the learnings that produce a phanton limb? What are the processes that enter into it?

The phantom limb is a phenomenon that occurs both in the uninformed and *in those having advanced academic and professional degrees* in both psychology and medicine. In a way it is a parallel of the phenomenon of partial body dissociation that can be produced hypnotically. Perhaps the same or similar mental processes are involved. The matters of dissociation, association, and reassociation are still a virgin field for hypnotic exploration, and much more can be accomplished by research than by the fervent presentation, without cognizance of the actual phenomena, of personal theories of role-playing and simulation. It is satisfying personally to offer theories and hypotheses, but it would be so much better to investigate actual phenomena. Research should be centered around phenomena, not around achieving fame by placing in the literature a well-argued theory intended to "explain" some unexamined manifestation. Profound studies of hypnotic phenomena themselves are needed rather than idle, though earnest, speculations and pronouncements. This constitutes the real need in scientific advancement.

In a related area, what are the forces, the sensations, the experiential learnings that enter into what we call the body image? The body image is an extremely important thing to all of us. When we lose a limb, or have a hand or foot amputated, it is important to remember that experientially we still have a body image in our total unrecognized understandings of ourselves which did not undergo an amputation. That vital sense of the "beingness" of the self is often overlooked, and this feeling of the integrity of the bodyself offers another point of departure in understanding what constitutes self-realization. Why should not the person in a hypnotic trance be able to develop upon suggestions manifestations conducive to a study of the nature of dissociation, depersonalization, and related phenomena? These are areas of research vital to both medicine and psychology.

Now I wish to consider another misconception about hypnosis. It is often asked whether or not some hypnotic phenomenon is real. Js the hypnotic trance a valid phenomenon? For instance, a question is asked that indicates that failure to close the eyelids or failure to be able to open the eyelids is definitive of the light state of hypnosis. To use eyelid closure to define hypnotic states even in part seems to be as absurd as defining mobile life as the ability to move in a *northerly* direction, as if the direction were pertinent. The

minimum of experience in hypnosis discloses that hypnotized subjects can open or close, or keep closed, the eyelids, as is also the case in the waking state. Why then, in various books on hypnosis, in various experimental studies, is there such effort to define hypnosis in terms of the presence of absence of little bits of isolated behavior, not even necessarily related to hypnosis? There are whole classifications devised to show that in the light trance you find phenomena "A" and "B" and "C," that in the medium trance there occur "D," "E," and "F," and in the deep trance there develop phenomena "G," "H," and "I," as if that were absolute law, as if human behavior followed rigid sequences and rigid relationships.

There are people who try to define hypnosis in terms of sequences of behavior, of selected situations, or of the interpersonal relationship (as if a tall, blue-eyed subject and short, brown-eyed operator were important in effecting a special form of hypnosis). There are also efforts to define it in special descriptive terms to be applied to both operator and subject.

Hypnosis is also falsely defined in terms of the purposes to be achieved, as if you could have "medical" hypnosis and "dental" hypnosis and "psychological" hypnosis. This is on a par with describing anaesthesia in surgery as "right kidney anaesthesia," "left kidney anaesthesia" and "gastric resection anaesthesia. " Hypnosis should not be defined in terms of the operators and their interests nor in terms of special points of view. This statement is but introductory to another point of interest, and that is the discounting of hypnosis if certain phenomena are not consistently present. For example, it is dogmatically asserted that if catalepsy is not consistently present, hypnosis is to be doubted, that if posthypnotic phenomena are not consistently present, hypnosis is doubtful. In other words the assertion is too frequently made that there is good reason to doubt hypnosis unless all of certain arbitrarily chosen hypnotic phenomena are present. Comparably, it might be declared with equal credibility that since vision, hearing, and limbs are universally present in human beings, congenital absence of one or more of these would raise serious doubts in a "scientific" mind about identifying such a person as a human creature.

There is the tendency to test hypnotic phenomena with nonspecific tests to determine specific results, with consequent negative findings and hence false negative conclusions. For example, the testing of anaesthesia with a psychogalvanometer may prove the presence of tissue responses and of neural behavior, but this is not necessarily pain. Yet because the psychogalvanometer may show fluctuations, the conclusion may be reached that there is no hypnotic anaesthesia, that the subject is fabricating or simulating or role-playing. The obvious possibility that the psychogalvanometer may also indicate sensations and reactions other than pain can be easily overlooked. A painful stimulus is not necessarily a pure stimulus, and other responses than those occluded by anaesthesia may register. The mere devising of a test, however thoughtfully done, does not mean that it is applicable or meaningful. It too must first be subject to rigorous testing. For example, even questionnaires and other similar studies, based upon carefully sought opinions, do not serve to define hypnotic phenomena, however well they may summarize more or less informed opinions.

I know clinically that there is such a phenomenon as psychological anaesthesia. I recall the instance of a World War II combat veteran with an excellent war record who, while attending college, leaped downstairs, sprawled on the floor, picked himself up, and walked home. The next day his foot and ankle were so badly swollen that he had to wear a bedroom slipper to class. Sometime later, since the swelling continued unabated, he came into the Veterans Administration hospital, where I examined him. As he walked across the room, the sound of crepitus was definitely audible. The X-ray film showed extensive comminuted fractures of the bones of the ankle and foot. When so informed, the patient astonishedly remarked, "But I thought broken bones hurt!"

Medical examination showed an apparent profound loss of all sensations—tactile, pressure, warmth, cold, and vibration—for the entire lower leg up to within three inches of the level of the lower end of the patella. Above this level sensations were normal. Obviously the patient, who disclaimed any pain experience with his injured ankle, had developed, apparently at the moment of injury, a profound, uncontrolled, hysterical anaesthesia that was nevertheless physically clearly delineated. Just as this sort of manifestation can occur as a spontaneous development in a person with an excellent "normal" record, a comparable hypnotic phenomenon of equal effectiveness can be developed for scientific study. The simple fact that analogous conditions can develop both in everyday life and in hypnotic states should be ample warrant to accept those of the hypnotic state as sufficiently valid to justify scientific examination.

Hypnosis is a state of awareness, a very definite state of awareness with special types of awareness. Hypnotic subjects are not unconscious in any sense of the word. Rather they are exceedingly aware of a great number of things and yet able to be unaware of an equally great number of things. They can direct and redirect their attention in remarkable ways ordinarily not possible in the waking state but possible in the nighttime dream state, which is a form of cerebration. They can do the same sort of things that they do in the ordinary waking state, but often in a more intentional, controlled, and directed manner. For example, consider all the things that are being overlooked in your present state of conscious awareness. Have you forgotten the shoes on your feet, the collar around your neck, and the glasses on your face? Certainly you have, and you will forget them again and again, but not consciously upon request. You can be sitting with a newly-made friend whose name you know when suddenly another train of thought comes along, and you find that you have forgotten his name, an easy thing to do unintentionally in the waking state, but also easy to do upon simple request in the hypnotic state. Quite probably the same mental processes are involved. Much research is needed to define these manifestations.

There is also the problem of pain. Hypnosis has been used repeatedly and successfully to alleviate or even to abolish pain in severe chronic cases and with startlingly successful results in some cases of terminal painful malignant disease. The clinical reality of the pain relief is unquestioned, but the scientific understanding of what is done, and how, leaves much to be desired. The clinical demands of the situation require that every presumably efficacious suggestion be employed, while a "scientific" approach demands

that a "controlled and systematic" approach be used. However, the situation is one involving human life and suffering, and advancement of objective scientific knowledge is not the primary goal. This fact should not exclude from acceptance the finding that pain can be abolished or alleviated, nor should the results be dismissed as "simulation" or "role-playing," because "controlled study of individual items" was not done. The problem is this: Can the laboratory worker devise an experimental study or analysis that will permit an understanding of the validity of the clinical results achieved instead of dismissing the results as attributable to unknown and unknowable factors? The true task of scientific research is to adapt itself to existent problems, not just to form hypotheses for examination.

The pain of cancer is an experiential reality. Too often the uncritical assumption is made that pain is a pure and simple sensation and therefore should be so tested in the laboratory. As a clinician I find that patients use a wealth of adjectives to describe pain-burning, surging, cutting, throbbing, dull, heavy, stabbing—and therefore as a clinician I offer suggestions directed not only to the pain but to the presumed aspects or attributes of that pain. The assumption is that if an aspect of the pain can be altered, then the entire pain experience can be changed. Clinically this is so. The job of laboratory research is to discover what does happen rather than to discount the validity of the patient's experience. Then, too, pain is not simply an experience of immediate reality, but is something that is interpreted in terms of past experiences as well as future expectations. The clinician knows that the patient with a painful terminal disease suffers from the pain of the immediate moment, to which is added the memory of past pain and the anticipation of future pain. Hence the clinician using hypnosis for pain relief knows the importance of suggesting amnesia for the memory of past pain as a means of reducing current pain. Equally important are suggestion to prevent the anticipation of future pain.

How does one examine the "frames of reference" within which the patient views and experiences pain in the laboratory, where pain is regarded as the response of a specific type of nerve to a noxious stimulus? The clinician has to formulate a general approach, and the laboratory worker who wishes to contribute to an understanding of human behavior and experience in relation to pain needs to devise experimental procedures to measure these matters.

Additionally, while alleviation or abolition of pain, especially by drugs, are the traditional methods of treatment, the spontaneous, natural way of dealing with pain involves a multitude of behavioral reactions such as distraction of attention from the pain, amnesia, dissociation, displacement, the development of analgesia or of anaesthesia, and a reinterpretation of the sensations. Clinically, and through our own daily experience, we know many varieties of behaviors can occur. In the use of hypnosis clinically it is our obligation to be aware of these possibilities and to utilize them. In the scientific psychological laboratory the obligation is to study as a phenomenon the reinterpretation, let us say, of pain as a worthy scientific phenomenon in itself.

Hypnosis, by permitting the individual to call upon and utilize singly or collectively the great multitude of bodily learnings accumulated in a fragmentary fashion over the years, offers endless opportunity for the laboratory scientist to single out and examine individual manifestations. In this way hypnosis offers a means of reaching an eventual understanding of the processes entering into the development of various behavioral phenomena. This will not be achieved, however, if scientists formulate a hypothesis of what things should be and then look for those items that fit the hypothesis and discard those that do not, as is the case with those who say that hypnosis is role-playing and consider any contrary hypnotic phenomena as invalid, or those who say that hypnosis is a regressive phenomenon and ignore the great wealth of obviously nonregressive hypnotic phenomena.

Perhaps the most important thing to be said in the matter of hypnotic research is that there is a phenomenon of behavior and experience best termed in our present state of understanding as "hypnosis." Nothing is gained by saying that there is no such thing as hypnosis, that hypnosis is not hypnosis but merely something else; just as nothing was gained by the emphatic and long "proved" declarations that iron, being heavier than water, would sink in water and that machines heavier than air could not fly through the air.

One needs to assume that certain forms of behavior and experience which differ from ordinary conscious awareness can, with common consent, be called hypnosis. With this achieved, there can then be a systematic study of the various individual items of manifestation. This would be far more fruitful than formulating an all-comprehensive definition of a set of phenomena occurring in a human being, especially since these phenomena are little understood and manifested by a human personality infinitely less understood.

I wish to discuss two other matters pertaining to areas for research in hypnosis, both of which have been touched upon repeatedly more or less indirectly. Foremost is the matter of how one should scientifically study hypnosis. It is not sufficient just to devise careful tests, measures, and procedures, and then apply them to phenomena to secure results. That is but a beginning, a means of discovering if a test may be useful. The testing of the specific gravity of iron against the specific gravity of water yielded no informative results in the matter of shipbuilding until the shape of the piece of iron became an essential part of the inquiry. And so it is with hypnosis. What are the tenuous shapes, forms, variations, and seemingly abstract considerations that will make possible concrete realizations? The readiness to accept, not to discard, to examine, not to disparage, each item of behavior that seems related to hypnosis is most important. We need to take the attitude that there are things we do not know or understand, and because we do not understand them, we ought not attempt to offer comprehensive formulations of hypnosis as a total phenomenon, but rather endeavor to identify manifestations as such and examine their relation to each other.

Finally there is another area of vital importance for research both in the clinic and the laboratory. This is the matter of induction of hypnosis. Throughout the ages there has

been a dependence upon, and an adherence to, formalized, ritualized, traditional methods of trance induction, as if hypnosis were a phenomenon dependent upon the utterance of certain words in a certain order while the subject sits in a certain position and physically performs certain designated acts. Too often it is completely overlooked that hypnosis, like physiological sleep, is a process of behavior that can occur under a great variety of circumstances. Physiological sleep is likely to occur most easily when lying in bed, but it can occur in a lecture room, while driving a car, or when helplessly angry with another person. It is what actually occurs during physiological sleep that is important, not the externalities, even though externalities of all kinds can be significant. So it is with hypnosis. Induction procedures are of service, but the question remains, "What is it that does occur when hypnosis develops?" The induction procedure provides a setting, and only a setting, in which hypnosis may develop; it offers a period of time during which it develops; it offers various distractions to absorb the attention of the subject while hypnosis occurs; but the question is, "What is it that actually takes place within the subject while the operator busies himself with a ritualistic recitation of a learned formula of procedure?"

This is an area of research that is of tremendous importance in determining the scientific nature and character of hypnosis itself. However, all attempts to study hypnosis in relation to eye fixation or body relaxation are simply confusing; they are like attempting to study physiological sleep in terms of (1) a hospital bed, (2) a studio chair, etc.

Hypnosis itself, what processes occur within the subject, in what manner the body alters its usual functioning, and out of what experiential learnings of the past the body so learned to function, all constitute a part of the exceedingly rich field for research in hypnosis.

In brief, we need to look upon research in hypnosis not in terms of what we can think and devise and hypothesize, but in terms of what we can, by actual observation and notation, discover about the unique, varying, and fascinating kind of behavior that we can recognize as a state of awareness that can be directed and utilized in accord with inherent but unknown laws.

Experience of Interviewing in the Presence of Observers

Milton H. Erickson

Reprinted with permission from L. A. Gottschalk and A. H. Auerback, *Methods of Research in Psychotherapy*. New York: Appleton-Century-Crofts, 1966, pp. 61-63.

The experience of interviewing two psychiatric patients in the presence of observers and of attempting to induce hypnotic trances in them with the knowledge at the time that my efforts were being filmed for subsequent critical analysis by highly qualified persons constituted an interesting project for me. The primary consideration for me was the execution of the proposed task as adequately as possible. My own personal emotions were considered neither important nor relevant.

The emotional reactions of my patients, however, in relation to me, to the interview, to the hypnosis, to the surroundings, to the attendant circumstances, or deriving from their own psychiatric condition, were all considered to be a proper part of the proposed study. Therefore it would be a part of my responsibilities to be as aware as possible of the patients' various emotional states, to direct and to utilize them in such fashion that the patients' attention and interest would be directed to me rather than elsewhere.

The proposed experimental procedure definitely interested me. It offered an opportunity to deal with a patient in an entirely new kind of situation that could be recorded most effectively for future and for independent study. It was also a situation that the patient presumably could comprehend to a considerable extent and to which he could quite conceivably react in a variety of interesting ways. Also, the proposed procedure gave rise in my mind to recurrent, curious questions of what manner of affective, sympathetic, and empathic responses the observers, immediate and subsequent, would make which were comparable or related to those I would experience in the actual work situation with the patient. As it later developed, now and then when I experienced one or another reaction to my patient, there would recur, momentarily only and not as a distraction, the curious question of what, if anything, the observer could possibly sense of a comparable character.

My mental set in approaching the task was that of discovering what I could understand of the patient's behavior and what I could do about it or with it. The fact that I was under observation was of no concern to me, however primary that fact might be to the observers. My task was that of observing the patient and working with him, not speculating about the possible activities of others.

To begin, my first procedure was to make a visual and auditory survey of the interview situation. I wanted to know what my patient could see and hear and how a shift of his gaze or a change of his position would change the object content of his visual field. I was also interested in the various sounds, probable, possible, and inclusive of street noises,

that could intrude upon the situation. I inquired about the age, height, weight, and sex of my patient, and I tested various possible seating arrangements to check relative physical comfort, the possibilities of adequate recording, and the predominant content of the patient's general field of vision. I also inquired about any special accommodations to be made to meet the requirements of the recording apparatus. As a measure of more adequately understanding my patient's possible reactions to the observers, I made special inquiries about their positioning. Since one observer (Dr. G.) was there by special request, I felt he should be placed so that he would have the least possible effect upon the others present.

Upon the arrival of my patient I immediately became intensely absorbed in the task confronting me. Occasionally I would feel momentarily oppressed by a sense of having only a limited time, followed by a strong need not to let my patient sense that hurried feeling. Now and then I became aware that I had been so attentive to my patient that I had forgotten where I was, but I would comfortably and instantly reorient myself. On at least three occasions I became momentarily puzzled by a pair of glasses on the side of the room toward which I was facing. Each time I was astonished to discover them on a face and then to recognize the face as that of Dr. G.

Now and then I felt an urgent need to give some brief recognition to the immediate environment in some casual way so that my patient would not be given the impression of an intentional avoidance. One other intense emotional reaction on my part concerned the use of my cane at a moment when I moved it rather ostentatiously. My purpose was to force the patient to give his attention to the cane and thereby to effect a displacement of his hostility from me to the cane. As this was being done, the thought flashed into my mind that perhaps the observers would not understand the purposefulness of the maneuver. There was an immediate feeling of strong dismay that this irrelevant thinking might have altered adversely the manner in which the cane was being moved. This emotional concern vanished upon noting that the patient was responding adequately.

At the close of the first interview I felt no particular fatigue and I was as interested in seeing the next patient as I had been in seeing the first. At the close of the second interview I had an immediate sensation of great fatigue, physical and mental, but this passed promptly. It was followed by a distressing feeling that I might have worked my patients too hard, but this was replaced by a feeling that I had completed a much longer and much more difficult task than I had realized at the outset. I then felt highly pleased that an experimental approach with adequate recording was being made to the difficult subjective, intuitive, interpersonal relationship that exists in the clinical interview. As I completed this thought, a sudden wave of recollections surged through my mind. Throughout both interviews, as I noted each item of behavior, each fleeting change of expressions on my patients' faces, I had comforted myself by thinking, "But I can have a second look at that." This was later mentioned to Dr. G. in discussing the experimental project.

I consider this sound-film recording of a physician-patient interview to be a most valuable research procedure for investigating what constitutes an interpersonal

relationship. It offers an opportunity to secure a fixed and reliable record of the actual occurrences, both pertinent and incidental, that record being in no way itself subject to alterations by mood, memory, bias, or any other behavioral force. Furthermore this record is impartial in its treatment of both the interviewer and the interviewed, and there can be no weighting or shading of the evidence in the record itself. It also permits a sharp and informative contrast with data obtained from the same situation by trained observers, and it should reveal much concerning the nature and character of human error.

Of exceeding value is the sound-film in recording those qualitative variables of interpersonal communication such as facial expressions, gestures, intonations, inflections, mispronunciations, changes of tempo, and all the other minimal but effective modifications of speech that carry significant meanings. A sound-film is of particular value since it permits at any time a review, again and again, of any minimal manifestations, which is what I meant when, during the interviews, I comforted myself by the thought, "But I can have a second look." In the actual clinical situation responses are often made in minimal fashion and similarly sensed; often the entire process of communication is unconscious, and a sudden irruption into the conscious mind may complete a long process of unrecognized communication. Also of great significance is the fact that the sound-film permits the participant to discover many things which he did unwittingly, unconsciously, and even perhaps with no realization that he could manifest that manner or kind of behavior. I know that in the situation of dealing with patients I often wish I knew exactly what I was doing and why, instead of feeling, as I know I did with both patients, that I was acting blindly and intuitively to elicit an as yet undetermined response with which, whatever it was, I would deal.

In brief, this method of recording the interactions between selected people in a chosen setting offers a rich potential for understandings of extensive value for both therapist and patient.

HYPNOTIC INVESTIGATION OF PSYCHODYNAMIC PROCESSES

MILTON H. ERICKSON

The Collected Papers of Milton H. Erickson on Hypnosis

Volume III

Edited by ERNEST L. ROSSI

A Brief Survey of Hypnotism

Milton H. Erickson

Reprinted with permission from the *Medical Record* for December 5, 1934

HISTORICAL SKETCH

Hypnotism, or the artificially enhanced state of suggestibility resembling sleep, has been known for many centuries. In ancient days, however, there was neither understanding of it nor appreciation of its nature, and it was attributed to the powers of darkness and magic. It is well known that ancient conjurers, magicians, and fakirs, particularly among the Hindus, practiced various forms of hypnotism. Even in the present day Hindu fakirs are peculiarly adept in this procedure, as observers of their art will attest. The ancient magicians in the time of Genghis Khan also practiced group suggestion and hypnosis in order to obtain visual and auditory hallucinations, of which practices Marco Polo has given several somewhat unsatisfactory accounts.

The first practice of suggestion as a therapeutic measure, although it was not recognized as such at the time, began with Mesmer, whose period was from 1734 to 1815. Because of his development of the art the word *mesmerism* was adopted as a descriptive term. Mesmer's practice of suggestion therapy consisted in the use of "the natural qualities of animal magnetism" which could be induced to manifest themselves in people, trees, or any chosen object. In establishing his clinic Mesmer appears to have had an unusual appreciation of clinical psychology. He had beautifully decorated apartments, illuminated carefully with subdued lights, the rooms filled with the odor of incense, and the walls covered with velvet hangings. In addition, there were usually the gentle tinkle of running water and soft, faint music. His patients waited as a group in a large treatment room, which he would enter elaborately gowned. He administered therapy by gently stroking the arms and ailing parts of the patients, thereby "transferring" to them the healing qualities of "animal magnetism." Often, as would be expected, he achieved satisfactory and even startling results with patients who had been abandoned by orthodox physicians. During his career he discovered that the "quality" of "animal magnetism" could be transmitted to inanimate objects and that patients coming in contact with those articles would experience a cure of their ills. Critical observers at his clinic saw patients sent out to touch "magnetized" trees, thereby becoming healed. However, it was noticed that patients were cured even though they touched the wrong tree. Consequently the opinion developed that Mesmer was a charlatan and there was no realization of the psychological truths of this therapy. Despite the unfortunate reputation Mesmer received, many physicians visited his clinic and acquired valuable ideas and information.

The next great figure in hypnotism was John Elliotson. He was born in 1791, studied medicine at Edinburgh, and in 1817 was appointed assistant physician at St. Thomas' Hospital, where he aroused much antagonism because of his liberal and radical attitudes toward the practice of medicine. He was one of the first men in England to

approve of Laennec's stethoscope, thereby incurring great ridicule for having accepted the "silly fad." In 1837 he was appointed professor of the practice of medicine at the University College in recognition of his outstanding clinical ability. At about the same time he began his researches in hypnotism, or "mesmerism" as it was called. He practiced it on patients, received much condemnation for this, and in 1846 for this reason was made the victim of a bitter attack by the *Lancet*. Unfortunately, Elliotson believed in phrenology, clairvoyance, and odyllic forces with the consequence that his researches in hypnotism were placed in a similar category. Nevertheless, he had a wide practice and left a great many records of bona fide cures.

Elliotson was succeeded as the champion of "mesmerism" by James Esdaille (1808-1859), who began his work in India, stimulated in the study of hypnotism by reading Elliotson's reports. Under governmental protection he succeeded in the application of hypnotism to medical cases, and was instrumental in the founding of a hospital for this express purpose. Before he left India, he had utilized it in thousands of minor and in about 300 major operations. Records of these cases are still available to the scientifically curious. Despite the protection of the government, he was subjected to much persecution by his fellow-practitioners.

Following Esdaille came James Braid, an English surgeon who was born in 1795 but who did not take up the study of hypnotism until 1841. At that time he witnessed a "mesmeric trance" and was loud in his denunciation of the entire scene as a fraud. By chance he was induced to make a medical examination of the subject, following which he became intensely interested in the phenomenon and devoted himself to a thorough investigation of the manifestation. It was due to the researches of Braid that hypnosis was placed on a scientific basis, and his coining and application of the terms *hypnotism* and *hypnosis* to the phenomenon instead of the misnomer of *mesmerism* facilitated its acceptance by the medical profession. In the course of his investigations Braid reached the conclusion that hypnotism was wholly a matter of suggestion, which constituted the first attempt at a scientific and psychological explanation. He made a detailed study of the technique of hypnosis and the various phenomena obtained in trances. He was a prolific writer and left extensive treatises which are surprisingly modern in their conceptions. Since Braid, various other well-known clinicians have been interested in the subjects, particularly Charcot, Li6bault, Bernheim, and Heidenhain. More recent scientific leaders who studied hypnosis are G. Stanley Hall, William James, Morton Prince, Sir William Crookes, and Pierre Janet.

METHODS OF HYPNOTIC TRANCE INDUCTION

The methods employed in inducing hypnotic trances vary widely among hypnotists. A good operator varies the details of his technique from subject to subject, fitting it to the peculiarities of each personality. Mesmer's method was to put his hands upon the shoulders of the patient and then to stroke the arms downward to the fingers. In addition, he made various passes and gentle, soothing contacts with his hand over forehead and the part to be healed. Esdaille usually put his subjects in a darkened room and told them to sleep, and thin made passes without contact over the entire body. Braid customarily had

his subjects look at some bright object and instructed them to relax and to fall asleep. Later he modified his technique to that of the direct verbal method in which repeated suggestions of fatigue and sleep were given. As a result of the present-day scientific understanding of the phenomenon, the direct verbal suggestion technique has become the more common. Drugs also may be utilized to produce hypnotic states, but the results are unsatisfactory since the narcotic effects frequently interfere with trance manifestations. Drugs which may be used are paraldehyde, barbital compounds, and amytal.

Usually the best method of inducing a trance consists in placing the subjects in a relaxed and comfortable position, giving them at the time a few brief explanations in order to relieve any misapprehensions and at the same time afford them some idea of what is about to happen. Then, suggestions are given in a carefully graduated form to the effect that they are getting tired and more tired, that they are getting sleepy and more sleepy, and that they will gradually go into a light sleep and thence into a deeper and deeper sleep. The period of time required varies with every subject, some taking less than one minute to go into the deep sleep for the first time and others requiring hours of effort. Once the subject is asleep the same manner of technique is utilized to elicit any of the characteristic manifestations of the trance state. Repeated suggestions to the effect desired are given until the subject responds. The trance is usually terminated by the request to awaken, but occasionally it becomes necessary to arouse subjects slowly by suggesting wakefulness in the same manner that sleep was suggested.

EXPLANATORY ASPECTS

There are a number of questions concerning hypnosis that must be mentioned since they arise at every discussion of the topic. In the first place many ask, “Is it harmful?” A study of the scientific literature reveals no good evidence of harm inflicted, or any very logical theoretical possibility of injury other than that which might accrue from ordinary personal contact in the waking state (Erickson, 1932).

Nevertheless, many unscientific writers, some of whom frankly confess their inexperience with hypnosis, are emphatic in their denunciation of it, basing their attacks upon medieval conceptions of the phenomenon. Earnest, thoroughgoing students, however, seriously question the possibility of harm. In the author’s experience, in which some of his subjects have been hypnotized from 300 to 500 times each over a period of years, no harmful effects have been noted. Nevertheless, hypnotism is not a matter for superficiality and carelessness, but should be utilized only by capable and trained workers even as are other complex and difficult techniques.

The second question is, “What would happen if you could not awaken the subject?” The experience of capable investigators who have questioned this possibility, as well as the author’s, indicates that such a likelihood could not occur. It is possible, and occasionally happens, that subjects are so comfortable in the hypnotic sleep that they are unwilling to awaken, but if the operator allows a subject to sleep despite commands to awaken, it would indicate merely his ignorance of proper hypnotic technique. Subjects can always be awakened by a series of suggestions paralleling those which put them to sleep.

Further, even if the subjects did continue to sleep, as soon as they were left alone the hypnotic sleep would spontaneously change into a natural sleep—an important though little appreciated fact. This is also true for sleep states induced by posthypnotic suggestion. As for the question of what would happen if the hypnotist suddenly died or left the subject in a deep trance, there would occur one of two possible things. Either the trance sleep would lapse into a natural sleep or the subject, becoming aware of the absence of the hypnotist and sensing the loss of contact with him, would awaken spontaneously to ascertain the nature of the situation. Essentially, hypnosis is a relationship between two people, and when one of them is removed from the situation, the phenomenon then ceases because there can no longer be the cooperation necessary between the two.

But there is another and indirect implication of these questions which deserves an answer. This is the assumption that the sudden and absolute removal of the hypnotist or his unwillingness to awaken the subject would wreak irreparable harm. This idea is a continuance of the ancient superstitition of "strong mind/weak will" arising from the mistaken idea that hypnotism in some subtle, occult fashion altered the very being of the subject, thereby giving the hypnotist unlimited power and control over the entranced person. This power had then to be relinquished formally and personally or otherwise the subject would be psychically crippled. Fortunately, the light of present-day psychological knowledge as well as experimental findings exposes the absurdity of such ideas.

Another problem which arises is the question of whether or not an unscrupulous hypnotist could make use of the art for malicious and criminal purposes. Briefly, the answer obtained by careful and thorough investigators is negative. Suggestions leading to antisocial acts or even to mere improprieties are rejected, and if pressed upon them, the subjects will invariably awaken with a disturbed and uneasy feeling and usually become uncooperative regarding further hypnosis. In unusually cooperative subjects when this is attempted there will be a seeming compliance with the suggestion but it will be executed in such a fashion as to defeat its purpose. The subject instructed to stab the first comer will pick up a strip of rubber or some such harmless object and simulate the act. If given a real dagger, the stabbing will be done slowly and carefully in empty space or else not at all. Authentic reports to this effect are given in the literature. In the author's experimentation his siblings were used as subjects, since there was a possibility that the relationship offered greater opportunities for positive findings and at the same time would enhance the value of negative ones. The results of repeated attempts to induce them to commit various improprieties can be summed up best in the uneasy and worried remark of one sister in the trance state, who said in her effort to explain her utter unwillingness to do as asked, "Well, if you want me to do that, you can wake me up and let me do it while I'm awake." The same and additional experiments were repeated on friends and acquaintances, all with negative results. Schilder and Kauders (1927), after extensive experience, have declared that hypnotism is a dubious aid for antisocial purposes.

The author's own experience indicates that the loss of environmental orientation in trance states constitutes an actual obstacle to the misuse of the art.

Also in this regard there should not be an oversight of the significance of the actual social contact of two personalities in the hypnotic situation. With this in mind there is the realization that harmful results may be attributed more properly to such social contact rather than to the hypnosis per se. Further, when it is considered that the hypnotist must implant his suggestions in the vast aggregate of mental reactions and patterns accumulated throughout the subject's lifetime, the great difficulty of causing extensive changes and alteration of behavior and personality reactions is apparent. Indeed, what marvels of mental catharsis and psychotherapy could be achieved were it possible to establish significant and meaningful alterations of personality reactions by a few suggestions given in a time-limited situation.

A fourth question is, "What is hypnotism? Some mystic occult magical thing based upon the overwhelming influence of a strong personality upon a weak will and accompanied by the emanation of a secret power?" Actually, of course, it is not this. On the contrary, it is a psychological phenomenon as little understood as most psychological phenomena. It requires no unusual personality or strong will on the part of the hypnotist or weak will or feeble intellect on the part of the subject. Any person willing to learn the psychological principles involved can perform hypnosis. It is purely a matter of technique, a technique of convincing and persuasive suggestion similar to that utilized every day in ordinary commercial life for quite other purposes. Just as anyone may be a hypnotist, so may anyone be a subject, whether man or woman, old or young, excluding only the extremes of age and those of too pronounced mental abnormality. The best subjects are the highly intelligent, highly sensitive people with good control of their mental faculties, while those of lesser endowments are more difficult and less satisfactory to work with and are limited in their performance.

What hypnosis actually is can be explained as yet only in descriptive terms. Thus it may be defined as an artificially enhanced state of suggestibility resembling sleep wherein there appears to be a normal, time-limited, and stimulus-limited dissociation of the "conscious" from the "subconscious" elements of the psyche. This dissociation is manifested by a quiescence of the "consciousness" simulating normal sleep and a delegation of the subjective control of the individual functions, ordinarily conscious, to the "subconsciousness." But any understanding of hypnosis beyond the descriptive phase is purely speculative.

THE PHENOMENA OF HYPNOTISM

The phenomena of hypnotism vary in degree and variety with every subject, depending, of course, upon the innate endowments of the person. Furthermore, all phenomena do not necessarily occur in every subject, but manifest themselves only as a rule, some subjects failing to show this or that particular characteristic.

First of all, hypnosis is a result of cooperation. Without full cooperation between the subject and hypnotist there can be no hypnotism. Unwillingness to be hypnotized, admitted or concealed, signifies the failure of the essential cooperation, and consequently a trance does not and cannot occur. This necessity for cooperation constitutes a further

indication of the improbability of inflicting harm upon the subject and also exposes the fallacy of the belief that one can be hypnotized surreptitiously.

As the subject goes into a hypnotic sleep, the field of consciousness narrows and external stimuli, except those given by the hypnotist, lose their significance. Ultimately the subject loses contact with the external world except for the operator. Essentially, the "consciousness" is in a state of sleep, while the "subconsciousness" is left in control and in rapport with the hypnotist. This rapport, which constitutes a fixed phenomenon of hypnotic trances, may be defined as a state of harmony between the subject and hypnotist, with a dependence of the former upon the latter for motivating and guiding stimuli, and is somewhat similar to the "transference" of the psychoanalytic situation. It enables the hypnotist to remain in full contact with the subject while to the rest of the world the hypnotized person remains an unresponsive object. This rapport may be transferred by the command of the operator to any designated person, and subjects who distrust the hypnotic state but permit hypnosis may spontaneously retain rapport with anybody they wish as they go into the trance.

Another phenomenon is the marked suggestibility occurring in the trance. Any suggestion not objectionable to the subject will be accepted and acted upon. Thus he will become paralyzed, anaesthetic, deaf, blind, hallucinated in all spheres, accept as the truth any variety of suggestions, and act upon them provided they are not objectionable. If they are offensive, there is a failure of cooperation and the suggestions are without effect.

A fourth phenomenon which characteristically appears without direct suggestion is catalepsy, which resembles cerea flexibilitas. In this state the subject's arm may be lifted and it will remain fixed in any position. The subject appears to be unable to move the arm, nor does he seem to experience any sense of fatigue. Some experimental work done in this regard suggests that there is a definite lessening of the sense of fatigue, permitting the performance of work actually past the point of normal capacity (Williams, 1929; Nicholson, 1920).

A fifth feature of the trance is that of posthypnotic suggestion. While in the trance state subjects may be given a suggestion to be performed or acted upon at a designated time after awakening, and they spontaneously—as they think—respond in the designated fashion with no realization of why they do so. In this phenomenon lies the greatest therapeutic advantage of hypnosis, since thereby the subjects can be given suggestions to guide their later conduct.

A sixth characteristic of hypnosis is amnesia. The subject's recollection of events occurring during the trance is approximately inversely proportional to its depth. One who has been in a profound trance has a complete amnesia for all events, suggestions, and experiences occurring therein, even though he has walked down the street, talked to friends, and eaten a meal. However, this amnesia may not remain total, since the subject may at a later date recall everything spontaneously as if in a dream. But for practical purposes there is essentially an actual amnesia.

Still other manifestations, similar in nature, are automatic writing and crystal-gazing. The activity involved in these is perhaps one of the best "proofs" of the existence of a "subconscious mind." They afford a wide avenue of approach to experimental studies and to therapeutic and exploratory measures.

Finally, there can be induced in trances by means of posthypnotic suggestions a state of somnambulism wherein the subjects appear to be normally awake. They may perform all the routine duties of daily life or successfully cope with any chosen situation, but they do so in a trance state and upon awakening have no recollection of any events which occurred. In appearance and nature this somnambulistic state is an experimental equivalent to the states of dissociation in dual personalities met in psychiatric practice. It differs only in being benign, time-limited, and wholly dependent upon definite suggestions from the hypnotist.

APPLICATION OF HYPNOTISM

Hypnosis has a definite value in the practice of medicine, which was shown very early in its history, and as medical men acquire a better understanding of psychology, its value will probably increase. In general practice the technique can be utilized to quiet and reassure the patient and to establish that desirable state of rapport between physician and patient connoted by "the bedside manner." In Europe, particularly in Germany and France, it has been used to some extent as a direct surgical aid in both major and minor procedures. In certain patients it can be used as a substitute for drugs in producing anaesthesia, and since the time of Esdaille it has been used repeatedly for this purpose. It has the advantage over anaesthetics of affording the patient peace of mind, a sense of security and confidence, and it has no afteraffects. However, even at the present day its application in the field of surgery should be limited properly to the minor field until the general medical practitioner as well as the laity have a better understanding of psychological manifestations. It has also been used successfully in obstetrics and undoubtedly would be used much more if there were not such a misapprehensive, fearful attitude toward it. A primary objection to its use by the medical man, remediable by proper study of the practice, is the difficulty experienced in inducing and maintaining trances. No hypnotists know for a certainty whether or not they are going to succeed with a particular subject at a given time or whether their technique for the occasion will be sufficient for the maintenance of the trance. But this is more fortunate than otherwise, since the therapeutic and medical application of hypnosis should not be taken lightly or left in the hands of the dilettante.

In the field of psychological medicine, however, hypnosis offers a unique approach to many mental problems and difficulties. Its value lies in the fact that it allows the physician to approach directly the subconsciousness of the person with its disturbing conflicts. It often serves as a gateway through his resistances and allows indirect approaches to many difficulties which otherwise could not be attacked. Further, induced states of dissociation can be established, exploratory measures developed, and vital information obtained which otherwise would be inaccessible both to the patient and to the therapist. Also of paramount importance is the fact that the hypnotized patient is in a

receptive state for psychotherapy. The difficulty involved in getting patients to accept therapeutic suggestions directly constitutes the greatest obstacle in psychotherapy. Hypnosis renders the person receptive. Indeed, as has been mentioned before, it is a state of enhanced suggestibility. Consequently, by means of hypnotism it is possible to implant therapeutic ideas upon the "subconsciousness" and to have them take effect when endless numbers of suggestions given in the waking state would be given no heed or even actively resisted. Thus the patient accepts hypnotic suggestions and acts upon them without conscious awareness and without building defense reactions. In so doing he allows them to become a valid part of his mental patterns, all the more so since fundamentally, if not immediately, he does desire aid against his conflicts. By this means patients can be given new mental equipment wherewith to deal with their difficulties, a new equipment which does not have to pass the protective scrutiny of their "consciousness." At the same time dissociated experiences and amnesic material are rendered available for reassociation and reorganization. Nevertheless, hypnosis is not to be looked upon as panacea nor is it to be discarded because it has definite limitations. On the contrary, it is a valuable addition to the medical armamentarium, most particularly to that of the psychiatrist.

Perhaps the most fertile and productive application of hypnotism is in the sphere of experimental psychology. More and more laboratories are becoming interested in the peculiar and significant problems which hypnosis renders available for study. This rapidly increasing interest in experimental hypnotism both in this country and abroad may be taken as an indication of a growing realization of the fruitfulness of hypnosis as a field of scientific research. It constitutes almost a virginal territory for psychological investigations, and it appears to offer a good approach to an understanding of many mental mechanisms which have hitherto defied comprehension.

Hypnosis: A General Review

Milton H. Erickson

Reprinted with permission from *Diseases of the Nervous System*, January, 1941, Vol. II, No. 1.

The history of hypnosis is as old as that of the human race. The most primitive of savages, both ancient and modern, were aware of this striking psychological manifestation, and it was utilized in the mystic rites of their medicine men to produce fear and to intensify belief in the supernatural and the occult. With this long historical past of supernaturalism and mysticism, coupled with its own startling, inexplicable, and bewildering phenomenology, it is not astonishing that the general public's attitude toward hypnosis has been and still is one of misunderstanding, antagonism, and actual fear, and that the first development of any scientific interest did not occur until the last half of the 18th century.

These first scientific beginnings in the study of hypnosis began with Anton Mesmer about 1775, from whose name has derived the term mesmerism still in current usage. Mesmer's use of hypnosis began with his discovery that selected types of medical patients responded satisfactorily to a stroking of their arms and ailing parts and suggestions of sleep. Mesmer attributed these therapeutic results to the transferring to the patients of a "quality" of "animal magnetism," and he developed the theory that animal magnetism was some peculiar cosmic fluid with healing properties. Despite Mesmer's excellent intuitive knowledge of clinical psychology, as evidenced by his elaborate clinic in which he employed colored lights, incense, music, and rich draperies to impress his patients and establish in them a receptive state of mind, he had no realization of the psychological nature of his therapy. Nevertheless, he treated successfully large numbers of patients on whom orthodox medical procedures had failed, but unfortunately his personality and the mystical character of his therapy served finally to bring him unjustly into disrepute. However, many physicians had visited his clinic during the height of its success and had learned unwittingly one of the first lessons in the then unknown art of psychotherapy—specifically, the importance of clinical psychology.

Since Mesmer there has been a succession of outstanding men who became interested in hypnosis and utilized it successfully in medical practice, giving it an increasingly more scientific foundation and validity. Elliotson, the first man in England to use the stethoscope, became interested in hypnosis about 1817, employed it extensively, and left excellent records of its therapeutic efficacy in selected cases. Esdaille, stimulated by Elliotson's case reports, became an ardent advocate of mesmerism, as it was then called, and actually succeeded in interesting the British government in building a hospital in India, where he used it extensively on all types of medical patients, leaving many excellent records of major and minor surgery performed under hypnotic anesthesia.

The initiation of a psychological understanding of the phenomenon began in 1841 with James Braid, at first an opponent and then later a most ardent investigator and supporter. It was he who invented the term *hypnosis*, recognized the psychological nature of hypnotic sleep, and described many of its manifestations, devising methods whereby to test their validity.

Since Braid there has been a constantly increasing number of clinicians first and psychologists later, among them many outstanding scientists, who have contributed greatly to an establishment of its scientific validity and opened it as a field of scientific investigation and therapeutic endeavor. The result now is that during the past 20 years there has been a progressively rapid increase in the amount of attention given to hypnosis as a problem of significant scientific interest by the medical profession, particularly psychiatrists, and by psychologists in university laboratories.

Unfortunately, particularly among the psychologists, there is still a tendency to develop research along the outmoded concepts and techniques of the 19th century. Thus, in a recent paper by a psychologist, the statement was made that the experimental technique was based entirely on Braid's original methods, and in another paper the declaration was that Forel's technique and criteria of fifty years ago had been used implicitly.
Thus, while interest in hypnosis as a scientific problem has advanced, it is still in its infancy and needs development in terms of present-day understandings and concepts of personality and interpersonal relationships.

General questions always arising when hypnosis is mentioned concern its possible detrimental effects upon the hypnotic subject, the possible antisocial use of hypnosis, the character of the relationship between the hypnotist and the subject, the controllability of the hypnotic state, and the relationship of hypnotic sleep to physiological sleep.

To all of these questions one may make a comprehensive reply by stating simply that the hypnotic state is essentially a psychological phenomenon, unrelated to physiological sleep, and dependent entirely upon full cooperation between hypnotist and subject; neither is it injurious or detrimental to the subject in any way, nor can it be used for antisocial or criminal purposes. Each of these statements is based upon extensive, carefully controlled experimental investigations too numerous to cite, and conducted by many investigators. References, however, will be listed at the conclusion of this paper.

The general mistaken belief is that hypnotists exercise some remarkable power over their subjects, that hypnosis is a matter of dominance and subservience, of strong mind over weak will, and that hence all manner of undesirable results may obtain. Actually, of course, hypnosis depends upon full cooperation between hypnotist and subject, and without willing cooperation there can be no hypnosis. Furthermore, the hypnotic subject can be both hypnotist and subject, and more than one hypnotist has been hypnotized in turn by his own subjects to further the development of experimental work. Because of the absolute need for cooperation, subjects cannot be hypnotized against their will or without their knowledge, nor can subjects be kept in a trance without their cooperation. Nor can cooperative subjects be left in a trance an unreasonable length of time without their full

understanding and cooperation. In brief, hypnosis and every use made of the trance state necessarily depends upon full and ready cooperation with adequate and direct understanding on the part of the subject of what is desired.

Another fact of importance is that there can occur no detrimental effects from repeated trances, even over a period of years. This fact has been confirmed by the experience of hypnotists who have been interested in this possibility and by the experience of subjects who have been hypnotized hundreds and even thousands of times. In addition, when one considers the difficulty in producing wanted therapeutic changes in the personality by hypnosis, the possibility of effecting unwanted changes becomes remote and most unlikely.

The best hypnotic subjects are normal people of superior intelligence, and any really cooperative person can be hypnotized. Maladjusted, hysterical, feebleminded, or psychotic persons are usually difficult to hypnotize, although there are many exceptions. For this reason hypnosis as a therapeutic measure is often difficult to apply despite full cooperation.

Concerning the technique of the induction of hypnotic trances, this is a relatively simple matter requiring primarily time, patience, and careful attention to and consideration for the subjects, their personalities, and their emotional attitudes and reactions. Properly, there is no set form or pattern to follow, just as there is no set form for a good bedside manner. One needs the respect, confidence, and trust of a subject, and then one suggests fatigue, a desire for sleep and rest, an increasing feeling of sleep, and finally a deep sound restful sleep. These suggestions are given repetitiously, with gradual progression from one to the next, always with careful reassurance of the subjects as they make response to them. The making of passes, the use of crystal balls, the staring into the subject's eyes, and various other mystical procedures belong to vaudeville or ancient history. One simply, persuasively, and patiently suggests sleep of a restful character until the subject does sleep, and then the subject is instructed to remain asleep until all reasonable purposes are accomplished. There should be no forcing or rushing of subjects, and every effort should be made to enable the subjects to appreciate any physical feeling they have suggestive of sleep. This simple technique can be learned by anyone, and anybody who has been hypnotized can employ it to hypnotize others, given cooperation and the patience to make use of it. As for awakening the subject, one can suggest an arousal directly, or give the subject suggestions to the effect that he is slowly and progressively awakening, repeating these suggestions until the subject is fully awake.

Once the trance state has been induced, there will become manifest various general phenomena characteristic of hypnosis, though not all are necessarily manifested by each individual subject. Foremost is the condition termed *rapport*, in which the hypnotic subjects respond only to the hypnotist. In the deep trance they are seemingly incapable of hearing or seeing anything unless so instructed by the hypnotist. However, this rapport may be transferred to others by appropriate suggestions by the hypnotist.

A second phenomenon is *catalepsy*. As a result of the hypnosis, there develops in the subjects an increase in muscular tonus so that there seems to be the same condition as exists in the stuporous catatonic patient manifesting flexibilitas cerea. Thus, the subject's hand, raised up in the air by the hypnotist, is held in that position apparently without fatigue until the hypnotist either puts it down or instructs the subject to lower it.

Amnesia constitutes another phenomenon of interest. Particularly after a deep trance the subject tends to have a profound amnesia for everything that occurred in the trance situation. This amnesia is subject to control, since the hypnotist can suggest the recovery of the memory of some or all items of the trance experience, or the subject may deliberately set himself the task of remembering everything. This phenomenon is most inconstant and uncertain, depends upon many individualistic and situational factors. In an experimental procedure the amnesia can be demonstrated to be as resistant to all nonhypnotic forces and as profound as amnesias developing pathologically.

Suggestibility is, of course, a primary feature of hypnosis, and is necessarily present. However, there is always a need, if serious and satisfactory purposes are to be achieved, to give suggestions in accord with the subject's understandings and desires, although in the type of hypnosis practiced on the vaudeville stage, ridiculous and undignified suggestions can be given. In the experimental psychological laboratory any number of behavioral responses can be suggested and subjected to study, such as suggestions of amnesia, recovery of memories, hallucinations, delusions, anesthesias, deafness, blindness, identifications, disorientation, etc. In the medical situation suggestions relating to the problem in hand can be given, such as the suggestion to recall a forgotten troublesome traumatic life experience, or the suggestion to avoid or to meet adequately some difficult problem.

However, regardless of the suggestibility of the subject, there is frequently a primary need to give suggestions indirectly rather than directly and dogmatically as if hypnotic suggestions were miraculous in effect.

Another common phenomenon is the capacity for visual hallucinations often described as "crystal-gazing." Essentially, this is the result of suggestions to the effect that the subject visualize various scenes and memories. This phenomenon is of great significance in investigative and experimental work upon legitimate psychological and medical problems. The ability, called forth by hypnotic suggestion, to reconstruct a visual image of a past and even forgotten experience is often of great service in psychological research and in psychotherapeutic procedures.

Automatic writing, long known but mystically regarded, is often easily elicited in the hypnotic state. It is essentially the act of writing without any awareness of the fact. Such writing is comparable in its processes to the unwitting mouthing and chewing the absorbed mother does when she spoon-feeds her baby. This automatic writing can be elicited without hypnosis, during hypnosis, and after hypnosis, and the context of the writing represents usually material of which the subjects are not consciously aware and which they often reject as not theirs, or as meaningless to them. In the psychological

laboratory or in the psychotherapeutic situation such automatic writing is of great value in the study or analysis of behavior and in the eliciting of important but otherwise unavailable information.

Posthypnotic suggestion, or the giving of suggestions to the hypnotized subjects to be acted upon at some later time when they are awake, constitutes another most interesting phenomenon. By this measure the hypnotic subject's behavior can be directed and controlled subsequent to the trance state, but only to a reasonable and acceptable degree. Thus the subjects may be told to perform a certain act at a given time in the future, and at that time they do as instructed, usually without awareness that they are doing so, or, if they are aware of their conduct, without any understanding of why they are so doing. Rather they think they are acting spontaneously since there is an amnesia for the posthypnotic instructions. In this way effective therapeutic suggestions can often be given.

The scientific applications of hypnosis are as yet only in the developmental stage. The persistence of unsound mystical beliefs and mistaken fears about hypnosis, now fortunately being discarded rapidly, have hampered and delayed its scientific growth. Also, much of the serious study made of hypnotic phenomena has been based upon concepts of hypnosis developed long before present-day understandings of dynamic psychology and psychiatry. Furthermore, many of the efforts made to study hypnosis scientifically in psychological laboratories have omitted all clinical personality considerations relating to the hypnotic subject as a person and have attempted unfortunately to deal with hypnotic manifestations as didactic academic items unconnected with a human personality. With the present rapid increase of recognition by psychologists of dynamic and personality factors and forces, there is developing a new and more fruitful trend in the study of hypnotic behavior, and the psychologists are now beginning to discard the old belief that hypnosis transforms a person into some strange, passive, dominated new creature. Instead they are beginning to realize that hypnosis can be used and should be used to elicit the natural and innate behavior and reactions of the subject, and that through such a measure human behavior can be studied in a controlled scientific manner.

Primarily, the greatest field of application for hypnosis is in the study and analysis of human behavior and disturbances in behavior. By means of the hypnotic trance it becomes possible to suggest to the subject any chosen form of behavior and response and thereby have literally a laboratory in which to synthesize and analyze any desired pattern of behavior. For example, the problem of amnesia can be treated as a laboratory investigation by creating, removing, and reestablishing an amnesia and slowly and systematically studying the psychological processes and mechanisms involved in such mental processes. Similarly, one can through hypnosis duplicate in a subject the symptomatic manifestations of personality disturbances and emotional stresses and have an opportunity to study such problems in laboratory form in a manner similar to the laboratory study of medical problems and procedures before application is made to an actual patient. Instead of speculating vaguely and attempting to deduce uncertainly the consequences of a patient's complexes and conflicts, necessarily of unknown character,

one can build up in a hypnotic subject a complex or conflict of known character and then have the direct opportunity of studying its results and consequences upon the subject with a view to determining the psychological sequences and interrelationships of the various manifestations and their significances to the personality.

The usefulness of hypnosis to medicine lies in two fields of application, that of research and that of psychotherapy. In relation to both fields its usefulness relates primarily to behavior problems, emotional disturbances, minor forms of psychopathology, and the neurotic or psychoneurotic illnesses which confront the general practitioner on every hand. However, its applications are greatly restricted, aside from the need for special laboratory situations for research and selected types of patients for psychotherapy, by the general public's misapprehensions concerning hypnosis, the irrational fears entertained about it, and the primary need for unlimited time and effort if effective results are to be obtained. Too often, in both fields of application, unsatisfactory results are obtained because of the tendency to regard hypnosis as a miracle producer and to substitute dogmatic emphatic hypnotic suggestion for a laborious, time-taking, systematic procedure of experimental investigation or of psycho-therapeutic reeducation. It is not a miracle worker, even though its results sometimes seem to be miraculous. Rather, it is an effective measure by which one can slowly, carefully, and thoroughly elicit, as a result of careful suggestions, forms of behavior, emotional reactions, insights, and understandings which would be impossible or nearly so in the ordinary waking state in which the subject's attention to a chosen field cannot be so completely secured and rigidly fixed as it can be in hypnosis.

Unfortunately for the development of adequate research in medical applications of hypnosis, most of such investigators are psychologists untrained in clinical medical and psychiatric aspects of personality disorders. However, as psychologists become increasingly aware of the personality implications of hypnotic research, such problems as amnesia will cease to be studied entirely in terms of statistical evaluations of nonsense syllables learned and forgotten and approached more frequently in terms dynamic behavior reactions peculiar to the personality of the hypnotic subject, who in turn will be recognized as a human being and not treated, as is the tendency of psychologists today, as a passively responsive laboratory instrument.

As for direct psychotherapeutic use of hypnosis, aside from the problems imposed by public mistrust and the need to select suitable patients, there is also the problem of avoiding the too common errors in psychotherapy of forcing the suggestions upon the subject. Rather than hypnotically treating patients suffering from a phobia for doorknobs by telling them in the trance to forget their phobia, to overcome it, to realize its foolishness, one tries instead by hypnosis to elicit indirectly and adequately the story of the genesis of that phobia and to build up in these patients anew their own forgotten and repressed pattern of normal behavior toward doorknobs. One does not try to force upon the patient a new pattern of normal doorknob behavior, but rather to reestablish the old, unused, and forgotten pattern of behavior the patient had previous to the development of his phobia. One may temporarily relieve symptoms, but medicine is interested in a cure

by complete removal and not in symptomatic relief. But such methods are slow and laborious, hence only those wishing to spend adequate time and effort should try them.

Recent clinical work (Bass, 1931; Beck, 1936; Bramwell, 1921; Brickner & Kubie, 1936; Erickson, 1932, 1933, 1934, 1935, 1937a, 1937b, 1938, 1939a, 1939b, 1939c; Erickson & Erickson, 1938; Erickson & Kubie, 1930, 1939; Huston et al, 1934; Luria, 1932; Platonov, 1933; Schilder & Kauders, 1927) has shown the possibilities and fruitfulness of hypnosis in approaching the problems of personality disturbances and psychoneurotic illnesses, and it is this field of medicine in which hypnosis can contribute greatly—and unquestionably will—as increasingly adequate recognition is given to the value of hypnosis.

Hypnotism

Milton H. Erickson

"Hypnotism" and "hypnosis" are the terms applied to a unique, complex form of unusual but normal behavior which can probably be induced in every normal person under suitable conditions and also in persons suffering from many types of abnormality. It is primarily a special psychological state with certain physiological attributes, resembling sleep only superficially, and characterized by a functioning of the individual at a level of awareness other than the ordinary state, a level of awareness termed, for convenience in conceptualization, unconscious or subconscious awareness.

When hypnotized, or in the hypnotic trance, the subject can think, act, and behave as adequately as, and often better than, he can in the ordinary state of psychological awareness, quite possibly because of the intensity of his attention to his task and his freedom from distraction.

He is not, as is commonly believed, without willpower or under the will of the hypnotist. Instead, the relationship between the hypnotist and subject is one of interpersonal cooperation, based upon mutually acceptable and reasonable considerations. Hence, the subject cannot be forced to do things against his will, but rather he can be aided in achieving desired goals. However, frequent failures in hypnotic therapy of patients disclose limitations of hypnosis in accomplishing even desired goals, and the more extensive and reliably controlled experimental studies discredit the possibility of utilizing hypnosis for antisocial purposes.

The history of hypnosis is as ancient as that of sorcery, magic and medicine, of the armamentarium of which practices it formed a part. Its scientific history began in the latter part of the 18th century with Franz A. Mesmer, a Viennese physician who used it in the treatment of psychiatric patients. However, because of his mistaken belief that it was an occult force, which he termed "animal magnetism," that flowed through the hypnotist to the subject, he was soon discredited; but mesmerism, as it was named after him, continued to interest medical men. Extensive use was made of it by outstanding clinicians without any real recognition of its nature until the middle of the 19th century, when James Braid, an English physician, became interested, recognized its psychological nature, studied its phenomena, and coined the terms *hypnotism* and *hypnosis* to name it. Thereafter many scientifically trained men worked on the problem, but only after World War I was much significant progress made. World War II gave added impetus to the study of hypnosis, greatly extended its recognition and use, and freed it from many of the superstitions, fears, and taboos that had hampered its scientific acceptance and investigation. However, because of its inexplicable character and the fascinating, startling

nature of its phenomena, it remained subject to exploitation by charlatans and misconceptions by well-intentioned but insufficiently trained and experienced experimenters.

HYPNOTIC TECHNIQUE

Popular beliefs still ascribe much superstitious significance to ritualistic magical devices such as stroking of the body, the use of "hypnotic crystals," the "eagle eye," and "willpower." Actually the important consideration in inducing hypnosis is a willing, cooperative, relaxed subject to whom a trusted hypnotist can persuasively and repetitiously suggest that he will become tired and sleepy, that his eyes will close, that he will lose progressively his interest in external events and become more and more completely absorbed in a feeling of being in a state of sleep in which he can function at a level of unconscious awareness. The length of time required to induce a trance differs greatly with subjects, and the time spent should be in reasonable accord with the importance of the hypnotic work. Thus, for an exhibitionistically inclined subject on the vaudeville stage, a few minutes may suffice, while hours might be required for a scientifically oriented study or for hypnotic therapy.

Another essential consideration in the technique of investigative or therapeutic work is the utilization of the subject's own patterns of response and capacities rather than an attempt to force upon the subject by suggestion the hypnotist's limited understanding of how and what the subject should do. The failures in hypnotic therapy and experimental work often derive from dealing with the subject as an automaton expected to execute commands in accord with the hypnotist's understanding, to the exclusion of a recognition of the subject as a personality with individual patterns of response and behavior.

HYPNOTIC PHENOMENA

Hypnotic phenomena will differ from one subject to another and from one trance to the next, depending upon the depth of the trance, since hypnosis is a phenomenon of degrees ranging from light to profound trance states. There are, however, certain basic manifestations, the extent and clarity of which may vary in accord with circumstances. Foremost among these is rapport, which signifies the limitation of the subject's awareness to what is included in the hypnotic situation. Usually the subject responds spontaneously only to stimuli from the hypnotist who may limit or direct the subject's state of awareness as he wishes. However, in response to personality needs or the demands of the situation, the subject may remain in contact with part of or even all the circumstances surrounding the trance. Rapport can then be discovered experimentally by investigating the rigidity of the subject's responsive patterns to the entire situation.

Catalepsy is another manifestation, properly tested only indirectly since direct tests often serve to effect a suggesting of it. This is a peculiar state of muscle tonus and balance which permits the subject to maintain postures and positions for unusually long periods of time without appreciable fatigue responses.

Suggestibility, or a state of remarkable receptiveness to suggestions, is a striking characteristic. However, the suggestions must be acceptable to the subject, and rejection of them can be based upon whims as easily as upon sound reasons. By the acceptance of suggestions, and acting upon them, subjects can become deaf, dumb, blind, hallucinated, disoriented, or anaesthetized, or they can manifest any type of behavior regarded by them as reasonable and desirable in the given situation. The process is essentially the vivification of memories, ideas, and understandings so effectively that they are subjectively experienced as external events rather than as internal processes, with a consequent endowment of them as reality experiences. This is the feature of hypnosis most often abused, since most persons will allow themselves to be imposed upon to provide entertainment even when not hypnotized and the same general tendency exists in the hypnotic subject.

A most fascinating manifestation is that of posthypnotic behavior. By this is meant the execution, at some later time, of instructions and suggestions given during a trance and intended to become a part of the pattern of some later activity. Thus, for example, subjects may be instructed to read a certain chapter in a chosen book at a specified later time—hours, days, months, and even years later—and at that time they perform the act without really understanding consciously why they do so. In this type of phenomenon lies probably the greatest medical and experimental value of hypnosis, since it permits a direction and a guidance of behavior, but only in terms of the patterns of response belonging to the individual.

The forgetting of things or the development of amnesias for minor memories is an everyday occurrence. In hypnosis, however, there occurs an amnesia of an extensive character which can be induced at will or become manifest spontaneously. The amnesia usually includes all the events of the trance state, but it can be altered by instruction to include any desired experience'. It is a reversible phenomenon, may be induced or abolished as desired by the hypnotist and also by the subject should there arise adequate personal motivation to alter a state of hypnotic amnesia. It is a useful tool both in therapy and in experimental work.

Conversely, hyperamnesia, an ability to remember transcending the everyday ability to remember the past, is found. Thus, in the trance state, the subject can remember vividly long-forgotten, even deeply repressed experiences, recount them fully and still have a complete amnesia for them when aroused from the trance state. This ability is remarkably useful in both therapeutic and experimental work, since it permits the recovery of memories otherwise unavailable, and hence the exploration of the experiential past of the subject.

A phenomenon of the profound trance of extreme interest is somnambulism. The subjects, seemingly awake in a state of ordinary awareness, behave, within reasonable limitations, as if they were not hypnotized, but actually they are in deep trance and capable of manifesting any desired hypnotic behavior within their personal capabilities. Experience and training are often required even to recognize the somnambulistic state,

and even more experience is required to induce it and to utilize it scientifically, particularly in therapy as well as in experimental work.

Regression, or a return to earlier and simpler patterns of behavior, characterizes all trances and can be utilized and enhanced to a remarkable degree. In the ordinary trance there tends to occur a significant literalness of a childlike character in the subject's understandings, the handwriting and other motor activities are childlike, and emotional attitudes reflect those of an earlier age level.

Experienced utilization of this phenomenon can result in the development of an effective amnesia for all experiences and learning subsequent to a chosen age level and the revivification of the actual patterns of behavior, responses, and understandings of the selected age level. Highly significant therapeutic and experimental work has been done in this regard, especially when regression characterized by revivification of past patterns of behavior has been employed rather than a less satisfactory procedure wherein the subject is permitted to limit his regression to his current understandings of what probably constituted his past.

There are two other phenomena which are of particular interest but which are essentially modifications and elaborations of those manifestations already described. One is crystal-gazing, which does not necessarily require an actual crystal and which consists of a clear vivid visualization of memories and ideas as if they were current reality experiences. The other is automatic writing, in which the subjects write without conscious volition and often without conscious knowledge of the fact that they are writing. Both these phenomena are of great value in experimental and therapeutic work, since they provide unusually effective methods for the recovery of the experiential past and for an integrative understanding of the self.

Autohypnosis is entirely possible, but it is a sterile procedure, despite various overenthusiastic claims. Even among the Balinese, who practice autohypnosis extensively, it is a social manifestation limited to established traditional and ritualistic activities. It can, however, be of value when practiced under the supervision of an experienced hypnotist who can guide the activities of the autohypnotic subject.

RELATED QUESTIONS

Certain questions are always asked by the general public about hypnosis. Among these is the possibility of employing hypnosis to commit crimes. The best scientific studies deny this possibility, therapeutic experience discredits it, and the only positive evidence is that investigators have induced subjects to pretend to commit crimes, but a pretense is not a reality. Experimenters have also been able to induce subjects to perform minor antisocial acts in a limited experimental situation, but waking subjects will do the same; hence, the findings cannot be regarded as of hypnotic origin only.

Concerning harmful effects, no well-experienced hypnotist has ever reported any. Occasionally, an amateur may hypnotize a subject suffering from a personality disorder

and elicit hysterical behavior, but this derives from the personality problem and not from hypnosis.

Can people be hypnotized against their will or without their knowledge?
As previously stated, hypnosis always requires cooperation on the part of the subject, but sometimes this cooperativeness is well concealed behind a superficial attitude of unwillingness, with a consequent distortion of the true situation. Additionally, a trance state cannot be maintained without the subject's awareness of the fact, or full cooperation and genuine acceptance of the situation. Then, too, there is the age-old question about the possibility of not being able to arouse the hypnotic subject from the trance state. This actually cannot occur. Occasionally, the amateur may have difficulty in arousing the subject who insists upon remaining in a trance, but this is easily corrected with a little experience in handling subjects.

In any scientific field as undeveloped as hypnosis, no definitive statement can be made of its values. However, the history of its development warrants the definite assertion that it is a significant and valuable instrument in the study of human behavior and in the therapy of selected types of personality disorders.

The Basis of Hypnosis: Panel Discussion on Hypnosis

Milton H. Erickson

Transcribed from a presentation before the Annual Meeting of the Washington Academy of General Practice, Longview, Washington, May 13, 1959. Reprinted with permission from *Northwest Medicine*, October, 1959.

In opening the discussion on hypnosis I would like to give you some background for understanding its usefulness in the general practice of medicine. Perhaps the best way to approach the subject would be through that phase of medicine which constitutes a good share of your practice the role of psychological forces in human behavior. An illuminating specific example is that of the combat veteran who jumped down the stairway in his hurry to get home from the college he was attending and fractured his ankle badly. He walked home but came back three weeks later for physical examination because his foot was so swollen and because it made funny grating noises when he walked. Examination showed a stocking anesthesia, not only superficially but deep. The X-ray films showed a comminuted fracture of every bone in his ankle.

INFLUENCE OF PSYCHOLOGICAL FORCES

How did this man manage to do a thing like that, without any help or any instruction whatever? It seems incredible, but all of you in the practice of medicine discover that patients can make use of their psychological forces to rule out, govern, or control physiological phenomena.

Another instance of psychological force influencing physiological behavior concerns the businessman whose firm is operating well. He is making a profit; he is successful, but he worries. He has imaginary worries. He can think of dozens of things which can happen to him or his firm. What does he do with these worries? He punctures holes in his duodenal or gastric mucosa.

There is the housewife who worries about various things and develops severe headache. There is no question about the severity of her headache; it is very real, although its cause may be quite imaginary. One of the most striking examples of this sort of thing is a 15-year-old boy I once saw who was put in a boarding school. He resented it terrifically, and he had a very strong feeling of rejection. What did he do about it? He developed ulcerative colitis, an expression of his resentment. These psychological forces are tremendously important.

EXPERIENTIAL LEARNING

The next thing I wish to call to your attention is the matter of the experiential learning that we all absorb during a lifetime of experiences. Little children practice walking and getting up and sitting down, lying down, rolling over, using every muscle and action of their extremities and torso. They get acquainted with the various parts of their bodies and learn the full extent of their capabilities. They learn these things so thoroughly that years later, when they are full-grown adults and have forgotten the process through which they learned their actions they will respond promptly when a mosquito lands on any part of their body. Say that the mosquito lands on a shoulder. Without any thought, without any analysis, without recognition that it is on the right shoulder, and even if the left hand happens to be in the pocket, a person can, with great speed and accuracy, withdraw the left hand from the pocket and swat the mosquito at the instant of its biting. How did the body learn this accuracy of movement?

Little children learn first to eat with their fingers. Later they take a spoon. At first they bite the spoon and probably scatter food over themselves and everything around them. Eventually they learn to measure all movements so that they can put the spoon in the mouth.

Children learn to twist their faces, to twist their shoulders, to wriggle their feet. When they first try to write script, they are apt to twist their bodies and wriggle their feet. Gradually they learn to do it with their right hand. You all once went through this phase, and if at that time someone had been curious, they could have discovered that, without one bit of practice, you could have written with your left hand, without going through all of the original learning practice. In fact, one who never has had any such training can with a pencil held in the toes, write just as legibly as any doctor can. This is true because of the transference of learning. Human beings, once they have learned anything, transfer this learning to the forces that govern their bodies.

UTILIZING THE UNCONSCIOUS MIND

In hypnosis we utilize the unconscious mind. What do I mean by the unconscious mind? I mean the back of the mind, the reservoir of learning. The unconscious mind constitutes a storehouse.

You can be in physiological sleep, lying on your back, and you can dream that, instead of lying on your back, you are walking through the house or that you are talking to a friend working in the yard. You can smell the flowers, listen to the birds, feel the breeze, and enjoy the conversation with your friend. Everything is utterly perfect and real because your unconscious mind allows this elaboration in a dream. The real truth is that you are in bed between the sheets. During the dream you may sit down in the garden chair. At that particular moment you probably turned over and rested your back against the mattress. That was the time when in your dream you leaned against the back of the garden chair. The great secret here is that the unconscious mind can deal with the reality of the bed mattress and blend with it the reality of eye memories or mental images of any kind.

What one does is primarily to get the patient interested in ideas, memories, understanding, or a concept of any kind. As the patients deal with these they can develop understanding. I will give a demonstration. I will hold up this notepad and tell you to keep looking at it. Actually, all you receive from this particular object is a visual image. You keep looking at it, but you will notice that I put it on the table and you can conceive seeing it right there. However, you still have the visual image and visual memory in your mind. You could project the visual image in the air exactly where it was—where the actual object was before. This is exactly what you do in your dream. You project memories of objects and ideas so that you can talk to a friend in the garden.

Understanding of this projection of memories is important to the understanding of hypnosis. This particular phenomenon can be defined as a state of ordinary awareness, but it is devoted primarily to the consideration of ideas in themselves, with full attentiveness to the idea. This differs from our conscious attention, which is directed only to reality. As I speak to you, you are aware that you are sitting in this room and listening to me, that I am holding a microphone, that there are lights above you, that there is someone to the left and someone to the right of you, someone in front of you, and someone behind you. All these observations are relevant to listening to me in the ordinary state of conscious awareness. You tend to orient to reality and to give your attention in a diffuse way.

In the state of hypnosis, as in the state of conscious awareness, you give your attention but you give your attention to selected ideas. Your mind is open to these ideas. For example, if I were to ask anyone of you what you wore on your third birthday, you would look at me and say: “That was a long time ago. How could I possibly remember it? It really is not important, and why should I remember it?” You would reject the task of recalling because of attendant circumstances and your appraisal of the difficulty. In the hypnotic state the subject is susceptible to ideas and accepts them. Under hypnosis you would accept the idea that what you wore on your third birthday is simply part of the birthday. You did have a third birthday, which is an historic fact. Furthermore, you did wear clothes, and furthermore, on that third birthday there was a momentous combination of one-time experiences. In the trance state you could start thinking in terms of those realities. Hypnosis, therefore, is essentially a state of receptiveness to ideas and the appraisal of their inherent values and significance. The subject may either accept or reject the idea but can respond to the idea in terms of experiential learning.

TRANCE INDUCTION

Concerning the phenomenon of hypnosis I should mention the matter of trance induction. There are many ways of inducing a trance. What you do is to ask patients primarily to give their attention to one particular idea. You get them to center their attention on their own experiential learning. You could suggest levitation to them and could have them lift a hand higher and higher. You could have them close their eyes bit by bit.
Either of these things tends to direct their attention to processes which are taking place within them. Thus you can induce a trance by directing patients’ attention to processes, to

memories, to ideas, to concepts that belong to them. All you do is direct the patients' attention to those processes within themselves.

There are different levels of trance behavior. These vary with the individual patient and vary with the need of the situation. A light trance, a medium trance, or a deep trance may be induced. You must vary the trance according to the patient's needs.

Another thing I should mention is the matter of hypnotizability. Who is hypnotizable? Any normal person is hypnotizable but not necessarily by you or by me or by Dr. Bryant or by Dr. Hershman. Every patient has the right to go into a trance in accord with his or her own choice of the operator. One hundred percent of normal people are hypnotizable. It does not necessarily follow that 100 percent are hypnotizable by any one individual. A mentally ill patient can be hypnotized, but it is difficult. The feebleminded person can be hypnotized, but it is difficult. Various types of neurotics can be hypnotized, but again, some of them are difficult subjects. It depends on the situation and on the motivation of the patient. The personal relationship established between the operator and the subject is of great importance. When you hypnotize patients you are asking them to pay attention to ideas or to any parts of reality pertinent to the situation. The patients then narrow their attention down to the task at hand and give their attention to you.

INCREASED MUSCLE TONICITY

One of the first phenomena is that of increased muscle tonicity. A result of this factor is that you can lift the arm and have it stay in a position indefinitely. In a sense this is a psychological laboratory activity, but it is sometimes very useful in the practice of medicine. Sometimes you want patients to lie quietly in bed because it aids their recovery. I recall reading about a burn case in England where the patient as a result of hypnosis stayed in the same position for three weeks. He did this at his own voluntary muscular level so that a pedicle skin graft could take. It is a very useful thing to be able to produce this muscle tonicity for three weeks so that a patient can stay in an awkward position.

ALTERED SENSE OF TIME

Another thing is the matter of a sense of time. Under hypnosis the patient is paying attention to ideas and memories in fields of attitude and understanding. Time has a different subjective value. For example, all of you know that five minutes of acute pain seem like an endless period, and yet an afternoon spent visiting with friends seems very, very short. Subjective time is a tremendously important thing, and you want your patients to experience pain as briefly as possible. You want them to experience pleasure for long periods of time. Cancer patients, for example, suffering acute pain should have that pain cut down in subjective time values, and they should have a period free from pain greatly exaggerated subjectively. You cannot alter the clock, but you can alter the way the patient feels about it. There are many things you can do in altering patients' feelings toward themselves so far as pain is concerned. Sitting in a dental chair, for instance, can be made to seem only about one minute when actually it was an hour.

IDEOMOTOR ACTIVITY

Another thing is the matter of ideomotor activity. All of you have been in the back seat of a car when you thought the driver should put on the brake, and you have automatically tried to put on the brake with him. You have released your foot from the floor only to start shoving it down again.

Have you ever tried to feed a baby and opened your own mouth? You opened your mouth when you thought the baby would open his mouth. This was the idea of motor activity, and you attempted to carry it out. I have had polio and I know something about it. When you put into a trance patients who have recovered from polio but lost a tremendous amount of muscular movement, you ask them to remember what the movements were like. By this means you give them the idea of what the movement is.
You can do a great deal of good in the matter of correction of polio handicaps in this way.

IDEOSENSORY BEHAVIOR

There are many fields in which to utilize hypnosis. Ideosensory behavior is another phenomenon. By this I mean the idea of sensory experience, the idea of sensation. Perhaps one of the best illustrations of this is the fact that after a dental appointment you may scratch your face out in thin air well away from the actual skin of your face. You do it that way because it does not feel right—it feels different.

What do you want patients to do if they have suffered a serious injury of the head? You want them to have numbness of the head or you want them to have anesthesia or you want them to have analgesia. You give them the idea of a particular sensory state because, you see, all hypnotic phenomena derive from learnings that you experience in everyday life. Did you ever go to a suspense movie with a severe headache or a severely painful corn, and did you get interested in the movie until you forgot all about the pain?

Right now, what about the anesthesia you have? You have anesthesia of various parts of your body, and you use it every day. You have forgotten the shoes on your feet, the glasses on your face, the collar on your neck. You recognize them very promptly when you pay attention to them. By inducing sensory changes in the patient you bring about these changes by utilizing the experiential learning of their everyday life.

POSTHYPNOTIC SUGGESTION

Another phenomenon is the matter of posthypnotic suggestion. By this
I mean a suggestion given here, now, today, to be carried out at some future time. The anesthesiologist may see patients the night before the operation, induce a trance, and suggest to the patients that they will get through the operation very nicely. He can relieve the fear and anxiety, and correct the insomnia that the patients may have. The next day the patients undergo the operation, and the anesthesiologist has already suggested that

they will recover from the anesthesic. “I would like you to have good physiologic sleep. I would like to have you feel very comfortable. I would like to have you make a very nice recovery postoperatively.” Your patient can accept that suggestion and have a good postoperative recovery.

You can use posthypnotic suggestion in another way. Suppose you have a patient who is going to have a baby. You teach her to go deeply into a trance and you find out what kind of delivery she wants to have. Does she want to participate in it? Does she want to have a sense of feeling with absence of pain? Just how does she want it? Would she want to see the baby immediately? Would she like to be discussing things in a friendly fashion with her obstetrician? You have her in a trance today. Six months later she will carry out your posthypnotic suggestions and participate in the birth of her baby free from pain, or have it with as much pain as she would like to have.

REGRESSION

Another possibility with hypnosis is regression. By this I mean reestablishment of long-forgotten memories. A 50-year-old man can remember what he wore on his third birthday and he can tell you what he ate for breakfast that morning. Sometimes experiences can be verified through old records and things that have been recorded in baby books, the family Bible, and such places. Somnambulism is another useful effect of hypnosis. By somnambulism we mean the profound hypnotic state in which the patient presents the appearance of being wide awake. I mentioned prior obstetrics hypnosis, where the patient can participate and visit and chat and be alert and aware of everything that is going on during her delivery, but feel only the amount of pain she wishes to experience. In somnambulism the patient can look as though she is wide awake. Actually, she is in a cooperative hypnotic situation. A patient in this room could be aware of the audience or of as many of the people in the audience as she wished to know about.

Autohypnosis is another phenomenon, but it is considerably more difficult. It is useful, but induction is difficult and instruction in autohypnosis actually belongs in an advanced course.

In the induction of an hypnotic trance, one induces suggestions and primarily gives the suggestions in an indirect fashion. You should try to avoid as much as possible commanding or dictating to your patient. If you wish to use hypnosis with the greatest possible success, you present your idea to patients so that they can accept and examine it for its inherent value.

ABLATION OF MEMORY

Hypnosis can involve the matter of ablation of memory as well as recall.
You can forget a man’s name with instant ability. Have you ever been introduced to someone, exchanged the usual courtesy, repeated his name, and immediately said to yourself, “Now what was his name?” and been embarrassed because you forgot it so quickly? Sometimes you wish to hypnotize patients and help them forget. You may want

patients to forget pain. You need to do this when you wish to control the pain experienced by cancer patients. You might wish to teach them how to experience a pain and then how to forget it so that they can spend the remaining days of their lives without having to look forward to anticipated pain. You want them to forget it so that each time the pain occurs they can forget that they ever had pain. In this way they can spend the remaining days of their lives in contact with their families.

CONCLUSION

Hypnosis can be useful to you, and with it you will be able to help the patients you see. You can understand it and you can help your patients to understand it by understanding the normal psychological phenomena we have been discussing. Hypnosis simply utilizes these normal reactions and the experiential learnings that are common to all of us.

The Investigation of a Specific Amnesia

Milton H. Erickson

Reprinted with permission from *The British Journal of Medical Psychology*, 1933, Vol. XIII, Part II.

Specific amnesias are an everyday occurrence. Their study and analysis offer a wide field of therapeutic and theoretical interest through the understanding they afford of the mechanisms of repression and the means of removing, overcoming, or circumventing repressive forces. Psycho-analysts have written much on the subject, particularly in regard to the role of affect and the utilization of free-association techniques in the recovery of the forgotten word or name or whatever the amnesia may be. Recently the problem of a specific amnesia was presented to the author for investigation and recovery of the forgotten material. In achieving the desired results, use was made of the various psychological techniques of free association, hypnosis, automatic writing, crystal-gazing, and dream activity. The complexity of psychological phenomena, the successful use of disguise mechanisms, the apparent though perhaps artificial sublevels of consciousness, and the peculiar behaviour of the affect encountered all invite speculation and give rise to problems for investigation.

The subject in this experiment was a young girl studying for her doctorate in psychology. She came to the author in October, stating that on the previous Christmas she had presented a gift to a young man in whom she was much interested. The identity of this gift she had forgotten, possibly because she had later considered it not entirely suitable. She refused to give any additional information, insisting that only the nature of the forgotten object interested her, and she suggested that the very scantiness of information given be considered a part of the experimental situation.

For two weeks previously she had been trying unsuccessfully to recall the forgotten material. She was advised to continue for another week, which she did without success, reaching the conclusion that she would have to write a letter of enquiry to her friend. (The significance of this conclusion will become apparent later.) Having failed in her efforts, she now wished the author to take charge of the problem.

Free association was the first technique employed, but her conscious unwillingness to reveal anything of a personal nature rendered this means futile. Accordingly it was discarded in favour of hypnotism, since she had been trained previously for experimental hypnotic work. In the use of this technique the subject was hypnotized and awakened repeatedly throughout the course of the investigation in accordance with the needs of the immediate situation. All trances were of the profound, somnambulistic type characterized by dissociation and an apparently complete amnesia for trance suggestions and experiences.

In the first trance she was asked to give free associations. She did this readily, producing many nonidentifying associations, but she persisted in her waking refusal to give additional pertinent information. When asked in the trance state to name the gift directly, she manifested strong emotional tension and declared that she was unable to do so, that it had been forgotten completely. Since apparently no progress could be made by this method, she was given posthypnotic suggestions to the effect that when she awakened she would talk freely in generalities about the gift and suddenly name it. This succeeded in all but the naming of the object. The attempt was repeated in a second induced-tranced state, with the additional suggestion that she would interrupt her general remarks to declare impulsively, "It was a (name)." These instructions were obeyed to the crucial point, when she became emotional, seemed surprised, and complained of sudden mental blankness. Questioning revealed that she did not even have the feeling of "something on the tip of her tongue."

A third trance state was induced, in which she was given posthypnotic suggestions to perform automatic writing upon awakening. In her writing she was to give various descriptive details and finally the identity of the gift. Meanwhile, she was to engage the author in an animated conversation as a means of absorbing her attention away from her writing. However, nothing definitely descriptive was written, and when it came to the point of writing the name of the gift, her hand moved more and more slowly while she twisted and squirmed on the chair, complained of feeling tired, and protested about the hopelessness of the experiment. When the probable nature of the complaints and protests was mentioned, she showed good insight but declared herself to be unable to control her emotions. She was shown her automatic writing, of which she had been unaware. She exhibited surprise, then eagerness expressed in the enquiry, "Did I write the name?", and finally disappointment when she noted her failure. The procedure was repeated, using more forceful suggestions, but with no better results.

A slight variation was made in the technique. Posthypnotic suggestions were given to the subject to write automatically and in mixed order the letters contained in the name of the object. An excessive number of consonants was obtained. The procedure was repeated, with instructions to write automatically the letters of the alphabet, underlining those which were significant. As before, an excess of consonants resulted. In both attempts marked affective disturbance was noted, but the particular letters could not be determined. When shown her production, the subject exhibited, as before, surprise, eagerness, and disappointment.

These failures indicated a need for a still further change of technique. While in a state of profound hypnotic sleep the subject was given the suggestion that she could reveal indirectly the information desired with neither "conscious" nor "subconscious" realization of what she was doing. To this end she was instructed to continue in a state of deep hypnosis, thereby "dissociating" her "conscious mind" and leaving it in a state of quiescence. At the same time, by means of her "subconscious" mind she was to engage the author in an animated conversation. Thus, with both "conscious" and "subconscious" minds engaged, a "third level of consciousness" in a response to hypnotic suggestion would "emerge from the depths of her mind" and would express itself by guiding her

hand in automatic writing, of which she would be aware neither consciously nor subconsciously.[1] On the first trial, in accordance with this instruction, she wrote vaguely descriptive material concerning the gift. Further suggestion was given to the effect that the "third level of consciousness" could now write the significant information, but in such disguised fashion that its true meaning would not be apparent. The sentence illustrated in Figure 1 was obtained. As she wrote the word box, she became emotionally disturbed and complained of feeling tired, uncomfortable, and "funny," but this behavior disappeared as she completed the sentence. She was shown the sentence in both the trance and waking states, but denied seeing any pertinent meaning in it and declared that it was not her handwriting, substantiating her contention by writing the same sentence in her normal waking state, as illustrated in Figure 2. Another trance was induced and the same instructions were given to her with the addition that the word box would influence her hand to write the exact identity of the gift, but in such guise as to lead both herself and the author astray. Obeying these instructions while conversing vivaciously in a deep trance state, her hand automatically wrote in a hesitant fashion the sentence illustrated in Figure 3. As she wrote the second, third, and fourth words she exhibited much emotion, sighed, flushed, squirmed, and complained of feeling "funny."

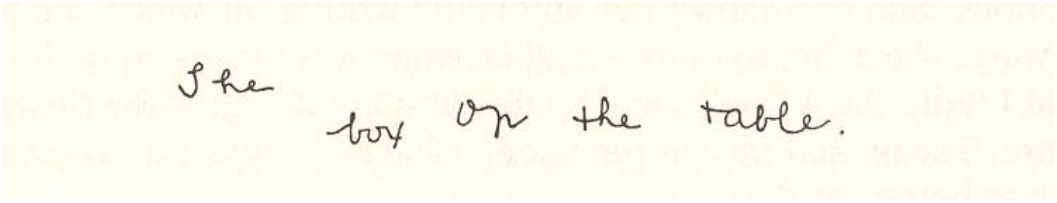

Figure 1.

She also expressed a scepticism toward whatever the author was trying to do, declaring that he must be trying to make her do something—what it was she did not know, but she did know that she could not do it.[2] When shown what she had written, she read it listlessly, declaring that it had no meaning for her and insisting that it was not her handwriting. Awakened, she likewise disowned the writing but she read the sentence with great interest and recalled for the first time that she had contemplated giving a cigarette case but had changed her mind. All associations became blocked at this point, and she was insistent that the experiment be discontinued as hopeless. However, her insight into the whole situation soon rendered her attitude more favorable.

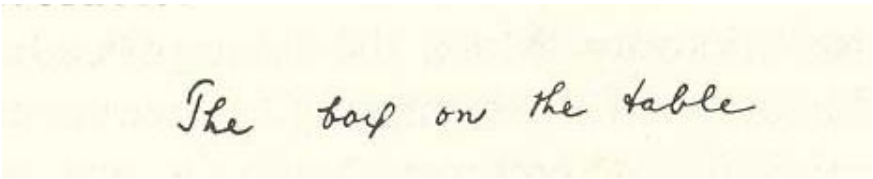

Figure 2.

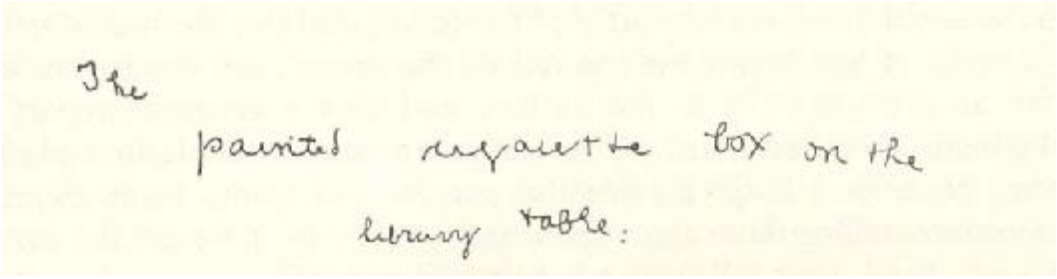

Figure 3.

Because of the subject's affective state, another change in technique was made by asking her to attempt crystal-gazing. In the crystal she saw herself walking down the street, entering a jewellery store in which she inspected cigarette cases, and then continuing down the street and entering a department store, whereupon she immediately lost sight of herself in the crowd. She saw herself next leaving the store with a small package under her arm. She took the package to her room and placed it in a bureau drawer. In response to further suggestions she watched herself prepare the gift for mailing, but each time that she was about to catch sight of the gift, her crystal image would turn in such fashion as to occlude her line of vision. All suggestions to the contrary were without effect other than that she was able to give the rough dimensions of the article, which had not been possible previously. Further variations of the crystal-gazing were without results. Finally she was rehypnotized deeply and given posthypnotic suggestions to the effect that she would dream that night about the gift but would not verbally identify it in her dream. The next morning, however, she could recall the dream and in so doing would recall the name of the gift.

Early the next day, with a complete amnesia for the posthypnotic suggestions, she related that she had awakened during the night in the midst of a dream about the forgotten article. She had recounted this dream to herself on the possibility that the author might be interested. In the morning, however, she recalled dreaming but not the dream content. Instead she suddenly recalled having a letter in her strong box thanking her for the present, and she felt herself forcibly impelled to read the letter. She did this and discovered that the object was a box of paints. She was shown the automatic writing illustrated above, and she exclaimed, "How different it looks now!"

The discovery of the identity of the gift did not end the problem, but gave rise to new and interesting aspects. A week later the subject complained that she was unable to recall her dream and that she felt a strong desire to know what it was. She asked that hypnosis be utilized in the securing of this lost memory. Much the same procedure was followed in this regard as had been used in attempting to recover the nature of the gift. All attempts were failures, however, until she was given suggestions disorienting her temporally. When these suggestions had been accepted, she was told that it was the night of her dream and that she was actually in the midst of her dream. As she relived the dream, she was instructed to give an account of it to the author, and thus a verbatim report was

obtained. The dream was: “There was a group of people in a place. It takes place in a hospital—hospital people. I’m telling them about the procedure, telling them about the results, telling them we got the name of the gift, but I don’t tell them what the gift was.” She was awakened with instructions to remember the dream. This she did, and expressed her pleasure, until suddenly she declared in great surprise, “I’ve forgotten the name of the gift now.” She was urged to try to recall the gift, but after much effort and numerous attempts at free association she failed. She repeated the dream content in an effort to reawaken her associations, but even this failed. A trance state was induced and she was told to recall the name of the gift after awakening. When aroused from the trance, she promptly declared, “Why, I remember it now. It’s a box of paints.” After a general conversation she was casually questioned about her dream content, and to her profound amazement she discovered that again she had forgotten the dream completely. Repeated investigations disclosed that she could not keep the identity of the gift and the dream content in her mind simultaneously. Finally, in the waking state in which she could recall the name of the gift, she was casually informed of the dream content. Following this she was able to remember both.

Four days later she complained to the author that she had been trying daily to write a letter to her friend in accordance with her regular custom, but that she could not do so. She had forced herself repeatedly to sit at her desk and begin the letter, but found herself unable to write more than a line or two before her thought processes became blocked and she felt emotionally disturbed and compelled to do something else. She was given the plausible explanation that the affect originally causing the repression had not been dissipated but had subsequently attached itself to the dream content, later to the identity of the gift, and finally, when both of these repressions had been circumvented. The affect had attached itself to the idea of a letter to her friend. After listening to this explanation the subject declared, “I understand now. Now I can write my letter.”

Contact was maintained with the subject following this experience, but no unusual occurrence came to either her or the author’s attention.

Because of the clinical interest aroused, attention may be called here to a consideration of the automatic writing. The word box was markedly displaced in the first sentence, which is suggestive of some unrecognized purpose. A similar displacement of the significant words in the second sentence enhances the possibility that this measure is a purposeful though unconscious means of self-betrayal. This conclusion is substantiated further by noting the relatively smaller size of the letters e and d in the word *painted*. The scrawling of the word cigarette appears superficially to be a clever method of distracting attention, but the account of the motivation suggests a deep and significant symbolism for it as well as for the other two words.

The peculiar behavior of the affect at the termination of the experiment, resulting in the alternate repression of the identity of the gift and of the dream content, with subsequent attachment to the related concept of the letter, suggests a strong conflict and an unwillingness or an unreadiness to accept the symbolic significance of the ideas concerned.

Not until the above report had been drafted into its final form for publication and submitted to the experimental subject for criticism was it possible to secure an account of the motivations for her repression. Fortunately she had kept a daily journal of her thoughts during the entire time of the amnesia, and from this and her elaborations of this journal the motivations were obtained. Minor and incidental points as well as elaborations of the symbolism are omitted for personal reasons.

For five years the subject, S., had been in love with M., a man belonging to another race and culture, artistic in nature and extremely idealistic, puritanical, and conventional in attitude. She had planned to marry him at the expiration of another year. Her own philosophy of life at the time was very similar to his. In the month of September preceding the amnesia she met C., a man of her own race and culture and whose personal philosophy was the antithesis of M.'s. A warm friendship rapidly developed between S. and C., with the consequence that she felt strongly inclined to relinquish her former teachings and ideals and to accept C.'s broader and freer ideals of life. Yet to do so would be essentially a negation of what she had considered to be the final principles of personal life and a destruction of her worthiness in the eyes of M., whom she loved. As she considered this problem, she realized that any independence for herself could evolve only from a deliberate choice on her part between these opposing personal philosophies. Yet she dared not choose C., although critical thinking suggested such a choice, because to do so would be to overthrow the conventional and idealistic precepts of her past teaching. To choose M. would mean the hampering of her intellectual and emotional nature. She hoped that something would happen which would force her to recognize her fundamental inclinations, because she knew that she lacked the courage to face the decision deliberately. It was then that the amnesia developed as one of the indications of her conflict. At first she considered the amnesia inconsequential, but soon she began to feel that it symbolized her choice, and she felt a compulsive need of discovering the nature of this amnesia in order to know its meaning, and yet she feared to know its meaning. Upon the recovery of the memory she immediately understood the rationale for the selection of the forgotten object. In purchasing the Christmas gift she had first inspected cigarette cases, thereby establishing an associative value. C. possessed a beautiful antique painted box which he used as a cigarette container. The one man, artistic and idealistic, was easily symbolized by the box of paints, while the other man possessed a painted box of practical personal use. With the recovery of the forgotten identity she sensed its import but dared not recognize it. To rob it of its meaning a second problem had to be created—namely, the amnesia of the dream. When this problem was solved, she still had the fundamental question to face, but could not do it, and so a second amnesia of the gift occurred. When finally forced to remember both the dream and the gift, she realized that she had made her choice and sat down to write a letter to M., thereby formulating her ideas and definitely committing herself. However, she could not do this until, with the aid of the author, she forced herself to recognize the affective features of the whole situation.

In summary, the problem investigated was an attempt to recover the content of a specific amnesia of the entity of a Christmas gift without the aid of supplementary information. Techniques of free association alone, free association and direct questioning in hypnosis,

automatic writing, and crystal-gazing were tried without success. Finally, by means of a specious argument concerning the existence of a third level of consciousness and the permission to use disguise mechanisms, the forgotten material was actually obtained, but in such guise that its true significance was not recognized. Then by means of dream activity a situation was created whereby the subject, without assuming the responsibility, could circumvent the repression. Following this a conflict state developed, characterized by the alternate repression of two ideas, and was ultimately resolved by the attachment of the affect to a related subject, from which it was eventually dispelled. The motivation of the amnesia was not learned until months later, when the subject disclosed its origin to lie in an emotional conflict concerning two men.

---

[1] The author assumes no responsibility for the validity of these concepts, and the trance state of the subject probably accounts for her acceptance of them, but at all events they served the purpose.

[2] The subject appeared to have a rather limited understanding of the whole situation when in the trance state.

6. Development of Apparent Unconsciousness During Hypnotic Reliving of a Traumatic Experience

Milton H. Erickson

A general experimental project, to be reported later in its entirety, was undertaken to investigate the possibility of exploration by means of hypnosis of the psychic development of a patient recently recovered from an acute psychotic episode of a schizophrenic reaction type. The method employed consisted of an attempt to have him relive his past life as completely as possible in a special state of hypnosis.

METHOD

The experimental procedure consisted of training the patient to enter profound somnambulistic hypnotic trances, during which, by means of a series of hypnotic suggestions, he was disoriented completely and then reoriented to an earlier period of his life. When thus reoriented, by theemployment of carefully worded systematic suggestions and questions, he was induced to relive past events in a chronologically progressive fashion, describing them in detail to the experimenter as if they were in the course of actual development in the immediate present. An attending stenographer recorded in full the entire course of the experimental events, including the descriptive material. In every instance for which adequate data were available from sources other than the patient himself, it was found that events of the distant past were relived and recounted by the patient with remarkable vividness and with richness and accuracy of detail.

In this connection mention should be made of the fact that neither detailed questioning in the normal waking state nor instruction to recall fully these past events in a state of ordinary deep hypnosis served to secure the same degree of accuracy and amount of detail as did the procedure of reorientation. Furthermore, even after the patient had relIved an experience while reoriented to that period of his life, such

Reprinted with permission from the *Archives of Neurology and Psychiatry,* December 1937, Vol. 38, pp. 1282-1288.

completeness of recall could not be secured without resort to posthypnotic suggestions worded in such fashion as to bridge the temporal gap between the actual present of the experimental situation and the chronological period to which the patient had been reoriented. The following example illustrates such posthypnotic suggestion: "This thing that has just happened to you and which you have told me about is important. You are to remember it fully and completely for the rest of your life, so that ten or even twenty years from now, it will be as fresh in your mind as it is now."

EXPERIMENTAL RESULTS

Study of the experimental findings disclosed an incident of peculiar interest, illustrative in an unusual fashion of psychosomatic interrelationships. This incident concerned the development of what appeared to be a state of unconsciousness as the patient relived the experience of a homicidal assault which had occurred two years previously, when he was 17 years old. All previous information concerning this assault consisted of the statement by the patient that he had been "taken for a ride" and beaten so badly that hospitalization had been necessary. He seemed to have complete amnesia for all informative details of this experience, including even the name of the hospital. Extensive and persistent questioning in the ordinary deep hypnotic trance, as well as in the normal waking state, secured only unimportant items, despite the fact that he seemed to be cooperating to the limit of his ability.

When the day of this event was reached in the hypnotic reliving of his past life, the patient expressed his fears over his employment as a police informer, vividly portraying intense anxiety concerning threatened criminal vengeance, and his entire behavior and appearance were suggestive of a most harried state of mind. When the hour of 4 P.M. was reached in his reexperiencing the events of this day, he relived, with marked intensity of feeling, the scene of his being ordered into an automobile by two men whom he knew to be criminal characters and his fearful behavior during the course of a long drive, during which he pleaded piteously with his abductors in a terrified fashion. Finally, he reenacted his forced acceptance of a bottle of pop from the criminals, fearfully and hesitantly drinking from an imaginary bottle. As he swallowed, he grimaced, mumbled that it tasted bitter, asked if it was poisoned, and dodged and cowered as if evading a blow. His entire appearance continued to denote intense terror. Shortly after completing the act of drinking, he belched and suddenly looked bewildered. His pupils, which previously had been fluctuating constantly in size, became widely dilated, and fine lateral nystagmus developed. He then rubbed his eyes, complained that he could

not see plainly, said that everything was getting dark and that he was dizzy, and began shaking his head as if to throw off something or to rouse himself. Questioning by the experimenter elicited the information that the patient felt himself becoming sleepy. It was noted that his speech, reviously clear, was now thick and indistinct and that his appearance had changed from that of terror to that of somnolence.

At this time the patient was sitting on a couch, and every few seconds he experimenter had been testing him for the presence of catalepsy as an index of his continuance in the hypnotic state. After about two minutes of decreasing activity, during which the patient shook his head more and more slowly and mumbled with increasing inarticulateness, his eyes closed, despite his apparent effort to keep them open. Suddenly he gave a short, gasping grunt and collapsed, sprawling inanimately over the couch. Immediate examination by the experimenter disclosed complete loss of hypnotic rapport, with absence of the catalepsy which hitherto had been consistently present. Physically, there were sagging of the lower jaw and
arked atony of the muscles of the legs and arms. Also, the patellar and upillary reflexes, which are consistently present during hypnotic states, were absent. The respiration and pulse, which had been greatly increased ouring the state of terror, had decreased somewhat during that of somnolence. Now they were found to be markedly diminished in rate and so weak and faint as to be barely perceptible. In brief, the patient presented every appearance of being unconscious. However, before the blood pressure and accurate counts of the pulse and respiration could be taken, the patient seemed to be recovering. He stirred slightly and moaned, and catalepsy returned slowly. Shortly he opened his eyes and, after staring vacantly around, weakly closed them again. It was noted that the pupils were still widely dilated, that fine nystagmus was present, and that the eyes were not focused. The patient licked his lips repeatedly, moaned for water, and weakly rubbed his forehead, grimacing with pain as he did so. He paid no attention to the experimenter's insistent questions, "What's the matter? What's happening?" except to say, "It's dark, dark." This was followed by a second collapse, of slower onset than the first but apparently of the same character, with the same physical findings except that the-respiration was deep and labored while the pulse was slow and firm. Repeated attempts were made by the experimenter to arouse the patient, but he remained unresponsive for several minutes.

Finally, catalepsy returned, and the patient opened his eyes and stared about unseeingly. Nystagmus was absent, and the pupils were somewhat dilated but responsive to light. He twisted his head about, moaned, rubbed his neck as if it were painful, rubbed his forehead gently, grimacing as if with pain, and shivered constantly. Again, he licked his lips repeatedly and kept moaning for water. No response was made to the experimenter's insistent questioning except the monosyllables "light" and

"woods." Now and then he put his hands to his ears, rubbed them feebly and mumbled, "buzzing."

Soon the patient seemed to recover to a considerable degree, and he again became fairly responsive to the experimenter's inquiries, which concerned the events he was reliving. There followed a relatively inadequate account, as compared with his initial communicativeness, of lying in a ditch alongside a road through a woods, of being cold, wet, and uncomfortable, and of suffering from intense thirst, roaring in the ears, headache, and a painful, bleeding wound on his forehead, from which he went through the act of wiping blood in a gingerly fashion. He also declared that it seemed to be morning.

From then, he recounted in a fragmentary fashion the experience of being picked up by some men and taken to a hospital. The reliving of the next two days was also disjointed and inadequate, but that of subsequent events was complete, during the course of which the name of the hospital was obtained.

The total time required by the patient to relive this entire experience, which had actually extended over a period of two and one-half days, was slightly more than four hours.

Later, inquiry was made at the hospital named by the patient, and the information was obtained that on the morning of the day specified by him he had been found lying in a confused, semiconscious state in a ditch beside a road leading through a woods, suffering from exposure and a contused laceration of the forehead, and that he had seemed not to recover full consciousness for nearly two days. In addition, inquiries made of the police force for which he presumably had acted as informer verified his account of such employment and served to identify one of the criminals whom he had described as a well-known police character having a record of being involved in several homicides and as one on whom the patient had informed. Also, the police records disclosed that the patient had made his usual morning report on the day of the assault but had failed to make his evening report and had not been heard from since.

The entire experimental project was interrupted by external circumstances for more than a year. On resumption it was repeated in its entirety, including the incident already reported. The records obtained were compared with those of the first investigation and were found to be essentially identical, including all the findings contained in this report.

The same descriptive details, the same sequences, the same physical manifestations, and even the same fragmentary utterances and gaps in the reexperiencing of the events were found. About five months later, in an endeavor to check certain aspects of the major project, the experimenter again had the patient repeat this event, among others. Again, the record obtained was identical with that of the first and second investigations, and the time required for each repetition ranged from three to four hours.

After each experimental session in which this experience was relived, the patient awakened from the hypnotic state with complete and persistent amnesia for everything that had taken place during the trance.

However, he complained bitterly in each instance of severe headache, Overwhelming fatigue and weakness, and extreme general discomfort; he was tremulous physically and unstable emotionally. All this he attributed to the hypnosis, although he readily admitted that previous hypnotic work had left no aftereffects. In addition, he became antagonistic and hostile toward the experimenter and the idea of further hypnotic work, and special effort, in one instance extending over a month, was necessary to secure continued cooperation.

COMMENT

One of the first considerations in determining the significance of the experimental findings is the validity of the entire investigational procedure. In this regard the reports in the literature disclose that hypnosis can be employed to arouse dormant associations and to recover amnesic material otherwise inaccessible (Erickson, 1933), and that it often makes possible an exceedingly vivid and complete recollection of apparently totally forgotten events. Furthermore, recent experimental work by Platonov and Prikhodivny (1930), among others, has indicated that· regression in a hypnotic state to an earlier period of life is possible, with the reestablishment of its corresponding patterns of behavior uninfluenced by subsequently acquired skills. Other experimental work demonstrates the possibility of producing in the hypnotic state significant personality-situation changes of ap objectively measurable character (Huston et al, 1934; Erickson, 1935). In the light of these facts, the practicability and validity of the major project as an experimental method become more readily apparent and serve to suggest the reliability of the findings reported here. In addition there is the confirmation from the hospital where the patient was treated of the facts of his injury and of his confused mental state, which he had duplicated in the experimental situation. The hospital report also served to indicate the possibility, apart from emohonal considerations, of a traumatic basis for the general amnesia manifested by the patient for the original experience in the normal waking state and in the simple deep hypnotic trance. Additional confirmation of the reliability of the experimental findings may be found in the identity of the results obtained on repetitions a year and nearly a year and a half later. Such identity suggests both the intrinsic completeness and the credibility of the date.

The possibility of reliving past experiences as a dynamic process is

becoming increasingly recognized, and the validity of the phenomenon has been repeatedly demonstrated in both psychiatric and psychoanalytic experience. Perhaps the best example that may be taken from normal life to illustrate the type of findings obtained in this experiment is the relatively common occurrence of the vivid dreaming of a long-past event as a current experience. In such dreams often no modifications may be found of the dream responses and behavior which should derive from the dreamer's experiences subsequent to the original dreamed-of occurrence, and this despite the fact that the course of the dreamer's life may have been such as to modify or to change completely his capacity to respond in the fashion depicted in the dream. Thus, the adult may dream vividly of being a child in all respects, without the dream responses and behavior reflecting the maturity of his actual status. Such a dream, however, is a spontaneous occurrence; thus it differs from the patient's experience in this investigation, which was the outcome of deliberate experimentation.

The reliving of this patient's experience did not take place in the usual sense in which it is observed in psychiatric and psychoanalytic practice, since it occurred at a "subconscious" level in a peculiar state of hypnosis which precluded any subsequent conscious recollection and since it involved an experience for which the patient had, and continued to have, essentially total amnesia.

The regression to the earlier period of life at which this experience originally occurred, occasioned by the hypnotic suggestions for reorientation, apparently functioned in such fashion that all experiences subsequent to that event, including even development of the amnesia, were eliminated by hypnotic dissociation from the patterns of response which were manifested in the experimental situation. Thereby, revival of the experience with its associated responses was permitted as if it were in the course of actual development. Once this process had been initiated by the evocation of readily accessible memories, the recovery of each item functioned in itself as an aid in recovering additional material in its original chronological order, thus constituting a continuous progression to completion of sequential activity. Hence there would be aroused in proper order and relationship the concomitant psychic and somatic activities with their corresponding alterations and adjustments of the mental and physical states, the entire process being directed by the originally established patterns of response.

The apparent state of unconsciousness developed in the patient raises immediately the question of psychosomatic interrelationships. It is unfortunate that the exigencies of the experimental situation, including the emphasis on the project as a whole, resulted in failure to secure more adequate data concerning his physical state. However, every item of such information which was secured, including the startling clinical effect of the patient's appearance, strongly suggests that he was actually unconscious.

More particularly is this indicated by the absence of the pupillary and tellar reflexes, the changes in pulse and respiration and the loss of pauscular tonus, all of which are unaffected by the hypnotic state, except muscular tonus, which may be slightly increased (Bass, 1931). Further confirmation of the possibility that actual unconsciousness was produced may be found in the familiar phenomenon of a faint produced by purely psychic stimuli and, more closely parallel with this experiment, in the faint that has been known to result from a terrifying dream.

Likewise the aftereffects of which the patient complained in each instance after the reliving of his experience are highly suggestive that the processes involved had been of such character as to produce definite somatic and physiological changes which were not limited to the experimental hypnotic state but persisted into the following waking condition.

Further evidence for the possibility that marked changes in the functioning of the body can result from psychic factors may be found in a report made before the American Psychiatric Association in May 1936 on the experimental production of deafness in the hypnotic state and published two years later in greater detail (Erickson, 1938a, 1938b).

The temporal abridgment in the experimental situation of the probable period of unconsciousness signifies possibly a qualitative as well as a quantitative difference, to be attributed to the fact that the experimental state of unconsciousness arose from mental and physical states of developing in response to internal stimuli, in contrast to the external factors involved in the original experience.

A question may be raised concerning the reason that the patient, on becoming unconscious in the trance state and thus disrupting the hypnotic condition, did not recover consciousness in the normal waking state.

Aside from the fact that the entire process was conditioned by hypnosis, the parallel phenomenon is frequently observed of recovery from sudden traumatically induced unconsciousness marked by reorientation to the situation immediately preceding the trauma.

In conclusion, mention may be made of the clinical psychiatric effects of the hypnotic reliving of the patient's traumatic experience. Unfortunately, a complete study of these changes was not made at the time, but certain clinically significant alterations of behavior occurred. After the first hypnotic reliving, despite the fact that no apparent change in his conscious amnesia was detected, the patient showed complete loss of his phobic reactions to visiting the city where he had been a police informer, although, as was learned on questioning, he did not revist his former haunts, rationalizing this failure with a casual explanation of lack of time. After the second and third experiences in reliving, no apparent trace of any of his fears remained, and he revisited his former haunts with every evidence of pleasure. Some months later, during a casual conversation, he reminded me that he had once told of being taken for a ride without being

able to remember many of the details. He then added that he had recalled more of that experience "a few days ago," stating that "Whitey and another guy picked me up on Washington Street about four o'clock one afternoon and took me for a ride. They drugged me, conked me, and shoved me in a hospital-I think it was in Providence-they were after me for squealing on them. They said they'd get me, but they didn't." This was all he seemed to recall, and he told it casually ,with no manifestation of the affective strain and tension previously much in evidence. The marked contrast between his original fearful, hesitant manner of telling what he remembered and this casual, unconcerned elaboration of the story suggests that a definite emotional catharsis had resulted from the hypnotic procedure, even though the entire process had occurred at a level below conscious awareness.

CONCLUSIONS

The specific conclusion to be derived from this report may be stated as follows:

Significant psychosomatic changes culminating in the development of, and recovery from, an apparently definite state of unconsciousness were produced in a patient during the hypnotic reliving of an amnesic traumatic experience. More general conclusions are:

1. Hypnosis can be employed to produce significant personality-situation changes, as evidenced by the definite psychic and somatic effects produced by the reorientation to, and the reliving of, a past experience as a current process.
2. The procedure of hypnotic reorientation to a past event makes possible the reliving of that experience as if in the course of the actual original development, thus excluding the modifying effects of the perspective and the secondary emotional reactions which obtain in the normal waking state and permitting revival of the experience in a more sequential order and in greater detail than is possible in the normal state.
3. Amnesia, even when associated in origin with the physical conditions of trauma to the head and possible narcosis, need not preclude recovery of the major memory images.

Clinical and Experimental Observations on Hypnotic Amnesia: Introduction to an Unpublished Paper

Milton H. Erickson

Unpublished manuscript, circa 1950's.

Hypnotic amnesia is a much more complex phenomenon than is commonly realized. The general tendency is to look upon it as a relatively simple, definite manifestation comparable if not identical with forgetting as ordinarily experienced, and controlled and regulated by hypnotic suggestions with almost the same ease and effectiveness as one can govern vision by opening or closing the eyes, or by turning the light on and off in a light-proof room. Extensive experience, however, discloses that, while hypnotic amnesia does derive from the trance state and is characterized by a functional loss of ability to recall or to identify past experiences, it constitutes a form of dynamic behavior quite different from ordinary forgetting. It resembles the latter superficially and primarily in the final end results—namely, the inaccessibility of memories. Because of this one point of resemblance there is a general tendency to investigate hypnotic amnesia by procedures primarily suitable for a study of learning and forgetting behavior. In such studies there is an oversight of the fact that hypnotic amnesia, which permits subjects to forget in a moment's time their name, age, and similar items of fact ordinarily impossible to forget, cannot be tested adequately by a procedure devised to test the retention of nonsense syllables. At best, such investigative measures can be employed to test the effects of hypnotic amnesia upon the retention of nonsense syllables, but a determination of such effects in relation to a chosen, limited form of behavior does not constitute a study of hypnotic amnesia as a phenomenon in itself.

Experiments may also be devised in which subjects are permitted to undergo certain experiences while in the trance state. Then, either with or without instructions to forget those experiences, subjects are awakened and tested directly or indirectly for any memories they may have of the events of the trance period. In such an experimental procedure it is assumed that any unusual decreases or inaccessibilities of the memories of the hypnotic experiences derive simply, directly, and immediately from the hypnotic state itself, from any suggestions to forget that may have been given or from a combination of both factors. Also, it is assumed that any decreases that are found constitute evidence of an actual process of forgetting as a simple, unitary, specific phenomenon and that any immediate failure to show such decreases in memory signifies the ineffectiveness of the effort to secure hypnotic amnesia.

In other words, in this type of experiment the basic assumptions are that hypnosis in and of itself may be an entirely adequate genetic factor for the development of an amnesia, that such an amnesia necessarily develops readily and immediately, that it may be elicited by simple suggestions to that effect, and that any amnesia developed is necessarily a

sufficiently stable manifestation to resist explorative measures despite the fundamental suggestibility of the hypnotic subject upon which the amnesia itself is based.

Another unfortunate assumption in this type of procedure is that a test procedure can be elaborated, controls established, and time limits set for the evocation of investigative results without adequate realization that reliable experimental results do not depend upon the completion of an experimental procedure, however well devised, that does not make full provision for the nature of the phenomenon under investigation.

Additionally, these general assumptions favor the continuance of the misconception of hypnotic amnesia as analogous to ordinary forgetting. They permit an oversight of the fact that the hypnotic state is a result of a dynamic, purposeful interplay of personality forces, and they do not make provision for the probability that any derivative or outcome of the hypnosis is also of a dynamic, purposeful character not comparable to the progressive, sequential processes of psycho- and neurophysiological functioning basic to forgetting as commonly experienced.

Consequently, experimental studies that have been based upon limited and inadequate assumptions and understandings and that have failed to make provision for a phenomenon quite different from ordinary forgetting have led to conflicting and confusing though occasionally informative findings. For example, reports have been made of no amnesia, of a partial or incomplete amnesia, of a profound amnesia, of an intentional or an unwitting simulation of amnesia, and of results similar in effect to amnesia such as blocking and repression.

Despite these contradictory investigative findings and the frequent uncertainty and unreliability of hypnotic amnesia as it is encountered both experimentally and clinically, experience discloses it to be a definite and significant trance phenomenon, exceedingly complicated in its manifestations, sometimes difficult to discover and to recognize and always difficult to test satisfactorily. It resembles ordinary forgetting in certain superficial aspects, and this resemblance can be greatly enhanced by a careful choice of hypnotic suggestions in inducing it. It is much more likely to seem to resemble or to parallel various forms of psychodynamic behavior seen in everyday life and to duplicate in many regards psychopathological states, from which it seems to differ mainly in the degree to which it can be manipulated and controlled rather than in its form, structure, and associated developments.

In addition to the difficulties caused by the complexity of hypnotic amnesia, there is another experimental difficulty of primary importance to investigative procedures—namely, the inherent contradictions of the total experimental situation. Stated simply, the total situation requires that an amnesia be suggested to a subject in a highly suggestible state. This suggestion of an amnesia is then followed by a second suggestion-direct, implied, or inherent in the test procedure—that the subject recover the amnesic material. Hence, the findings obtained are more likely to be a measure of the relative strength of the two opposing suggestions rather than a measure of the extent of the hypnotic amnesia originally induced.

Nor can this inherent contradiction be circumvented easily, since the amnesia is an induced phenomenon, more or less sharply defined as an experience, and not the outcome of progressive processes of behavior as is ordinary forgetting. For example, the induction of hypnotic amnesia for learned nonsense syllables, followed by the task of learning a new set of nonsense syllables actually inclusive of some of the presumable amnesic syllables, does not constitute a satisfactory experimental situation. In undertaking the new task the subjects, if they cooperate fully, are at liberty to do anything that can aid their performance—and this may include in their understanding the recovery of any memories or associations that might help in the new task. Hence the greater rapidity of learning for the amnesic syllables is not necessarily a measure of the incompleteness of the hypnotic amnesia; it may equally well be a measure of the degree to which the subjects were to abolish the amnesia in their effort to perform the new task.

Another important consideration, definitely related to the problem of suitable experimental conditions, lies in the highly significant role played by associations—whether chance, incidental, relevant, or irrelevant—in permitting the recovery of amnesic material. Although this is fairly well recognized generally, it is often overlooked in experimental settings. The following account is an example of ordinary forgetting that discloses the readiness with which amnesic barriers may be overcome by an item of experience serving to arouse associations related to the forgotten data.

A college graduate, in anticipation of a visit with his senior-year roommate whom he had not seen for 15 years, was led to discover a 20-year-old college directory in which, at the end of his freshman year, he had placed a checkmark opposite the names of all his college mates whom he knew well. To his amazement he could call to mind very few of them. Repeated efforts during the next two weeks permitted the recovery of a few more identities. Upon the arrival of the guest, and before there had been any exchange of reminiscences, the directory was produced. To the man's astonishment he discovered at once, and with no help other than the mere presence of his former roommate, that a wealth of recollections came flooding back, and he was able to recall a large number of the forgotten identities.

Two weeks after the departure of his friend he again looked through the directory, only to discover that he had again forgotten nearly all of the names, retaining only a few more than he had originally recovered by himself.

This chance observation led to several experimental investigations under controlled conditions of a similar problem. The subjects were chiefly psychiatrists who had formerly worked in the same mental hospital. They were tested separately and together for their recollection of the names of former ward patients, among which were listed names unfamiliar to them. The results obtained in each instance confirmed those of the original observation. Furthermore, similar observations and experimental inquiries that yielded comparable results have been related to the author by a number of associates.

Discussion of the above observations is hardly necessary. They serve to emphasize the importance, in a memory-searching situation, of realities and associations, even those remotely connected with the amnesic material, in permitting a recollection of otherwise inaccessible memories. In the same vein they show that the removal of those associations—as in the above instances, mere physical removal of the person constituting the source of associations—is sufficient to reestablish the amnesia in large part.

Hence in any study of hypnotic amnesia there is a need to be most appreciative of the possible removal of an established amnesia through the force of associations unintentionally established by an experimental setting, with a consequent misinterpretation of test results. Since hypnosis and presumably its derivatives are based upon dynamic interpersonal relationships, the significant effectiveness of associations may be of primary importance in maintaining or abolishing an induced amnesia.

Also pertinent to the importance of associations in the accessibility and utilization of past learnings is the following example from the field of animal psychology. Although it bears more upon the problem of learning than upon amnesia, it effectively illustrates that something well learned can become meaningless when encountered out of context, thus giving an effect comparable to a failure of recognition and such as may occur in amnesia.

This example relates to the teaching of a series of tricks to the family dog. By force of circumstances this teaching and all performances of the tricks occurred in a basement room, although the dog had the run of the entire house. One day, long after the dog had not only learned the tricks well but would perform them spontaneously in anticipation of a food reward, visitors asked for a demonstration. The dog was called into the living room, a crust of bread was offered, and the usual commands were given. The dog gave every evidence of wanting the bread but seemed to have no understanding of the commands or of what was wanted, despite patient, repeated efforts. When everyone went down to the basement, the sight of the bread crust was sufficient to elicit repeated spontaneous performances of all her tricks without commands being given. Even after having eaten the bread, she performed readily upon commands from anybody without further reward. Upon return to the living room the dog again seemed unable to understand commands, nor did the offer of food do more than elicit restless, hungry behavior. Giving her small morsels didn't help, but another trip to the basement resulted in an adequate performance. Finally, after repeated commands and offering of food and much restless puzzled behavior by the dog, she finally began to understand the familiar command of "Roll over." She responded by racing to the basement, performing the task, and then racing back for the food reward, repeating this behavior at every new command.

While this behavior cannot legitimately be called an amnesia, certain of the results were comparable to those that would derive from an amnesia. Furthermore, when it is realized fully how extensively hypnotic amnesia depends upon associated circumstances and conditions of a limited character, the possible parallel with this example becomes apparent and serves to demonstrate the need, in any experimental study, to make adequate provision for possible association factors.

This brief discussion of the difficulties involved in the experimental study of hypnotic amnesia is not intended to be exhaustive or to define all of those problems for which provision must be made if satisfactory findings are to be obtained. Rather, the immediate purpose of this discussion is to direct attention to certain general considerations that seem to be of basic importance in such studies as a preliminary to a report of the author's clinical and experimental studies of hypnotic amnesia. The objective of these studies was primarily an extensive observation of the general characteristics, forms, and varieties of hypnotic amnesia, rather that an attempt to define presumably possible behavior in terms of a precisely controlled situation. By such observational studies it was felt than one might obtain a more extensive knowledge of the possible manifestations of hypnotic amnesia, which could then more readily permit the devising of experimental situations offering better provision for the nature of the phenomena under study and for a more precise definition of the behavior elicited.

The Problem of Amnesia in Waking and Hypnotic States

Milton H. Erickson

Unpublished manuscript planned with André Weitzenhoffer, circa 1960s.

In the experience of this author, which extends over 40 years, amnesia as a phenomenon of hypnosis is of three varieties—all of which have their counterparts in the ordinary state of conscious awareness. The primary differences between hypnotically induced amnesias and those of everyday life are that the former can be intentionally controlled or directed by others, while those of daily life are not easily amenable to external direction but are dependent upon processes within the person for their manifestation.

Yet, in many ways the development of hypnotic and waking amnesias occurs in much the same way; both types can be spontaneous and directly or indirectly suggested. However, hypnotic amnesias can be determined deliberately and controlled extensively, but not necessarily completely, by someone else. Perhaps the best way of clarifying this subject of hypnotic amnesia, which is much debated and even denied as a phenomenon of actual occurrence by a few critics of hypnosis, is by discussing the various types.

SPONTANEOUS AMNESIAS: WAKING AND HYPNOTIC

Perhaps the best examples of spontaneous amnesias of the waking state are those that occur frequently in the experience of most people. One example is the experience of being introduced to someone, shaking hands and acknowledging the introduction by repeating the person's name, and a moment or so later wondering desperately what that person's name is. Another common experience is asking directions when intent on reaching a certain destination, repeating the directions as they are given, only to wonder a few minutes later at which intersection to turn and whether to turn right or left.

Then there is that common occurrence where a professor carefully specifies to an attentive class the day, the hour, and the room in which the final examination of the course is to be given, only to find members of the class a few minutes later in the hallway wrongly debating the hour, the day, and the room specified. This rapidly teaches instructors to say, as a preliminary remark, "Now write this down carefully," before giving such vital information. Even so, students highly interested in the course and fully expectant of a high grade will discover their need later, perhaps by the time they reach the dormitory, to consult their notes in order to know what instructions they had been given.

In all three examples the primary element is something quite different from lack of attentiveness. In the first instance the social gathering is of primary importance—not some stranger's name, no matter how attentively received. In the second instance the

reaching of the destination, not the precise noting of distances, is of primary importance. Similarly, in relationship to the predicament of the students the final completion of the course is important, not the hour of the exam, which is usually different from the class hour; not the day, which has no bearing upon the course; not the specified room, which so often is not the regular classroom. We tend to spontaneously forget the parts or details of a situation when we are fixated or motivated by the total Gestalt or major goal of that situation.

Still another type of peculiar and spontaneous waking amnesia is that encountered when asking directions from a stranger for a specific goal well known to that stranger. For example, the author was riding in a car with some colleagues when we arrived at a small town. Our general information was that the meeting we were to attend was being held in a hall across the street from St. Mary's Church. Noting a woman who had just concluded an animated conversation with a gas station attendant, our driver stopped at the curb and, as the woman reached the sidewalk, asked her if she knew where St. Mary's Church was. She answered promptly, ``I certainly do. I go there for Mass every Sunday. Just drive straight ahead for exactly one mile, and at the top of the hill there, turn right. It's right near the corner." Our driver thanked her, whereupon she asked curiously why we were going there at that time in the evening. The driver explained that we were attending a medical meeting in a building opposite the church. She replied, "Oh, yes, I know that medical building, but it's not straight across from the church. It's about two houses further down." She was thanked, and our driver drove on two blocks, then stopped the car and declared, "Something is wrong. She was too explicit, too precise, so completely certain in each statement. I'm going back to that gas station and get correct directions."

The gas station attendant was told precisely the directions the woman had given. The man looked puzzled, then his face cleared and he laughed and said, "My wife gave you exactly the right directions, only she must have forgotten she was downtown and not at home. You're headed in the right direction now, but at that stoplight one block down, turn right, go about three blocks, and at the top of the hill you'll see it—the only church there." His directions were correct.

What brings about such an occurrence? *There is a dominance of a well-established item of memory that takes precedence over the incidental, immediate realities of the situation which are spontaneously forgotten* so that a response is made accurately in terms of the well-established memory belonging to a totally different situation. More than once the author has experimentally inquired for directions to the location of a landmark familiar to him. Upon receiving explicit instructions, the author has carefully repeated them with an introduction such as, "Now let's see, we are at the corner of 7th and Wall Street and. . . ." Not infrequently the informant has remarked in astonishment, "Oh, no! I told you the way I usually think. I just forgot for the moment that I was *here*, " and then corrects the previous instructions.

Numerous other instances of spontaneous waking amnesia could be cited, varying in type, but the above should be sufficiently common experiences to establish the reality of

this phenomenon. Also, the amnesia can be experimentally elicited without the use of suggestion by evoking processes occurring within the person.

Yet another example of spontaneous everyday amnesia comes to mind. This is best exemplified by the sudden, dismayed remark, "I was just about to say something very important to you. I know it was important—it's been on my mind for an hour—and just as I was about to say it, someone slammed the door, and for the life of me I can't remember it." And they do not, though perhaps an hour, a day, a week, or even months later the specific communication will be inexplicably recalled, perhaps in a dream, perhaps by another sudden slamming of a door, or the occurrence of some specific stimulus evocative of that intended communication. *Here the amnesia is evidently due to the loss of an important associative connection caused by an outer interruption that momentarily distracts the person and "breaks his train of thought*. " Then, too, there is the somewhat compable experience of leaving a room and entering another on a specific errand with the frustrating realization that the purpose in mind has vanished upon arrival in that room. One can puzzle and puzzle and not recall, but often a return to the original room and/or a resumption of the interrupted task brings a flash of recollection, which is then laboriously kept in mind while the trip to the other room is successfully repeated. *Here the amnesia is due to a break in important, momentary environmental associative connections because of a sudden loss of the support that the outer situation contributes to the memory item*.

Both of these last two types of spontaneous waking amnesia can be deliberately induced by the simple expedient of speaking to subjects on some topic unrelated to their thinking or intentions. As they become aware of their amnesia, they might remark exasperatedly, "Now you've broken my train of thought and I can't remember what I was going to say or do." But again, the process is experienced as occurring within the self, not actually induced by the other person except incidentally. Also, in both of these last two types one can often aid the amnesia victim by saying, for example, "You just came out of the kitchen," or "you were just doing (such and such interrupted task) . . ." whereupon, by some inner process, the "broken train of thought" is reestablished.

Yet there are those persons who, for reasons not clear to this author, disclaim the phenomenon of hypnosis as no more than complaisant behavior or as "role-playing," and that the "amnesia" of this so-called hypnosis is nothing more than an "as-if pretense." In other words, the claim of these critics is that a nonexistent phenomenon (hypnosis) so alters the behavior of people that they cannot manifest the same behavior (amnesia) under hypnosis that they spontaneously manifest in the ordinary waking state.

In this author's experience there can be developed in a person a special state of awareness that is termed, for the sake of convenience and historical considerations, *hypnosis* or *trance*. This state is characterized by the subject's ability to retain the same capacities possessed in the waking state and to manifest these capacities in ways possibly, though not necessarily, dissimilar to the usual actions of conscious awareness. *Trance permits the operator to evoke in a controlled manner the same mental mechanisms that are operative spontaneously in everyday life*.

Thus, certain hypnotic subjects may develop without instruction a totally spontaneous amnesia because of an interruption of the ordinary state of awareness by the establishment of a different state of awareness (due to hypnosis, drugs, shock) with no associative connections to the ordinary state of awareness. On arousal from this special state and return to the usual state of consciousness there will frequently be an amnesia for the events that transpired during the special state [see the "state-bound" theory presented in the next paper]. One might consider the hypnotic state marked by a total amnesia a phenomenon this author has found can last for 40 years—as an intrusion of a special state of awareness into the ordinary state to which it has no relationship or associative connections. It is similar to the common situation in life when one may drive automatically through heavy traffic so intently interested in a conversation with a companion that the arrival at the destination becomes a total surprise, and there is no recollection of having stopped at red lights or of being delayed at police-patrolled intersections. The only proof of competent driving is the safe arrival without a citation. *The absorbing conversation was a special state that precluded any memory of irrelevant details of the situation in which it took place*.

These examples indicate that there can be separate states of awareness that develop spontaneously in ordinary life: they are independent of each other, and can give rise to a total amnesia. If this can occur spontaneously, why then should there be any doubt that similar situations can be set up psychologically in order deliberately and intentionally to evoke hypnotic amnesias?

In addition to total spontaneous hypnotic amnesia there may be a partial spontaneous amnesia in which the recollections are unclear and vague, such as, "You had me read something—maybe it was a book—I'm not even sure it wasn't writing—something about something blue." A year later the subject—without further hypnosis, but upon being reminded of something we did last year—might very well reply, "Oh, yes, something about a book or writing, maybe something about a color." This has occurred whether or not the person was used as an hypnotic subject in the meantime.

There can also occur a spontaneous selective amnesia in which only certain events are remembered—just as in the ordinary waking state some people always remember either the pleasant or the unpleasant aspects of past occasions, but not the total event. In subsequent trances, however, a full recollection of the previous trances could occur, but again and again the same selective spontaneous amnesias and the same spontaneous recollections would also occur. Repeated efforts have failed to discover the reasons for such selectiveness, since the amnesia involves minor, unimportant matters as frequently as it involves major matters.

Another item of interest is the inconstancy of spontaneous amnesia as a phenomenon. Only a few subjects consistently develop a spontaneous amnesia. The great majority of such subjects are likely at times to have spontaneous recall either immediately or later. There seems to be no known way of predicting in advance what will occur in any individual trance situation or for any particular subject. The same is true of subjects

showing spontaneous selective amnesia and partial amnesia as is true of those showing complete spontaneous amnesia. They may manifest on one occasion a complete spontaneous amnesia; at another time only partial amnesia is present; at still other times an immediate or delayed recall, either partial or complete, will appear.

Predictions as to trance outcome can be made only at a statistical level for repeated trances in the same subject. However, continued experience with a single subject often provides minimal cues that, when perceived by the sensitive operator, can lead to fairly accurate predictions.

DIRECT SUGGESTIONS FOR AMNESIA

Amnesia resulting from direct suggestion is a phenomenon that occurs in everyday life most commonly in relation to children, though it also occurs in relation to adults. One of the most typical examples involving children would be the case of the child who comes dashing into the house to complain bitterly about a violent disagreement with a favorite playmate and is told casually but sagaciously by the parent, "Oh, forget it and go out and have a good time with Milly." An hour later, when the child is questioned at length, one frequently discovers that the child reacted literally as told and even looks blankly as the playmate relates the quarrel. Upon hearing the story retold, there is often a slow recovery of the forgotten quarrel.

A typical example of this type of amnesia among adults is the situation that occurs within a social group dining out in a restaurant. When the tab arrives, one of the group usually says, "Oh, forget it, boys. This is on me." Then, if the group goes for a social hour after the dinner to the home of someone other than the man who paid the bill, the various guests can be casually asked, "Who paid for the dinner?" Frequently the answer is, "I was going to, and so was everybody else, but I just don't remember who did. I only know I didn't pay the bill." However, if the wives present are asked, they invariably remember (they are not one of the boys). Also significant is the fact that if the social gathering is held at the home of the man who paid the bill, the dinner host is usually remembered without fail.

In teaching nurses, social service workers, postgraduate psychology students, medical students, interns, and residents in psychiatry, a certain experiment has been conducted repeatedly both verbally, and by mimeographed material. The procedure is simple. One selects 10 or 20 items of any subject matter judged to be of equal value. All of these items are explained in equal detail, but to the explanation of some items there is added the casual statement, "This is just for your general knowledge, so you can forget about it now."

This can also be carried out in written form, using mimeographed sheets with that parenthetical statement appended to the chosen item. The experiment can then be repeated in many different ways: using different groups of subjects and altering the choice of item for each group; repeating the same procedure both verbally and with mimeographed material; and by using different sets of comparable items, with one item

always marked by that casual admonition. Tests given on the various series of the items always show a higher percentage of failure on the item carrying the instruction to forget it for both instances of verbal or mimeographed presentation.

A comparable experiment was conducted in which the casual statement was appended parenthetically to one item: “This is for your general information, and now that you know it you might as well remember it.” Tests given some three months later yielded higher percentages of recall on this item. This experiment was repeated many times with different groups of subjects, always with similar results.

It was also observed that if the tests were given too close together in time, the admonition to forget or to remember would be remembered from the previous occasion. Under these circumstances the admonition to forget had an opposite effect and the one to remember led to even higher percentages of remembering. Over the long period of years during which the author taught, there was adequate opportunity in which to space these experiments over relatively long intervals.

Still another type of direct suggestion witnessed by the author on more than one occasion concerns a group of teenagers at a local hangout. A police officer, sensing something about to happen, authoritatively says,
“All right, boys, break it up and move along.” More than once the author has subsequently questioned one of the dispersed gang and received the resentful reply to the effect that they were planning some fun when the cop came around and spoiled their plan. When asked what the proposed fun was, quite frequently a surprised look followed by one of resentment developed, and the answer given was, “I just got so damn mad that I forgot what it was.”

Interviews with teenagers who have a tendency toward delinquency have frequently elicited the complaint, “We were just minding our own business planning something when Old Baldy [the high school principal] came along and said, `No loitering in the corridor. Just forget what you’re about to do and go to your respective classes.”‘ Asked what had been planned, the reply would be, in effect, “It was plenty sharp, but Old Baldy got me so mad that I can’t remember.”

In the ordinary state of awareness, then, direct suggestion can be given to elicit amnesias. In this author’s experience, however, such suggestions are most effective if given in a casual, nonrepetitive fashion and under circumstances involving some form of increased emotion. Too frequent a repetition of the word forget will usually have the opposite effect. Thus, when the following conditions were present and mimeographed material was given to the subjects, the opposite of what had been admonished would occur: The item chosen for them to forget was prefaced by the statement, “This item you may forget if you wish, since it is only for your general information,” followed by the material chosen for them to forget. The admonition was repeated at the end of the test. Repetition of the instruction to forget produced a better recollection of it than of the other “neutral” items. In this way direct suggestion to forget in the ordinary waking state can be effective—particularly if it is given in a casual manner.

Moreover, such forgetting is characterized by considerable difficulty in recall. The person usually "puts it out of mind," and when told to remember "that which is forgotten," responds with a blank and wondering look. However, if the material that is amnesic is identified in part, there is an immediate and complete recall often followed by the explanation, "Do you know, that slipped my mind completely."

In hypnosis the matter of direct suggestion to forget is of another character. It can be given directly, emphatically, and repetitiously as a specific instruction rather than as an incidental, casual admonition or suggestion. Furthermore, the amnesia that develops is effective in both the trance state as well as posthypnotically. For example, a female subject may be told to forget what she had eaten for breakfast that morning. As she accepts the suggestion, she can then be questioned by naming a variety of possible foods, among them those she actually did have for breakfast. She may reject each one readily, or she may thoughtfully consider each one and recall previous occasions on which certain items were eaten. But those of the morning's breakfast are not recognized. They do not "come to mind" when mentioned as they do in the waking state. Additionally, the duration of the directly suggested amnesia can often be easily determined, and its recovery can be made contingent upon any chosen cue or even a minimal nonpertinent stimulus at some later time. This is not true of the forgetting that occurs in the waking state.

Then, too, such a recovered memory can be hypnotically abolished immediately upon a direct request—almost an absurdity in the waking state. It can also be abolished by minimal nonpertinent posthypnotic cues which can be repeated indefinitely. Such amnesias are dependent upon external stimuli rather than upon inner associative processes.

INDIRECT SUGGESTIONS FOR AMNESIA

A remarkable anecdote taken from a clinical case history best illustrates indirectly suggested hypnotic amnesia. A rather paranoid patient of the author's kept his Monday appointment, stating in belligerent, obscene, and profane language that he wanted no further nonsensical efforts at psychotherapy. He wanted a deep hypnotic trance induced without any further evasion or delay.

The author's response, as the patient seated himself in a chair, was to lean back comfortably in his own chair and in a soft voice, slowly, gently offer suggestions of increasing relaxation, fatigue, sleepiness, and the development of a deep, sound hypnotic trance.

Irately the patient leaned forward with his hands on his knees, scornfully denounced the author as being idiotic in using "that soft, gentle voice of yours," and demanded instantly that a strong authoritarian technique be used. Unconcerned, the author continued his "soft, gentle technique" uninterrupted by the continuously repeated demands of the patient for the next 50 minutes. Then the author glanced openly at the clock and sat up to

dismiss the patient. Bitterly the patient commented on another "wasted hour," declaring that the whole procedure was a total failure and that he could remember everything the author had so stupidly said. At this point the author said, in the same gentle, soft voice, "Naturally you heard everything I said here in the office, and you remember it here in the office. You are sitting within six feet of me, and so here in the office you remember everything I said. Your next appointment will be the usual hour on Wednesday." Still in a rage the patient left after a few more caustic remarks.

The next Wednesday he was carefully met in the waiting room, not the office. In a puzzled manner he asked, "Did I keep my Monday appointment?" The author replied, "Naturally, if you kept your appointment on Monday, you would remember it!"

He then explained that on Monday he had found himself sitting in his car outside his apartment, trying to remember if he had just come back from the university or from the author's office. He did not know how long he sat there debating with himself, but he was sure it was a long time. Finally he looked at his watch and realized that it was definitely more than an hour later than the scheduled appointment. Again he asked if he had kept his appointment, and the same reply was given.

The author led the way into the office, and as the patient stepped over the threshold into the office, he declared irately, "I did too keep my Monday appointment, and you wasted the whole hour and charged me for it, with that soft, gentle technique!" He had much more to say and did so emphatically. When he finished, the author casually remarked, "There's a magazine in the other room I want you to look at." Obediently, the patient followed the author out of the office, only to repeat in full the foregoing scene, with the author giving the same replies. Upon reentry of the office, the behavior of a few minutes before was repeated. The same casual comment about a magazine was again made, and upon returning to the waiting room there was yet another repetition of the amnesic behavior.

A return to the office elicited the same response a third. time, but as he concluded the patient added in astonishment, "Why this is the third time I've remembered keeping my Monday appointment!" Instantly the author replied, "Naturally, here in the office you remember."

The patient then became interested in his out-of-the-office amnesia and promptly stepped out of the room. Hesitantly he paused and with embarrassment turned around to remark, "I can't understand why I found myself walking backward toward your office. But I am puzzled to know if I kept my Monday appointment." He was invited to come into the office, and he immediately declared, "I wasn't backing into your office. I was going out to see if I could remember out there if I kept my Monday appointment, but I didn't. Now I'm going to back out of the office and see what happens."

This he did, and just outside the door he asked, "Will it be all right if I come in now? I'm curious about my Monday appointment." He was invited to enter and immediately said, "I remember everything in here—why that's what you said! `Here in the office you can

remember everything!' And I thought you weren't hypnotizing me, and I was mad at you because I thought you were failing me. But you must have put me in a trance and given me a posthypnotic amnesia. I wonder if it still works." With that he stepped outside the office, turned around, looked at his watch, and said, "I guess I'm about twenty minutes late. All the way here I've been trying to remember if I kept my Monday appointment."

He was invited into the office, developed full recollection, and said, "That settles it. I apologize for my rudeness last Monday. And I do have a posthypnotic amnesia outside this office. You must have thought me some kind of fool bouncing back and forth, forgetting out there, remembering in here, then forgetting out there again. From now on you do therapy on me any damn way you want to. It's plain you know more about me than I do."

Since then the patient has developed a complete amnesia for the entire matter. Several times he has inquired if the therapist thought hypnosis would be of any value, and he has readily acceded to the author's negation. From that day on steady therapeutic progress was made.

Hypnotic amnesias can be given time limits that are not possible in the ordinary waking state. An example is that of a student repeatedly hypnotized during the author's senior year in medical school. This subject was unable to develop a spontaneous amnesia, but he could develop amnesia upon direct suggestion. He had sought hypnotherapy by the author, who at that time was working under the joint supervision of the departments of psychology, psychiatry, and pharmacology and a psychiatrist-lawyer, all of whom acted as his sponsors to prevent, the Dean of the College of Liberal Arts from expelling him for daring to deal with the black art of hypnosis.

This particular student was seeking therapy for stuttering. It was discovered that in the trance state he spoke fluently. A posthypnotic suggestion for a total amnesia of all trance experiences was offered as an experimental measure and out of curiosity following the first few trances, during which an effort had been made to secure a history of his stuttering. No therapeutic progress was made with the patient, but he was insistent upon continuing and expressed a willingness to be an experimental subject for the author to compensate him for the hoped-for therapy.

Accordingly, because of the author's interest in hypnotic amnesia, the following direct suggestions were offered: That he develop a complete amnesia for all trance experiences; that he visit the author socially once a week for the remainder of the month; and that he develop a deep trance each time he talked fluently.

Two more social visits occurred, and upon opening the door the student spontaneously developed a deep trance, awakening only as he left the author's apartment. On each of these visits he offered the information that he had not been stuttering since he had been instructed to have a waking amnesia for trance experiences.

On the last visit, while in a profound trance, he was told that the author was leaving Madison for an internship in Colorado and thus might not see him again for a period of a year—perhaps many years—and since an amnesia for his trance experiences seemed to correct his stuttering, he might as well continue to maintain that amnesia for all hypnotic work. Additionally, he was given the posthypnotic suggestion, "On the occasion of our next meeting, no matter where or when, as we greet each other with a handshake, you will immediately develop a profound trance state so that I can ask you a few questions." To this he readily agreed.

Approximately nine years later the author called upon another hypnotic subject who was then the city editor for a daily paper in Madison. As the author was about to enter the editor's office, his former stuttering patient came rushing out on an assignment, recognized the author at once, extended his hand in greeting, and developed a deep trance state. A hasty social visit with him occurred, and he explained that he was a reporter for the paper and on a rush assignment. Special inquiry elicited that he had maintained his amnesia and that he had not stuttered in the past nine years. He was told to "keep up the good work" and to continue his amnesia.

During the visit with the editor, mention was made of meeting Jimmy just before entering the office. The editor remarked, "I didn't know you knew him. He is our prize reporter, and I just sent him out on a big story that has to be covered fast." The author then asked the editor if Jimmy stuttered. The editor was astonished by the question and stated, "In the five years he has worked for me, he has never stuttered, and I know him thoroughly. He's my prize man. Did you know him before?" An evasive reply was made, and the editor was asked if his wife was still as opposed to hypnosis as she had been nine years previously. He replied, "Oh, yes, Nan never got over her prejudices, but now and then I call at Herb's office [Herb was a classmate of the author's and was Nan's brother], and he puts me in a trance to relax me. You know, being the city editor is not the most relaxing job you can have, especially when big news stories break fast." Just why or how a posthypnotic amnesia served to effect a correction of stuttering is completely inexplicable. But then, much psychopathology is also completely inexplicable.

This is not the only case. Another Wisconsin student had sought out the author, explaining that he was a bad stutterer and that he hoped hypnosis could be used to correct it. He had undergone much speech therapy in various schools but without any good effect. In fact, he felt that his condition had worsened, and he was having much difficulty in his premedical course work. All of this constituted a serious handicap for him, and he earnestly pleaded for at least a trial at therapy. He was told that the author was leaving Madison within two weeks to take up his internship and had barely time to teach him how to go into hypnosis. Upon his insistence, however, hypnosis was attempted, and he was found to be an easy somnambulistic subject with complete spontaneous amnesia. He was deeply hypnotized on four occasions, and each time he talked fluently in the trance state. Because of the author's clinical ignorance as to what to do in the way of therapy, the following suggestion was offered: That since he really knew how to forget his trance experiences when in the state of conscious awareness, and since he could talk fluently in the trance state, he might undertake to spend the summer putting his stuttering into his

unconscious mind and replacing it with the fluent speech of the trance state, all the while maintaining his total amnesia of trance experiences.

Some 13 years later a patient walked into the author's office bearing a letter of referral from this former premedical student, stating that he had failed in his psychoanalytic therapy of the patient but that hypnotherapy might be of value. This was the author's first knowledge of what had become of that premedical student. A few years later, when lecturing at a psychoanalytic institute, one of the psychoanalysts came up and introduced himself. It was the former premedical student. Inquiry was made about the progress of the patient referred, and the author cautiously inquired why he had referred that patient. The analyst stated that he had long followed the author's publications and that his own frustration with the patient had led him to wonder if another type of therapy might be of value.

Since the analyst was speaking fluently, he was even more cautiously asked if he and the author had ever met before. He replied with a laugh that the author probably would not remember, but the last year the author had been in medical school, he had consulted with him about a bad stammer with which he had then been afflicted. The author effected to recall vaguely and asked if his analysis had corrected the stammer. The astonishing reply was, "No, it just naturally disappeared that summer." Thereupon he was asked what his own psychoanalysis had revealed about the past in relation to the stammering. The reply was made, "That was one area of my life that has been completely blacked out, and I'm not really interested in ever learning anything at all about it." He was asked if this was an emotionally based attitude. He answered, "Well, it might be, but I haven't stuttered since that summer. During my analysis I became curious about it, but nothing ever came through."

As if to change the subject, the author asked what interest the analyst had in hypnosis. His reply was that he was entirely content with psychoanalysis and did not have any interest at all in hypnosis except that for some unknown reason he was extremely interested in the author's publications and that he had continued to read them during the time of his analysis despite his analyst's objections. He had never withheld this fact from his analyst, but neither of them had ever uncovered the source of his peculiar interest in the author's, and only the author's, publications on hypnosis. Thereupon he introduced the author to his analyst, who remarked, "I've often wanted to meet you since John always violated my instructions in relation to you and your writings. What is the relationship between the two of you?" My reply was simply, "Well, we both were at the University of Wisconsin at the same time one year, and we are both interested in human behavior." Since then, despite other referrals and some casual meetings at conventions, nothing further has developed.

One can only futilely speculate on what did occur in this particular patient—not only therapeutically, but also in relation to the significance of the hypnosis, the spontaneous amnesia, and the remarkable known persistence of that amnesia from 1928 to the time of our last meeting in 1958. It also gives rise to a number of questions concerning psychoanalysis as an exploratory, investigatory, or evocative modality, since the man

underwent three years of “therapeutic” psychoanalysis and two years of “controlled” psychoanalysis without recall of his hypnotic experience.

Varieties of Hypnotic Amnesia

Milton H. Erickson and Ernest L. Rossi

Reprinted with permission from *The American Journal of Clinical Hypnosis*, April, 1974, Vol. 16, No. 4.

This paper is a condensation and synthesis of three unpublished efforts by Milton H. Erickson during the years 1936 to 1970 to illustrate his studies of hypnotic amnesia in clinical and naturalistic settings. The complexity of hypnotic amnesia, long recognized by Erickson as a result of such studies, has become established fact during the ensuing years of controlled laboratory investigations. There still remains a stark contrast between the results obtained in clinical and laboratory settings, however.

A recent interview (Cooper, 1972) of the research literature on hypnotic amnesia summarizes this problem by stating, "What needs yet to be done is to systematize and carefully record the important factors in the clinical situation, and then study their influence in a clinical laboratory setting; that is, a laboratory setting in which the clinical factors are maximally operative (p. 252)."

As a contribution to recording "the important factors in the clinical situation" a number of Erickson's original studies illustrating the varieties of hypnotic amnesia will be presented together with some of his innovations in producing amnesia. These studies were chosen because they illustrate the complex behavior that may result from investigative work where the clinician is able to explore and utilize the individuality of each patient to enhance the development of hypnotic amnesia. They disclose interesting mental phenomena which are usually overlooked in the usual experimental situation. These phenomena may also account for some of the unreliable findings of the typically standardized and statistical approach, where the significance of individual differences and the psychodynamics of each individual trance situation are presumably neutralized or controlled rather than directly utilized, as they can be in the clinical situation.

A case will then be made for conceptualizing hypnotic amnesia in clinical practice as "state-bound." We will conclude with a summary of the very important place of amnesia in hypnotherapy.

AMNESIA FLUCTUATING IN TIME AND PLACE

Amnesia by Distraction

Example 1. This first example centers about a subject who had often been used for demonstration purposes and who occasionally delighted in deliberately recalling past hypnotic experiences to prove that there was no such thing as hypnotic amnesia. One morning Erickson found him relating to Erickson's secretary a detailed account of the

hypnotic demonstration in which the subject had been used the previous evening. Erickson's appearance somewhat embarrassed him, but he was immediately reassured that Erickson would be most interested in discovering how adequately he could recall those events. Thereupon, directing his full attention to Erickson, the subject proceeded to give a remarkably complete account of the entire demonstration. During his running narrative Erickson's secretary, without the subject's knowledge, took complete notes. Several days later Erickson gave the typewritten account to the subject with the request that he read and correct it. As was discovered later, he understood Erickson's request to mean merely that he was to proofread a manuscript, a task he had often performed for Erickson. After reading for several minutes he suddenly remarked, "This is most interesting." Since Erickson could not understand his comment, he made no reply. The subject continued his reading and then expressed the wish that he could have seen the demonstration and that he would like to know who the subject was. Not fully comprehending these remarks, Erickson evasively replied that it was just one of his hypnotic subjects.

On a subsequent occasion he was handed the same manuscript to read, but he immediately recognized it as one he had already read. Upon Erickson's insistence, however, he reread it, remarking that it was sufficiently interesting to be worth reading a second time, but he was obviously rather curious about Erickson's insistence. This same procedure was repeated on several more occasions, but it succeeded only in arousing his curiosity as to Erickson's purpose. He even advanced the idea that Erickson was trying indirect suggestion on him so that he himself might give a similar demonstration sometime. At no time did he become aware that it was an account of his own hypnotic experience.

On a still later occasion Erickson rehypnotized him deeply and questioned him about what had happened to him in reference to that specific demonstration. He immediately manifested a full understanding of the total situation and simply explained that after his narration of that experience he had forgotten it completely at a conscious waking level. Hence he had been able to read the typewritten account with the full conscious belief that it concerned someone else. When asked if that amnesia at a conscious level of awareness would persist in the future, he replied that it probably would unless Erickson gave him instructions to the contrary.

No such instructions were given, and, although the subject has since spontaneously recalled various experiences of subsequent trances, this particular amnesia still persists. Nor has additional reading of the account done more than remind him of his previous readings.

To summarize, a hypnotic subject recalled in detail a prolonged hypnotic experience and described it adequately to others. Subsequently he developed a spontaneous amnesia, not only for the hypnotic experience itself, but also for the conscious waking experience of recalling and verbalizing it. This amnesia persisted, and even the record of his performance aroused no memories. Nevertheless, in a new trance state full understanding was found, but in the subsequent waking state the amnesia was again present.

A spontaneous amnesia together with full recall of trance events in another trance constitutes the classical evidence for hypnotic amnesia; there is a continuity of memory from one trance to another and from one awake state to another, but there is an amnesia between trance and awake state. What is unusual in this account is the fact that the subject apparently had a full memory of all trance events in the awake state until he developed a spontaneous amnesia at a later time.

The relevance of this example of hypnotic amnesia developing at a later time, after a full recall of all trance events had taken place in the awake state, for experimental work is obvious. The typical research design testing for hypnotic amnesia immediately upon trance termination misses the spontaneous and suggested amnesias that develop at a later time.

Erickson, in fact, makes it a routine practice not to talk to the patient about trance events immediately upon awakening. The trance state persists for a few moments after the appearance of wakefulness. Questioning during this period frequently permits full recall. Erickson typically engages the patient in casual conversations, anecdotes, and shaggy dog stories very remote from the hypnotic experience for a while after trance termination to effect an *amnesia by distraction*. Alternatively Erickson will sometimes "rush" a patient out of the office to avoid talk about trance. He will distract and do just about anything he can to make the waking situation very different from the trance situation and thus promote amnesia.

Amnesia by Indirect Suggestion

Example 2. Another example illustrating the development of a suggested amnesia at a later time and place after the subject had actually rehearsed all trance events in the awake state is as follows:

A professional psychologist related to Erickson her history of failing to go into a deep trance with a number of different hypnotherapists. She claimed that an amnesia for all trance events would be a satisfactory criterion of trance depth. She very much wanted to be surprised by her amnesia. Erickson acknowledged her story with the compound waking suggestion, "You haven't failed this time since we haven't started yet." This is a favorite approach with Erickson: The suggestion contained in the first half of the sentence, "You haven't failed this time," tends to be accepted when associated with the obvious truth of what follows, "since we haven't started yet."

Erickson then proceeded to fixate her attention: "You haven't looked at this glass paperweight before, therefore you don't know what effect it will have on a deep trance." This is another compound suggestion: This time an obvious truth is in the first half of the sentence, with a suggestion implying deep trance in the second half. Erickson then proceeded with a typical induction which included a 20-minute period during which the psychologist was instructed to go deeper all by herself. Immediately upon awakening the dialogue went as follows:

Subject: I was in a pretty deep trance, but I remember everything.
Erickson: Isn't that all right?
Subject: I expected an amnesia.
Erickson: When?
Subject: Immediately.
Erickson: Is it necessary that it happen immediately? Won't you be surprised when you find it has happened?

Thus Erickson implied the possibility of a later amnesia by the indirect suggestions contained in his questions. His last comment, "won't you be surprised . . ." is an effort to utilize her expressed wish to experience a surprise.

The psychologist then verbalized all trance events to prove she had no amnesia and actually rehearsed them on her long drive home from Arizona to California. On arriving home she began writing a letter to Erickson stating she still recalled all trance events but left the letter unfinished when she went to bed. The next morning she awakened with an amnesia for all trance events, even though she recalled that she had been to Arizona to visit Erickson.

It will be noted that while this was a suggested amnesia, it was indirectly suggested. This type of indirectly suggested amnesia is vastly more effective for clinical purposes than the baldly asserted direct suggestions used in most experimental work (e.g., the Stanford Hypnotic Susceptibility Scale, Form A, uses the following direct suggestions: "You will have difficulty in remembering; you will have no desire to try to recall . . ."). When such direct suggestions had been used in this patient's previous hypnosis work with other therapists, they were conspicuously ineffective in producing amnesia.

The reason for the greater effectiveness of indirect suggestions may be formulated as follows: In most trances some consciousness is invariably present in the form of an observer attitude; the subject is in part lost in the experience, but in part the ego is quietly observing what is happening, just as it can in dreams (Rossi, 1972 a, b).

When a direct suggestion for amnesia is given, the observing ego takes note of it, just as it quietly takes note of most direct suggestions. Having noted the suggestion, the ego later has the power of choice as to whether or not the suggestion shall be carried out. When the subject has this awareness of a suggestion, he can debate with himself regarding its merits and decide about carrying it out. When a suggestion is made indirectly, however, even the observing ego tends to miss the fact that a suggestion has been given. With little or no awareness of the suggestion there is little or no ability to debate and negate it. Indirectly administered suggestions are programmed more easily into preconscious or unconscious levels and can then emerge more naturally in the patient's ordinary course of behavior.

Amnesic Material in Dreams

Example 3. This example concerns a graduate nurse who was hypnotized on many occasions and invariably had a spontaneous amnesia for all trance events. Even the reading of a full stenographic account of her trance behavior would not awaken a sense of recognition for the items described. Upon being rehypnotized, she would disclose a full recollection of the hypnotic experience, but upon awakening the amnesia would again become manifest.

One day this subject approached Erickson and reported that she had a most interesting dream and proceeded to give an adequate account of a previous hypnotic demonstration before a group. Full notes made of her dream and subsequently compared with the stenographic account of that demonstration proved the correctness of her dream account.

Uncertain as to her purpose in such a communication, Erickson inquired cautiously as to the possible relationship of this dream to hypnosis. She explained that she always dreamed quite vividly for some nights following hyponotic trances, but this was the first occasion on which she had had so extensive and interesting a dream. Further questioning disclosed her to be entirely sincere in her belief that her account was only a dream and that Erickson would naturally be interested in it for psychiatric reasons. Asked why she knew her account to be a dream and not the recovered memory of a forgotten trance, she explained that dreams are characterized by a quality of unreality. This unreality permitted unreasonable things to occur. And in her dream she and Erickson had been alone in a large room in which there had suddenly and inexplicably appeared an inconstant audience which came and went, or grew large or small for no apparent reason, and which sometimes included people she knew definitely could not have been at a hypnotic demonstration.

No effort was made to explain that these peculiarities of the audience, as the stenographic account itself disclosed, really resulted from the hypnotic suggestions she had been given. For some time the subject was encouraged to report her dreams. Further investigation disclosed that in the trance state she had an adequate understanding of her dreams as indirect recoveries of trance memories. However, specific hypnotic instruction had to be given for her to recall in the waking state both the trance experience and the dream revival of it before she could go through a slow process of fusing them into a single understanding.

In summary, this hypnotic subject developed spontaneous amnesia for trance experiences but spontaneously recovered that amnesic material in the form of dreams. She thus had a complete amnesia for one experience (trance) and a full awareness of an entirely different kind of an experience (dream) with an identical content.

Example 4. Another subject was found who reviewed in her dreams many events of the trance session. She was aware, however, of the nature of her dreams and purposely utilized dream activity to overcome hypnotic amnesia. Her explanation was that she had an intense curiosity about what occurred in trance, but her hypnotic amnesia had constituted an effective barrier until she spontaneously dreamed about a trance session

and recalled the dream the next morning. In reviewing the dream she became aware that it was a valid recollection of trance events. Thereafter, whenever she wished to know what she had done in a trance state, she circumvented the hypnotic amnesia by dream activity.

Further investigation disclosed that her dreams were much less extensive than the first subject's, and that the dream content related only to those things of most interest to her. When this was pointed out to her by having her read a complete stenographic account which contained much material she did not recall, she responded that night with a more extensive dream. In this dream she recovered approximately all of the details of another trance experience.

The behavior of these subjects who circumvented hypnotic amnesia by dream revivals is most informative. It strongly suggests that neuro- and psychophysiological processes of normal sleep can be employed as a medium by which to gain access to experiences not available to the waking state. Hence, the assumption seems justified that extensive neuro- and psychophysiological processes are involved in hypnosis and in hypnotic amnesia.

Amnesia by the Displacement and Distortion of Memories

Example 5. This example concerns an investigation of suggested hypnotic amnesia in an informal setting. The subject, in a deep trance, was instructed that after awakening he was to smoke a special Russian cigarette which would be furnished at a given cue. Upon lighting the cigarette he was to join enthusiastically in the general conversation with those present. Upon finishing the cigarette he was to extinguish the butt and then develop a complete amnesia for all occurrences between the giving of the cue and the discarding of the cigarette.

This sequence of events developed as intended, and notes were made of the subject's behavior and the topics of conversation. For some minutes after disposing of his cigarette the subject seemed to be self-absorbed. These few minutes of self-absorption may be understood as a spontaneously generated posthypnotic trance (Erickson & Erickson, 1941), which was required for the profound neuropsychological changes to effect the suggested amnesia. Then, suddenly, he joined in the conversation of the group. Shortly the topic of smoking was raised, the subject was questioned about his habits, and then, in a progressive and systematic fashion, he was questioned more and more closely about the events of the presumably amnesic period.

At first no evidence of any recollections could be secured from him, but after some 30 minutes of insistent questioning with extensive use of the notes made, particularly those relating his expressed opinions on controversial topics, the subject suddenly began to recover his memories of the entire period. When an adequate recall finally had been obtained, he was asked to account for his previous failures to recognize items that had suddenly become familiar. He proceeded by offering various rationalizations and then began to insist, with obvious sincerity, that he had not experienced amnesia at all. He claimed he had merely simulated it by evading questions, misunderstanding remarks, and

by deliberate suppression. Checking these assertions against the notations that had been made of his actual behavior, however, suggested the probability of a retrospective falsification.

The experiment was then apparently discontinued, and more than an hour was spent in casual conversation on other topics. Finally references were again made to the events of the amnesic period. It was immediately apparent that the subject was confused by such references, and he was again amnesic for the entire period between lighting and extinguishing his cigarette. This second amnesia also included the questioning that led to the breakdown of the original amnesia and all his assertions and rationalizations about it.

The subject now believed that on another occasion three months earlier, in a different social group (that included only one of the present group) and under entirely different circumstances, he had smoked a Russian cigarette while discussing the conversational topics about which he had just been questioned. Extensive inquiry about this new belief disclosed that the content of the amnesic experience had been displaced in time and setting; it had been interpolated into an older and different experience. In this new belief the subject could not be shaken.

In summary, this subject developed an extensive amnesia, recovered the amnesic material under mass social stimulation, and then unaccountably developed another amnesia that included both the original material and the associated experience of recovering it. He then recovered the original amnesic material through a total displacement of it onto an entirely different past experience.

On the surface this subject's amnesia sounds a bit like hypnotic "source amnesia" (Evans & Thorn, 1966), wherein the subject can recall material learned in trance but forgets that he learned it under hypnosis. Source amnesia has been frequently contrasted in the recent research literature with the more conventional "recall amnesia." In one unusually protracted period of naturalistic observation Erickson explored the dynamics of both recall and source amnesia; he made an extensive effort to discern exactly what happens to the amnesic material and some of the factors effecting its recall.

Example 6. This man, 25 years old, of superior intelligence and decidedly capable as a hypnotic subject, had been used on many occasions for both experimental and demonstration purposes. After extensive experience he developed the firm belief, expressed privately to others rather than Erickson, that hypnotic amnesia was entirely a matter of voluntary suppression of memories and of deliberate redirection of attention to other thoughts. In support of this conviction he frequently recalled and related secretly to his friends accounts of his trance experiences. Chance discovery by Erickson of this practice suggested the possibility of naturalistic investigation of hypnotic amnesia free from the handicaps and limitations of an artificial laboratory setting and the distortion of results that might arise from purposeful cooperation by the subject.

Accordingly, arrangements were made with his friends to report in detail to Erickson any of the subject's accounts of his trance experiences. These could then be checked against

the original complete stenographic record usually made of this subject's hypnotic work, sometimes without his knowledge. Most of the 23 observers who participated in this study were college-educated, and in addition the majority were trained in psychology, medicine, or psychiatry.

The findings obtained by this procedure varied greatly as a function of the associative situations, the subject's relation to the observers, and the intrinsic interest the subject had in the trance experiences. Time itself did not seem to be important, and the type of material, whether emotional or nonemotional, did not seem to have any remarkable effect. For convenience the results will be discussed under seven headings.

1. Recall of trance events dependent upon associative situation.
While often a remarkably complete account of a hypnotic session could be obtained, it was found that the completeness of this depended upon certain factors. The closer the subject was to the trance situation in the matter of associations, the more extensive was the account. The most extensive accounts were obtained by observers present or believed by the subject to have been present at the time of the trance, and when the subject was interviewed in the actual physical setting in which the trance state had been induced and the trance behavior elicited. An account secured in the same room where the trance had taken place was more complete than one secured in a similar room. The same building permitted a more adequate account than a totally different physical setting; similarly, observers actually present during the trance were given more complete accounts than those not present. Time itself, within reasonable limits, did not seem to be a significant factor. Furthermore, an account elicited in the physical setting of the trance situation by an observer present at that time could not be secured in the same detail subsequently by the same observer if the questions were repeated in a situation other than the trance setting. Yet, upon return to the trance setting the same observer could obtain a repetition of the first detailed account. Repeated efforts served to confirm this observation.

2. Variation in recall with different observers.
Accounts given to different observers separately often varied extensively in details. When a repetition of an account was called for in the presence of two or more observers to whom the account had already been related separately, there was usually a recovery of still further material but without awareness that more was being related. Occasionally, however, the account would be definitely abbreviated and the subject would not remember details previously related to one or the other or both of the observers separately. The subject was not aware of these discrepancies. There were frequently omissions which seemed to be definitely associated with one or another of the observers. In the presence of certain persons the subject seemed to be unable to recall certain items readily accessible in the presence of other persons.

3. Substitution of detailed partial accounts for total recall.
Another frequent finding was the substitution of an extremely detailed recollection of minor details for a comprehensive account of the total trance events with no realization by the subject that other activities had occurred. For example, a remarkably vivid detailed

account was given of a checker game with no apparent evidence of awareness of the wealth of other activities that had preceded and followed the checker game.

4. Telescoping of two or more events or sessions.
Often the events of several different trance sessions, separated by as much as a period of a week, would be recounted as the narrative of one single trance session. Especially was this true when the trances had been induced in the same general physical setting. For example, in telescoping into a single account the events of two separate trances, the subject described his activities in relation to two persons. His account of the actual activities was accurate in all details, except for the fact that one of the two persons had left the hospital a week before the other had arrived, hence his account placing them together in the same room was obviously inaccurate. Confronted with this fact the subject slowly realized its truth but nevertheless continued to "remember clearly" making certain remarks to one of them and making other remarks to the other sitting in an adjacent chair. Checking of the original records disclosed that he had made the remarks he claimed and that he did remember correctly the chairs which had been occupied and their relative positions. Despite earnest effort on his part he was not able to reconcile his "memories" with his knowledge of the actual facts. This distressed him seriously and resulted in an apparently total amnesia for both the trance sessions. Numerous instances of this occurred repeatedly.

5. Failure to distinguish between hallucination and fact.
Another distortion of marked interest was the substitution of hypnotically suggested hallucinations for factual items. A typical example was when a footstool was presented to the subject while in trance with much elaborate description as a rocking chair which was finally offered him as his seat for the rest of the session. Near the close of the session care was taken to offend him slightly as a measure of arousing antagonism that would tend to preclude the development of hypnotic amnesia. This was followed shortly by insistent commands that he develop a total amnesia for all events of that session. Some days later, with much pleasure, he related to his friends an adequate account of the entire session with the one major inaccuracy that the footstool was described as an actual rocking chair, an understanding from which he could not be shaken.

Similarly, in another trance session he was induced to hallucinate a colleague of Erickson's entering the room, borrowing a book, and then leaving. Subsequently, in recounting the events of the trance, he related this as a factual occurrence. The measure of repeating this procedure by having him hallucinate various colleagues who were on vacation at the time led to several more instances of hallucinatory experiences reported as factual occurrences. Confronted by this fact on one occasion he became distressed and confused, offered various rationalizations, and finally developed an apparently total amnesia for the trance events and for the waking experience of having given an account of them.

Much later he was again hypnotized and inquiry made into one such instance. The subject recalled the whole experience and the original suggestions. He was distressed by Erickson's detailed knowledge of his posttrance behavior, but cooperated by explaining that at the time he had related the story to his friends, he had believed fully in its truth. When they confronted him with the facts, he had at first been very much puzzled and was unwilling to think about the matter further, and then forgot the entire thing. He explained further that as he now viewed the matter, the hallucination had been so clear and vivid that he had, in the original trance, forgotten all about the experience of having the hallucinations suggested to him. Hence, in relating the trance events to his friends he had not recalled those original suggestions because they were doubly forgotten—that is, forgotten in the original trance state and then forgotten a second time in consequence of the hypnotic amnesia.

6. Persistent amnesia for certain trance experiences.
Although the subject demonstrated an ability spontaneously to recover memories of many trance experiences, sometimes all of those belonging to a single trance session, there were numerous instances where he failed to recover certain memories. On these occasions simple or leading questioning would serve to assist him materially in recovering the forgotten items. However, there were many instances of persistent amnesia for certain trance events that did not yield to any of the measures employed to facilitate recall. Even relating the amnesic material to the subject would not elicit recognition from him. Some of this persistent amnesic material was emotional in character, but just as frequently it seemed to be entirely neutral.

The only measure that was at all effective in these instances was rehypnosis and questioning about the forgotten material. Invariably he would readily recall it in the trance state. After awakening and relating the events of this second trance, he might gain access to the previously inaccessible memories. Sometimes, however, he would remember all of the trance events except those concerning the previously inaccessible memories, and thus there would continue a persistent, conscious amnesia despite his ability under hypnosis to recover all forgotten material.

7. Development of amnesia after full recall while awake.
Another frequent observation was that after having awakened and related his memories of a trance session, he would spontaneously develop an amnesia for both the trance events and the fact of having related them. An illustrative instance of this phenomenon with another subject was reported above as Example l.

Structured Amnesia (Amnesia by Reorientation in Time)

Example 7. While Erickson was carrying on an experimental study, a 27-year-old female interne volunteered her services as a hypnotic subject. Her offer was tentatively accepted with the explanation that the experiment might require too much of her time and hence preclude her participation. An appointment was made to meet her in the laboratory where she could avail herself of books to pass away time until Erickson's experimental work permitted him to see her. She kept the appointment and read until Erickson was free. She

then proved to be a most capable subject, and in the hypnotic trance full arrangements were made with her to report regularly at the laboratory for the experimental work, which would continue over a period of many weeks. At that time and on all subsequent occasions she was instructed to have a posthypnotic amnesia for all events of the trance sessions.

She kept all appointments, usually arriving about a half-hour early and devoting the waiting period to study. *When the time came to hypnotize her, use was made of a posthypnotic cue to induce the trance while she was reading. When the experimental work was completed, she was always returned and awakened carefully at the same desk where she did her reading and waiting for the experimental session to begin.*

Then one day in the staff dining room mention was made of a new hypnotic subject with whom Erickson hoped to work. Immediately she burst into an infuriated tirade, the burden of which was that a long time ago she had volunteered her services, that she had been put off with an evasive answer by Erickson, and that no effort of any sort had been made to utilize her services which she had offered in good faith. She declared that the least Erickson could have done was to offer her some explanation of why he did not consider her worthwhile as a hypnotic subject. Since this outburst of temper was not understood, and since another hypnotic session was scheduled for that afternoon, no explanation was offered her. Furthermore, it was considered undesirable to give her an explanation because it might interfere with the experiment in progress.

That afternoon she appeared at the laboratory at the proper time, was decidedly short in her greeting of Erickson, and continued to read the book she was studying. However, at the posthypnotic cue she developed a deep trance, and the experimental work was continued. No effort was made to explore the situation. For an additional two weeks she was seen regularly for experimental work. During this period of time she continued to be unfriendly and resentful in her attitude toward Erickson in social situations.

When the experiment was completed, however, inquiry was made in the trance state concerning her outburst of temper and her unfriendly attitude toward Erickson. Her explanation was simple. She stated that she had no unfriendly feeling or resentment toward Erickson while she was in the trance because she knew that she was participating in the experiment. However, when she was awake she knew nothing at all about the experiment or the fact that she was contributing, hence she believed fully in the waking state that her offer had been disregarded. Therefore, she was left in the uncomfortable position of believing in the waking state that she was not acceptable as a hypnotic subject, and there was nothing she could do to correct this misunderstanding because of the posthypnotic suggestion of amnesia for all trance events. When she was asked what she wished Erickson to do, she stated that she felt all explanation should be postponed until the experimental work was completed, since, obviously, Erickson felt it unwise to apprise her of the actual situation. She was asked if she wished Erickson to give her a full explanation upon the completion of the experiment or if it would be better to let events follow the natural course of development. After thinking this over, she suggested that the latter course might be the better to follow. She was again dismissed in the usual way.

Her unfriendly attitude toward Erickson continued for another two weeks, when again she lost her temper in another situation similar to the first. With many apologies Erickson attempted to explain the total situation to her. She was most critical of the explanation and rejected it completely. She declared that she knew that she had never been hypnotized, and she explained her regular appearances in the laboratory as resulting from her self-imposed course of study. The only significant admission secured from her was the statement that she felt she had gained very little from her studies despite the great amount of time she had spent, and she explained Erickson's invariable presence there as coincidental and as not related to her.

When finally it became apparent that no amount of argument or discussion could correct her understandings, a suggestion was offered that a trip to the laboratory and an examination of the experimental records might serve to prove to her that she had been acting as a subject. She denounced this suggestion as a futile, useless proposal but finally consented to examine Erickson's records. These she was shown in full detail. Thus, she was forcibly convinced that she had been acting as a subject over a period of many weeks. However, as she explained, this knowledge, while acceptable as factual, did not give her any feeling of inner conviction that she had been a subject. She then asked that she be hypnotized so that she could learn if she could be hypnotized. She also suggested that use be made of hypnotic suggestion to convince her of the facts of the total situation.

She was promptly hypnotized and then instructed to abolish the posthypnotic amnesia and to recall in chronological order the entire course of events for which she had developed an amnesia. Upon awakening a casual conversation was initiated during which she was reminded of her temper outbursts. Then she was asked to give an account of any memories that she might recover. To her great amazement she experienced a sudden flow of recollections and associations, which she related in detail. These were discussed fully with her.

The reason for this deep experience of hypnotic amnesia will be lost on the uninitiated reader who does not understand the significance of the italicized material in the second paragraph. This italicized procedure was instrumental in effecting a carefully "structured hypnotic amnesia." The literature on hypnotic amnesia generally classifies two basic types according to the manner in which they are generated-spontaneous and suggested. Erickson is here utilizing a third way of generating hypnotic amnesia: *The structured amnesia is effected by awakening the subjects in a manner that reorients them to the exact place, time, and associative content of consciousness where they were when they entered trance*. The total situation is so structured that the trance period falls into a lacuna between two events structured to be so identical that consciousness does not recognize them as two and is thus amnesic for all that occurred between them. Erickson (1964) has described it as follows: "This measure of reorientation in time by reawakening trains of thought and associations preceding trance inductions, in this author's experience, is far more effective in inducing posthypnotic amnesia than direct forceful suggestions for its development. One merely makes dominant the previous thought patterns and idea associations [p. 299]." Because the subject may have a feeling of duration or the passage

of time (Erickson, Haley, & Weakland, 1959), even though amnesic for events, it would seem that the more general term *structured amnesia* is a more accurate description than *reorientation in time*.

AMNESIA BY INTERRUPTING THE SPONTANEOUS POSTHYPNOTIC TRANCE

This category is another of Erickson's original methods of evoking hypnotic amnesia. It is mentioned here only for the sake of completeness but will not be illustrated since it has already been adequately described (Erickson & Erickson, 1941). In brief, Erickson has established that the execution of a posthypnotic suggestion spontaneously evokes a brief hypnotic trance while the posthypnotic act is taking place. If subjects are interrupted and prevented from executing the posthypnotic act, they remain in trance, and this posthypnotic trance can be utilized to interpolate new hypnotic work. Subjects are then allowed to complete the original posthypnotic act and then awaken with a spontaneous amnesia for the interpolated events.

THE ALTERNATION OF HYPNOTIC AND NATURAL AMNESIA

Example 8. A patient under therapy for a personality problem was found to have an extensive amnesia for a significant life experience. Exploration in the hypnotic state finally elicited a complete account of that experience, as was subsequently verified. When she was awakened from the trance, however, she continued to be amnesic for that experience and also for the fact of having recovered the memory of it while in the trance state. This occurred despite the fact that in the trance state she had reacted to the recovered material with much emotional intensity.

When progress of the therapy permitted, systematic suggestions enabled her to recover her memories of that trance experience in full. She gained access to the details of the forgotten experience, but she recovered that amnesic material as an account of what she had recollected in the trance rather than an actual memory from the past. She recognized the trance experience as unquestionably true, and she was able to add further details about it while in the waking state, but it still had no vital meaningful significance to her except as a recent trance experience of recalling something she knew to be true but which she could not recognize emotionally as really belonging to her past life.

Rehypnotized, she again recalled the past experience as a vital occurrence in her life and was greatly distressed emotionally by it. Reawakened, she had an amnesia for this second trance but recalled having been awakened from the first trance and recollecting the experiences belonging to it. Her problem then became, as she verbalized it:

> What I have really got to do now is to remember that it happened when it did and not remember it just as something I remembered about when I was in a trance. Right now, it's just something that I recall remembering about even though I really know that it must all have happened. But knowing that it must have happened doesn't make that experience mean anything to me. It's just like reading

> something about yourself that you know is true but which you have just completely forgotten. In the trance, I knew it did happen, that's why I cried so. But now when I'm awake, all of it is just something that I remembered in the trance, and that's all it is.

When further therapeutic progress had been made, it became possible for the patient to recall the forgotten experience while in the waking state and to react to it emotionally as she had originally in the trance state. This waking recollection, however, was accompanied by a spontaneous amnesia for all developments centering around recall in the first trance. There was thus a spontaneous alternation of hypnotic and natural amnesia.

Subsequent to her recovery, rehypnosis disclosed her to have a full understanding of all that had occurred. She now reported her feeling that only the waking account had been of sufficient importance to warrant recalling. The two previous trance recollections were regarded simply as preparatory measures in which she had been enabled to assemble all of the forgotten data and to prepare herself for a waking recollection.

This is a frequent finding in hypnotic therapy. Amnesic memories may be recovered in the trance state and reacted to at the time, but the total experience of this does not carry over into the waking state. When, subsequently, the patient recovers the amnesic material in the waking state, preliminary trance activity becomes unimportant to the personality and is not recollected. As one patient explained:

> It's like baking and serving a cake. You remember doing that, but you never bother to remember about studying the recipe, mixing the batter and that sort of thing. All of that's very important, probably even more important than serving the cake, but you just remember that you served the cake that you baked. It's the same way when it comes to remembering forgotten things in a trance. When you had me remember while I was asleep those things I had forgotten, I suppose I was just getting them in order, and arranging them, and getting all set so that when the right time came when I was awake I could give them out. Then, when I remembered them when I was awake, just getting them ready to remember wasn't important any more so I just forgot about what I did in the trance just like you forget which bowl you mix an important cake in.

To summarize this account briefly, the patient originally had an amnesia of spontaneous origin for a traumatic experience. In hypnosis the factual data were recovered, but the patient awakened with no recollection of the trance work. When the amnesia for the trance activities was abolished in another trance, she recovered the factual memories of the past experience and recognized their validity, but found that they lacked all meaningfulness to her as a personality. When she later recovered in the waking state the same amnesic material as a personally meaningful past experience, she developed a secondary amnesia for those previous trance activities in which she had first recalled the amnesic material. In clinical practice it is frequently found that a spontaneous amnesia

develops for trance work after the memories originally recovered in trance are integrated in the conscious personality.

That hypnotic amnesia and amnesia as naturally experienced are two entirely different phenomena is strongly indicated by the observations reported in this example. There can exist simultaneously, but totally independently of one another, two types of amnesia for the same items of fact. The abolition of one of the two amnesias had no effect upon the other, and each had to be recovered as a separate experience. This is an observation of much significance in relation to many failures of hypnotic psychotherapy. It is not enough simply to recover amnesic material in trance. Such trance work is often only preparatory to the full integration of the material by the conscious personality in the awake state.

THE "STATE-BOUND" NATURE OF HYPNOTIC AMNESIA

Taken together these clinical and naturalistic investigations strongly suggest that hypnotic trance is an altered *state* of consciousness and amnesia, in particular, is a natural consequence of this altered state. Recent research in "state-dependent learning" lends experimental support to the general view of all amnesias as being "state-bound." We can now understand hypnotic amnesia as only one of a general class of verifiable phenomenon rather than a special case. Fischer (1971) has recently summarized the relation between state-dependent learning and amnesia as follows:

> Inasmuch as experience arises from the binding or coupling of a particular state or level of arousal with a particular symbolic interpretation of that arousal, experience is state-bound; thus, it can be evoked either by inducing the particular level of arousal, or by presenting some symbol of its interpretation, such as an image, melody, or taste.
>
> Recently, some researchers had 48 subjects memorize nonsense syllables while drunk. When sober, these volunteers had difficulty recalling what they had learned, but they could recall significantly better when they were drunk again. Another scientist also observed amphetamine-induced excitatory, and amobarbital-induced, "inhibitory," state-dependent recall of geometric configurations. His volunteers both memorized and later recalled the configurations under one of the two drugs. However, while remembering from one state to another is usually called "state-dependent learning," extended practice, learning, or conditioning is *not* necessary for producing "state-boundness." On the contrary, a single experience may be sufficient to establish state-boundness.
>
> Deja vu experiences and the so-called LSD flashbacks are special cases of the general phenomenon of state-boundness. Note that neither focal lesions nor molecules of a hallucinogenic drug are necessary for the induction of a flashback—a symbol evoking a past drug experience may be sufficient to produce an LSD flashback.

> It follows from the state-bound nature of experience, and from the fact that amnesia exists between the state of normal daily experience and all other states of hyper- and hypoarousal, that what is called the "subconscious" is but another name for this amnesia. Therefore, instead of postulating one subconscious, I recognize as many layers of self-awareness as there are levels of arousal and corresponding symbolic interpretations in the individual's interpretive repertoire. This is how multiple existences become possible: by living from one waking state to another waking state; from one dream to the next; from LSD to LSD; from one creative, artistic, religious, or psychotic inspiration or possession to another; from trance to trance; and from reverie to reverie [p. 904].

We would submit that hypnotic trance itself can be most usefully conceptualized as but one vivid example of *the fundamental nature of all phenomenological experience as "state-bound*." The apparent continuity of consciousness that exists in everyday normal awareness is in fact a precarious illusion that is only made possible by the associative connections that exist between related bits of conversation, task orientation, etc. We have all experienced the instant amnesias that occur when we go too far on some tangent so we "lose the thread of thought" or "forget just what we were going to, do," etc. Without the bridging associative connections, consciousness would break down into a series of discrete states with as little contiguity as is apparent in our dream life.

It is now a question of definition and further empirical work as to whether these states are discrete and different in mental content alone or whether more gross physiological indicators can be used in defining them. A drug obviously introduces a physiological change that may or may not be measurable with current techniques. With hypnotic trance the case is more equivocal. The case is further complicated by the fact, as Fisher indicates above, that once an altered state is produced, "symbolic" associations alone are sufficient to reinduce it.

How can we reconcile this special state theory of hypnotic trance with the many informative experimental studies which support the alternative paradigm (Barber, 1972) of hypnosis as a "responsive waking state" that is not discontinuous or essentially different from normal ordinary consciousness? In many of his papers Erickson (1939, 1952, 1966) has emphasized that deep or really satisfactory trance experience is dependent upon the ability to subordinate and eliminate waking patterns of behavior. To achieve this end Erickson evolved many new techniques of induction and stressed the need for careful "hypnotic training" whereby the individuality of each subject was carefully taken into account to maximize the presence of involuntary or autonomous behavior in trance with as little participation of waking patterns as possible. Erickson rarely gives therapeutic suggestions until the trance has developed for at least 20 minutes, and this only after hours of previous hypnotic training.

In actual practice it is admittedly difficult if not impossible to eliminate *all* waking patterns. This is particularly true in the typical experimental study, where standardized instructions and direct suggestions are utilized with little or no extensive hypnotic

training directed to the elimination or at least the mitigation of waking patterns in trance. The presence of many verbal, sensory, perceptual, and psychodynamic associations common to both the trance and waking situation in most experimental studies bridges the gap between them and further reduces their discontinuity. We would therefore submit that the alternative paradigm, which views the trance and waking conditions as more or less continuous, with no evidence of a "special state of trance," is correct in evaluating the typical experimental situation. It does not, however, adequately conceptualize those clinical situations where the skill of the therapist together with the needs of the patient interact to produce the striking discontinuities between trance and the normal state of consciousness that are so suggestive of special state theory.

The issue is analogous to the heated controversy about the fundamental nature of light as continuous (waves) or discontinuous (bundles) that plagued physicists of the past generation. In practice it has been found helpful sometimes to think of light as waves and other times as bundles. The most adequate conceptualization, however, is through mathematical symbols that cannot be meaningfully related to in terms of everyday associations on the verbal and imagery level. Likewise in clinical practice it may be helpful to conceptualize and stress those antecedent and mediating variables that promote discontinuity between trance and waking state, while in experimental work there may be more theoretical interest in dealing with the continuities.

UTILIZING AMNESIA IN HYPNOTHERAPY

The practical problem of coping with the bridging associations between trance and waking state takes us directly to Erickson's utilization of amnesia to facilitate the effectiveness of hypnotherapeutic suggestion. As implied in our earlier discussion of the superiority of indirect over directly administered suggestions, the basic problem of securing reliable results from suggestions is to "protect" them from the doubting, debating, and potentially negating effects of the patient's conscious sets and attitudes. Patients are patients because of the erroneous and rigid sets that govern their maladaptive behavior. By administering suggestions indirectly so they are not recognized by consciousness, the suggestions are able to enter the patient's preconscious and/or unconscious and are there utilized in an optimal manner for the patient's overall development. Hypnotic amnesia is thus a convenient approach for coping with consciousness and protecting therapeutic suggestions from the limitations of the patient's conscious sets. Hypnotic amnesia effectively breaks the bridging associations between the trance and waking situation and thus seals hypnotic suggestions from the potentially negating effects of the patient's conscious attitudes (Erickson, 1954).

Literalness: An Experimental Study

Milton H. Erickson

Unpublished manuscript, circa 1940s.

A form of experimental inquiry, simple in character and effective in eliciting remarkably different results from waking and from hypnotized subjects, has been carried on over a period of more than 25 years on many hundreds of subjects. The experiment was based originally upon the observed literalness of hypnotic subjects when responding to instructions, questions, or suggestions. Such literalness of response is decidedly infrequent in everyday living—when it does occur then is suspect of being a deliberate play, as it often is. Innumerable persons were asked in the ordinary waking state such questions as: "Do you mind telling me your name?" "Do you mind standing up?" "Do you mind reading this?" (handing them a card bearing a typed sentence such as, `This is a nice day.')" "Do you mind taking a step forward?" "Do you mind sitting in this other chair?" The usual response received from subjects in the ordinary waking state—whether friend, acquaintance, or even a total stranger—was almost always an acquiescence to the *implication* of the question, not a simple reply to the actual question. Thus, the awake subject would actually say his name, stand up, read the card, or whatever. In exceptional cases the response might be a challenging, "Why should IT" or an obvious rejection such as "I don't want to," or an ignoring of the request, usually with a questioning or doubting facial expression.

Comparable questions with dozens of hypnotic subjects led almost invariably to a simple verbal affirmative reply *without any movement to acquiesce to the behavioral implications of the inquiry*. This was particularly true with somnambulistic subjects, somewhat less so with medium subjects, and slightly less so with subjects in the light trance. On rare occasions the reply would be complete inaction, explained upon request by the statement that they were comfortable as they were or that there was no need to do so. On the other hand, the waking subject would explain a negative response with the challenging, "Why should IT" or "I don't want to," or "It doesn't make sense to do that."

These repeated findings suggested the possibility of establishing the fact of a recognizable difference between waking and hypnotic behavior *without corrupting the experimental investigation by disclosing to the subjects that an experiment was being performed by a testing of specific behavioral responses or by asking for deliberate simulation of behavioral responses or any other intentional or planned distortion of experimentally elicited responses*.

With the formulation of this experimental inquiry, the project was carried out with many hundreds of subjects in the ordinary waking state.
These subjects fell into one of the following categories:

(1) Those who had never been hypnotized and never were subsequently by the experimenter.
(2) Those who had never been hypnotized, were used as subjects, and subsequently were hypnotized and used as subjects.
(3) Those who had been hypnotized previously and were used as subjects, sometimes first in the waking state, and next in the trance state, and equally often by a reversal of this order of procedure.
(4) Those who had been tested on the same occasion for both types of behavior, sometimes first in the trance, sometimes first in the waking state.
(5) Those who had been tested in one or the other states first on a separate occasion with a following completion of the inquiry at a later date.
(6) Those who were tested singly or in group situations, under both private and public circumstances, and in group situations where all present were hypnotic subjects but not necessarily all in a trance at the time.

The age distribution ranged from four to 80 years, and age was not found to be a factor. The sex distribution was essentially equal, and no sex differences were found. The subjects employed included Japanese, Chinese, Filippino, Hindu, Hawaiian, Indian, Negro, Caucasian, and such ethnic groupings as native Americans, Mexicans, Venezuelans, Scandinavians, Germans, English, French, etc. The one thing in common was that they understood English, some less well than others, but all subjects gave comparable results.

The educational levels ranged from grade school to doctoral degrees.
Psychiatric patients, some of whom were psychotic but most of whom were neurotic, were employed. The results from this group were comparable to those from subjects not receiving psychiatric care. There were also inmates of penal institutions, but none of these varied from the ordinary population except for a greater number showing challenging non-compliance. Of these, more males than females were tested, but there were no recognizable differences except that there was less open aggressiveness on the part of the women.

As would be expected, total strangers were the most uncooperative. For example, a total stranger approached in an airport and asked, “Would you mind standing up?” could readily reply, “And what business is it of yours if I sit down or stand up?” The social ice thus engendered could easily be broken by the plausible statement, “I’m a physician, and my hobby is visually comparing sitting and standing heights, and if you ask people informatively, they invariably sit higher and stand higher instead of more naturally.” Such an explanation usually led to ready compliance with the implications of the original request, but since the response was actually to the explanatory statements, it would not be included in the experimental results except as a rejection.

In the early years of the experimental study exact records were kept of age, sex, education, occupation, hypnotic history or sophistication, and experimental setting, but as the data accumulated it became progressively apparent that the important factors in the

experiment were (1) the state of ordinary waking awareness and (2) the existence of a hypnotic state. The results were enhanced by increasing depths of the trance state.

In all about 4,000 subjects were employed, of whom approximately 1,800 were in a hypnotic state. The greater number of nonhypnotic subjects arises from the fact that many subjects were employed who never became hypnotic subjects. However, it must be borne in mind that these two groups, nonhypnotic and hypnotic, are not mutually exclusive, since many subjects were used for both hypnotic and nonhypnotic experimentation. The reason for this was that behavioral differences between waking subjects and hypnotic subjects were found to be directly in accord with the existing state of awareness at the actual time of the experiment, whether hypnotic or waking. Previous experience with hypnosis had no bearing on the results. Subjects showing the typical waking response would subsequently manifest the typical hypnotic response, then again the waking response, and then again the hypnotic. The exceptions were those who were sophisticated in hypnotic behavior. Thus, a physician used first as a hypnotic subject gave the characteristic response and later the usual waking response. Shortly after the waking test he exclaimed in a startled fashion, "Doesn't that beat all? I was caught by the very test I use myself to see if my patient is in a trance." (Comment will be made on this later.)

Undoubtedly a major factor in the success of the experimental study was the fact that the test was always used as an extremely minor part of some other attention-commanding task. Thus there was no opportunity or occasion for direct critical thinking or analysis. For both hypnotic and nonhypnotic subjects, with the exception of total strangers, there was the implication that the experimental request was preliminary to some other more important task that was expected to follow.

The method of procedure was essentially the same for both waking and hypnotic states in a great variety of situations and under many different sets of circumstances. Also, the actual experiment was not always carried out by the experimenter but would be done at his secret request by a colleague who did not know the purpose. Perhaps the best example to illustrate the procedure is the following: At a lecture gathering, topic unannounced, the request would be made quietly of various people, "Would you mind telling me your name?" or "Would you mind standing up for a moment?" or "Would you mind sitting in that other seat?"

A lecture on therapy for the neuroses might then be presented with carefully calculated remarks leading to the introduction of the subject of hypnosis. This would lead to an offer to demonstrate hypnosis with several volunteers. Upon the induction of a trance, precisely the same questions would be put to the subjects as had been put to the members of the audience in the waking state. This would be done in a manner inaudible to the audience, and then the same questions would be directed to members of the audience not previously so questioned. Then the questions would be repeated to the subjects, this time so as to be audible to the audience.

Immediately the audience would become aware that the affirmative verbal response of the hypnotic subjects without responsive action was markedly different from the possibly wondering but silent responsive behavior of the waking subjects, who had promptly acted upon the implications of the questions rather than verbally offering a simple yes or no, as had the hypnotic subjects.

It was soon learned that even after this had been demonstrated, unexpected repetitions with the audience would elicit either complete or partial execution of the implied response before there would be realization of what was happening and consequent self-conscious inhibition of the acquiescent behavior.

It was also learned that somnambulistic subjects in full visual and auditory rapport with the audience could describe what waking persons did when so spoken to but did not apply that understanding to their own conduct when so addressed.

Nor did it invalidate findings to let the audience observe the behavior of both waking and hypnotic subjects without discussing it and then call upon observers who had been employed as waking subjects to act as hypnotic subjects. While they had observed behavior of others in both waking and trance states, and had so responded themselves in the waking pattern before trance induction, they had drawn no understandings or inferences of a governing character from what they had observed. In the trance state, they gave hypnotic responses, but in subsequent waking states, they continued to give waking responses. Nor did intellectual sophistication of hypnotic subjects serve to alter their characteristic behavior, but repetitions and instructions in the trance state would institute ‘ the waking pattern of behavior.

As the experiments continued over the years, it was progressively confirmed that by making the experimental inquiry an incidental, minor, and hence unnoticed part of a larger activity, there could be a study of behavior in either the waking or the hypnotic states without the response in the one state of awareness influencing the behavior in the other state of awareness. Situations reasonably expected to lead the subjects to become sophisticated and thus to inhibit the natural response failed to do so completely. For example, the physician cited above, as well as other subjects subsequently employed repeatedly, invariably made a partial response before self-consciously inhibiting the waking responsive behavior. Yet, the physician continued to use this measure as a means of determining the presence of a trance successfully and knowingly.

THE RESULTS

The following table does not give the total number of responses, since tabulation was discontinued when the consistency of results had been repeatedly noted. The experiment was continued as a testing measure with the hope of securing data on other aspects of hypnotic behavior, and the noting of data not in accord with that already recorded was not laborious. In other words, a greater proportion of variant responses were recorded than of the single positive results. This fact in no way significantly alters the overwhelming character of the positive data.

FIRST-TIME RESPONSES[1]

Waking State		*Hypnotic State*	
	Light Trance	**Medium Trance**	**Deep Trance**
3,000	**350**	**300**	**250**

SECOND-TIME RESPONSES[2]

Waking State		*Hypnotic State*	
	Light Trance	**Medium Trance**	**Deep Trance**
1,800[3]	**350**	**300**	**250**

The experimental results may be classified as follows:

WAKING STATE

1. Acquiescence by executing the implied request	95%
2. Challenge (Why should I?; Is it necessary? etc.)	3
3. Rejection (by ignoring or a direct negation of the implied action)	2

HYPNOTIC STATE

Light Trance:

1. An utterance of "no" or a negative shaking of the head.[4]	80
2. The question of "Do you want me to?" or a comparable inquiry.	12
3. Answer of "I don't want to" or its equivalent	3
4. Hesitant, sluggish, inadequate effort to acquiesce to implied question.	3
5. Slow, uncertain, but actual acquiescence.	2

Medium Trance:

1. An utterance of "no" or a negative shaking of the head.	90
2. The question of "Do you want me to?" or a comparable inquiry.	1
3. Answer of "I don't want to" or its equivalent.	2
4. Hesitant, sluggish, inadequate effort to acquiesce to implied question.	1
5. "Can't."	1

Deep Trance:

1. An utterance of "No" or a negative shaking of the head.	97
2. The question of "Do you want me to?" or its equivalent.	2
3. No response.	2

Occasionally a light- or a deep-trance subject would say, "Can't," and an occasional deep subject would say, "I don't want to," "I'm fine," or a comparable response.

Special further experimental study was conducted with a large number of both types of subjects to determine the effect of repeated experimental trials—as before, these trials were an incidental part of a much larger activity. It was learned that the experimental procedure could be repeated indefinitely, the only adverse result being that the waking

subject became too alertly interested or annoyed. There was no such effect upon the hypnotic subject unless the questions were put in rapid succession too many times. Then there would be acquiescence.

Direct sophistication by explanation of their behavior to subjects with no instructions concerning the response they were then to make resulted in a voluntary, usually embarrassed inhibition of the usual response in the waking subject and an effort to duplicate the hypnotic subject's precisions of literal response. Unless fully attentive and alert, however, waking subjects tended to make their natural response. This was not so with the hypnotic subjects, who continued with their own typical response until definitely instructed otherwise. Then they would easily and naturally respond in the same manner that characterized the unsophisticated waking response. It was also learned that sophistication of the hypnotic subject could come from long, continued hypnotic work, particularly when the subject in a trance studied the hypnotic behavior of other subjects.

The experiment had been set up originally as an incidental part of a major activity for the purpose of concealing the fact that a specific item of behavior was under study. This helped to avoid the distortion or falsification of responses that results from a realization that one's behavior is under scrutiny. When a large number of results had been obtained, a study was made including only the pertinent matters as the total experiment. Very quickly the waking subjects became aware that the question and their response constituted a vital issue, and efforts at repetition led to a variety of conflicting, uncertain, and inconsistent results. For the hypnotic subject this rigid limitation had little or no effect until too many repetitions aroused a definite interest in the purposes being served by such repetition. Even in this connection there was a significant difference between waking and hypnotic subjects in that the waking subjects inhibited their natural responses while the hypnotic subjects did not become inhibited. Instead they became curious about the experimenter's purposes asking, "Tell me why you ask," or assuming that acquiescence was desired and making a corresponding ready response with no inhibitory reactions.

In other words the predominant natural response to such an inquiry, as "Do you mind standing up, stating your name," etc. was an acquiescence by subjects in the waking state to the behavior implied by the question. In the hypnotic state the responsive behavior was of another character entirely. Most often the question itself was answered negatively, thereby implying positive willingness to acquiesce to the implied action of the question if and when such request were made explicitly.

Even variations of the predominant responses were of a totally different character, ranging from a direct refusal of an act regarded as possible in the waking state to the recognition of a physical inability to act in the trance state.

Repeated experience with the same experimental situation in both the waking and the trance states did not alter the natural response of each state of awareness. Direct sophistication of the subjects had the effect of inhibiting the natural response in the waking state with some degree of self-consciousness. Both sophistication by direct

enlightenment or by permitting long-continued, interested study of hypnotic behavior in the self and others had the effect of making the hypnotic-state response identical to the unsophisticated waking response—again, a difference of behavior for the two states of awareness.

Nor has this finding been restricted to this experimenter's studies. He has encountered various colleagues who have themselves noted this literalness of response to questions and have used comparable questions as clinical tests for determination of the presence of the hypnotic state.

This general difference between waking and hypnotized persons in the meaningfulness of communications has been noted in many other regards and has led to the general admonition to offer suggestions to the hypnotic subject with clarity and meaningfulness. Operators must be aware of what they are actually saying.

---

[1]All first-time waking subjects included subjects used subsequently as trance subjects. Their number is disproportionately large since a good number refused to be hypnotic subjects and could not be tested a second time in the trance state.

[2]Both types of subjects were employed for repetitions of the experiment, but data thus secured was only confirmatory of the original results obtained; hence the results of multiple trials were not included in this experiment.

[3]This figure is doubled in value, however, since all hypnotic subjects were tested for the second time in the waking state on the assumption that their hypnotic response might alter their waking response.

[4]Meaning, "No, I do not mind…" telling one's name, changing seats, standing up, or whatever the request too alertly interested or annoyed. There was no such effect upon the hypnotic subject unless the questions were put in rapid succession too many times. Then there would be acquiescence.

Literalness and the Use of Trance in Neurosis

Milton H. Erickson and Ernest L. Rossi

Dialogue between Milton H. Erickson and Ernest L. Rossi, 1973.

E: The conscious mind already has its own set ideas about the neurosis. It has its fixed, rigid perceptions that constitute a neurotic set. It's very difficult to get people at the conscious level to accept an alteration of their general thinking about themselves. You use the trance state so that you can get around the self-protection which the neurosis provides on an unrecognized level. The neurotic is self-protective of the neurosis.

R: How does trance get around that self-protective aspect of neurosis?

E: The *literalness* of the trance state causes the patient to have a new pattern of listening. He listens to the words in the trance state rather than to the ideas.

R: The therapeutic words that the therapist says?

E: Yes. The patient gets those individual words and can hear the therapist say, for example, "you ... don't ... want ... to ... smoke." In the ordinary waking state he only hears, "You ... don't." He feels that is condemnatory, as if he is being attacked. So he becomes defensive and is unable to hear the rest of the sentence.

R: So trance gives the patient a chance to hear your entire message, to hear exactly what you are saying without screening out any elements.

E: Without screening and without lifting or activating defense mechanisms. When you hear a *pleading tone in the patient's voice*,—for example, when he says, "I just can't stop smoking . . . ," that is a signal to make use of his unconscious by letting him go into trance because consciously he cannot listen to you.

R: He has a pleading tone because his conscious mind is distressed?

E: Yes. When you hear this conscious distress

R: That means consciousness is in a weak position relative to the forces of neurosis, and it needs help.

E: Yes, it needs help, and that help can be given so much more easily and directly in trance. You drop the patient into a trance state and you say, "You came to me, you stated your problem as 'I don't want to smoke,' [spoken as a weak plea] and you have a lot of feeling in your voice. A lot of meaning in that tone of your voice. You put it there. It's

your meaning. Now think it over and recognize the meaning that you put there." That begins his inner recognition, "I don't want to *smoke*! [spoken firmly and with conviction] rather than a plea of distress.

R: You let him think quietly at that point in trance?

E: That's right.

R: And then does he talk to you about what conclusion he came to? What's the next step?

E: Patients' reactions vary tremendously. Some will ask, "Have I got the strength?" rather than making a piteous plea. Another will ask, "What approach should I take?" "Will I get fat?" etc. The answer to the last question is, "You don't want any problem." You see, that's a very comprehensive statement.

R: Because that statement is made in the trance state, it helps free the patient from "any problem."

E: Yes. "What you really want is the comfort of enjoying not smoking."
That helps him focus on *comfort* as he gives up smoking rather than looking for other problems.

R: You give the patient an alternative that is better than the problems.

E: *An alternative that you have defined in such general terms:* "You don't want any problem. You want the enjoyment that is rightfully yours."

R: A general suggestion given in a positive way.

E: But it seems so specific when you listen to it.

R: Because the patient applies it to specifics (such as the things he wants to enjoy) within himself.

E: Yes. You make general statements that a person can apply to specifics within his own life.

R: This is a general approach that could be applicable to a great variety of neurotic problems.

E: That's right!

Age Regression: Two Unpublished Fragments of a Student's Study

Milton H. Erickson

Written between 1924 and 1931.

FRAGMENT ONE: THE CONCEPT OF AGE REGRESSION

The psychiatric concept of regression, originally developed by the psychoanalytic school of thought, has proved a most useful measure in the classification and evaluation of various forms of behavior, both normal and abnormal. Psychiatrically, regression may be defined loosely as the tendency on the part of the personality to revert to some method or form of expression belonging to an earlier phase of personality development. The use of this concept, however, has remained largely on the descriptive level at which it originated, chiefly because it relates to data obtained in the main observation of a post hoc character. Hence there has been little opportunity to evaluate this concept except by the method of relative comparisons of observational material.

Another difficulty involved in the evaluation of the concept lies in the fact that its application must remain individualistic, since the varying degrees of development among different personalities and among the various aspects of the same personality may render precisely the same mode of expression regressive for one individual, progressive (in the sense of being the opposite of regressive) for another, or regressive in relation to certain aspects of the personality and not regressive in relation to certain other aspects. Then, when it is taken into consideration that the "degree of development" upon which the concept of regression is fundamentally based is in itself a vague, speculative concept, the difficulty of evaluating regression directly becomes all the more apparent. Hence there arises the question of the advisability of approaching the problem by qualitative and quantitative measures of some of the mental processes that presumably are involved in regressive phenomena.

In this regard, since regression consists of the reestablishment of a form of self-expression or behavior belonging to an earlier phase of development, a likely approach would seem to be any experimental procedure that would serve to reestablish individuals in an earlier period of their lives in such a fashion that the reestablishment would constitute a reorientation not based on memories or recollections as such—with their consequent and, for experimental purposes, distorting, perspectives—but a reorientation in the past as an immediate actuality with its evocation of corresponding attitudes and behavior.

That such an experimental reorientation can be achieved satisfactorily is a serious question despite the fact that the psychological and psychiatric literature is replete with

instances of such spontaneous occurrences on what is known as a functional basis and many of which were of a reversible character, permitting the person to live alternately in the chronological present or in the immediate present of the reestablished past.

Further, experimental psychological work, particularly in the field of hypnotism, has shown that mental states can be induced that are unrelated to immediate reality but are, so far as can be determined, actual reactivation of mental states previously experienced and uninfluenced by mental patterns acquired subsequent to the original experiences. Examples may be found in the restoration of the original awkwardness and uncertainty in skilled acts, the evocation in deep hypnosis of long-lost skills and knowledge, and the reestablishment of previous attitudes and behavior contrary to that required by the chronological present.

In the observational and experimental work that has been done, however, the validity of the findings could be judged only by the method of relative comparison—that is, by a comparison of the established attitudes and behavior of the chronological present with the attitudes and behavior elicited in the presumed reactivation of the past. By such a method the conclusions drawn are, at best, only inferential.

Theoretically, the ideal approach to the problem would be the recording of all essential data regarding the experimental subject and then, at a suitable subsequent time, activating the original situation in which the data were collected. However, the length of time requisite to eliminate factors of simple memory and immediate relationships to the chronological present render such a procedure impractical.

FRAGMENT TWO: AN INDIRECT APPROACH TO AGE REGRESSION

My initial efforts to induce age regression by the traditional approach of direct suggestion gave inconsistent results. Although age regression could be readily induced by direct suggestion, the subject's general behavior was usually characterized both by remarkable accuracies and gross errors. The fidelity with which various minute details of behavior in a given situation for a specified age were often portrayed, however, suggested that the errors and inconsistencies were the result of inadequacies in the technique of hypnotic suggestion. Accordingly, an indirect technique of suggestion for this experiment was then worked out through a trial-and-error method on a number of hypnotic subjects. As a measure of avoiding possible coaching effects, none of these subjects was used subsequently in the experiment itself. Instead, four other subjects were employed, three female and one male. All were college graduates; all were unaware of the nature or purpose of the experiment; and all were able to develop profound somnambulistic trances because they had been thoroughly trained to do so in connection with other experimental work. In addition, confirmatory data were obtained on another subject, a recovered mental patient who had been reoriented by the experimental technique to the period of his acute illness; for this time there was an adequate psychometric record by which the validity of his reorientation might be tested.

The indirect approach to age regression that was used with these subjects consisted of four stages:

1. The allotment of enough time for both the induction of the trance state itself and for reorientating the subject to the desired age level. A minimum of 20 minutes was allowed for each of these processes. Contrary to general opinion, the induction of a sound, consistent, and firmly established trance or the execution of difficult, complicated hypnotic suggestions are not matters of simple, prompt obedience to emphatic hypnotic commands, but rather the results of a profound psychophysiological process requiring time for the organization and development of patterns of response and behavior. Particularly is this so when subjects are called upon for difficult, complex performances.

2. The giving of suggestions in accord with a definite pattern of presentation that has been found clinically to be effective. This consisted in first giving the suggestions vaguely and indefinitely, so that the subjects became rather uncertain and confused about exactly what was wanted and meant and definitely desirous of receiving any further understandings that might be offered to them. There followed then a repetition of the suggestions more and more clearly, concisely, and insistently until the subjects had a clear understanding of them and had accepted them, as indicated by the subjects' general behavior and responses. This done, the suggestions were again repeated over and over, but this time in broad, general, inclusive terms to preclude the subjects from taking exception to, or resisting, any of the suggestions, thus emphasizing the commands and yet leaving the subjects free to react fully and completely despite any inadequacy of the suggestions themselves. While this was being done, the next series of suggestions was introduced in vague, general terms. There was thus an interweaving of suggestions, permitting a slow, gradual, virtually unnoticeable progression from one type of suggestion to the next. This served to promote the shifting from one mental attitude to another—an essential basis for the experiment.

3. The giving of a series of suggestions to secure the following sequence of effects upon the subjects:

(a) general state of emotional indifference and unconcern:
(b) general state of confusion and uncertainty;
(c) general slowness, uncertainty, and blocking of memories, particularly those for the events of the current day, week, and month;
(d) general state of disorientation for person, place, and time;
(e) development of a definite amnesia for the events of the current day, week, and month;
(f) development of an amnesia for the events of the past year, the year before that, etc., and a forgetting even of the existence of those years;
(g) the realization that "time is changing" and "everything is changing," that soon the subjects, completely forgetful of all those stated years, will feel themselves to be of a specified age, then believe themselves to be of that age, and then know that they are exactly so old, while at the same time they will realize that the current

year actually belongs to the remote future—as, indeed, do all the years subsequent to their specified age year;

(h) the subjects' realization that soon they will find themselves in a pleasant situation at the specified age, knowing all those things they should know—not less, not more—experiencing the feelings that all people know they have, possessed of the interests and desires rightfully theirs, being themselves and just themselves and enjoying their rightful span of specified years;

(i) finally the realization that they are of the specified age, feeling, thinking, knowing, and experiencing all those things rightfully theirs, just as they experienced and enjoyed those feelings and things not only today but yesterday and last week, and just as they will tomorrow and the next day and next week, and that now they are to open their eyes, ready and willing to pick up a pencil and to do whatever they are asked to the very best of their ability and as rapidly and thoroughly as they can.

4. The repetition of the entire procedure of suggestion for each age level tested for from 8 to 18 years, and the limitation of each experimental session to the investigation of a single age level.

EXPERIMENTAL PROCEDURE

Upon being hypnotized and reoriented in accord with the technique described, each subject was given one of the four forms, A, B, C or D, of the Higher Examination of the Otis Self-Administering Tests of Mental Ability. A time period of 20 minutes was allotted to each for the test performance. The order of administration of the various forms of the test, together with the order of suggestion of the various age levels, was systematically random to secure an irregular succession both of test forms and of age levels without there being a sequence of identical forms or of successive years.

At the expiration of the allotted time the subjects were reoriented and suggestions were given for an amnesia of the entire experience. At a later date—perhaps the next day, perhaps the next week—they were again approached with the request to contribute an hour or two for some hypnotic work the experimenter was planning. The time actually required for the experiment averaged between 25 and 30 hours per subject. The experimental sessions were spread over a period of five to six weeks, for the purpose of confusing any spontaneous memories and to impede any deliberate organization of test performances. In addition, from time to time the tests were given in the simple trance state to safeguard still further against spontaneous memories or deliberate systematization of responses.

When the experimental aspect of the problem had been completed, the subjects were asked (through an associate of the experimenter's, to avoid possible hypnotic effects) to perform in the waking state, item by item, the tasks already accomplished without their apparent knowledge in the trance state. Upon their consent they were given a detailed description of what was desired in terms embodying essentially the same points as had the hypnotic instructions. This was done as a measure of giving them the same type of

cues as had been given in the trance state. Once these complete instructions had been given, the subjects were found to be unwilling to listen to repetitions for further test performances.

As an additional control measure a group of six nonhypnotic subjects, comparable in training and intelligence to the experimental subjects, were asked to perform the same experimental task at a waking level. They were given the same full instructions as had been given the experimental subjects for the control series. The entire series of tests was not performed, however, because some of the control subjects were found to be unable to perform the task, while others governed their performance by arbitrary standards serving to establish the exact extent of their performance for any specified age level.

EXPERIMENTAL RESULTS AND SUMMARY

The data as finally obtained included complete experimental and control results on three hypnotic subjects, nearly complete data on a fourth, confirmatory data from a single age regression on an additional hypnotic subject, and control data on six nonhypnotic subjects, adequate in character but incomplete in quantity because of the significant character of the first test performance by those subjects.

In addition to the experimental results many clinical observations were also made. All of them contributed significantly to the experimental findings, serving to clarify and to explain them and to give a better realization of the actual effects of the hypnotic suggestions and of the general problems to be met in this type of hypnotic experimentation. However, for this report these will not be given except in general outline.

A summary of the findings of this investigation may be given briefly in the following paragraphs:

1. A total of four hypnotic subjects in a deep trance, reoriented to earlier age levels and subjected to intelligence tests, gave evidence of a definite approximation of the mental patterns of the specified age levels. Three of the four subjects were reoriented to the age levels of 8, 9, 10, 11, 12, 14, 16, 17, and 18 years, and two of these to the additional years of 13 and 15. One subject was reoriented only to the age levels of 8, 10, 12, 14, 16, and 18. For these subjects the results obtained both in general behavior and in test performance were appropriate to the age levels suggested to them. Their performances on the test were straightforward and serious; it was taken always at face value, and the entire allotted period of 20 minutes was invariably utilized to the utmost. There was a distribution of correct and incorrect answers and of omitted questions appropriate to the various suggested age levels: For the earlier ages there were frequent evidences of juvenile misunderstandings and approximations in various of the wrong answers. There was no evidence of any carrying over of memories from one test situation to another. The same subjects gave right and wrong answers to the same question, in keeping with appropriate age levels.

2. Of the same subjects asked to perform under normal waking conditions the task already completed in the hypnotic state, two actually made an attempt somewhat similar to their trance performance. A third, through a process of specious reasoning, gave a highly systematized adult performance, and when asked to perform the task again, but in a different fashion because of the falsity of his first attempt, found it too difficult. A fourth subject, on whom the trance data were incomplete, found the task entirely too difficult to be done in the waking state, despite repeated conscientious attempts. The results obtained on the first two subjects resembled the trance findings only in the mental age as derived from the test scores. The performance of each subject was entirely that of an adult, in full awareness of his adult mental state, seeking to limit his adult performance to a lesser one that was presumably appropriate to a specified age level. In no instance did there seem to be any recognition or understanding of what the task actually implied—namely, behavior appropriate to the specified age level. In brief, the test performance under the control conditions was characterized wholly by adult behavior; responses were systematically calculated and organized in accord with a full adult conception of what might constitute the lesser performance appropriate to the specified age level. To this end the subjects arbitrarily restricted the amount of time used of the allotted 20 minutes to a period of three to eight minutes for the earlier age levels. Similarly, the number of questions answered at each age level was arbitrarily limited by the individual subject and systematically increased for each higher age level. In addition, all answers were correct; there seemed to be no realization on the part of the subjects that mistakes might and would be made at the various age levels. Also, there was little or no omission of specific questions because of their difficulty, except as a process of deliberate calculation, but there were mass omissions of questions for the sole purpose of limiting the total quantity of the performance. In brief, in the control examinations the subjects arbitrarily limited the time and quantity of their performance in accord with their adult understanding of what might be accomplished at a specified age limit. There was no effort to attempt either the behavior or the test performance appropriate to the specified age level.
3. The performance of the nonhypnotic control subjects was characterized by the same type of adult behavior as had been shown by the hypnotic subjects in their waking control performance, and the findings obtained, both as to method and actual results, were essentially comparable.
4. This experiment led to an attempt at testing the experimental results by reorienting a recovered mental patient to the time of the height of his acute mental illness more than a year previous, at which time a complete psychometric record had been obtained. Psychometric examination upon reorientation served to secure results in remarkable agreement with those actually obtained more than a year previously. For example, on the Otis Intermediate Test administered originally, his mental age was found to be seven years, ten months; on the same test, upon reorientation to that period, his performance scored seven years, eleven months. Likewise his ratings on the Stanford-Binet, the Army Alpha, and various performance tests showed similar remarkable agreement. In addition a

psychometric examination made previous to the reorientation experiment disclosed his normal mental age to be 13 years, 6 months.

Past Weekday Determination in Hypnotic and Waking States

Milton H. Erickson and Allan H. Erickson

Unpublished manuscript written with Allan Erickson, 1962.

Since the mid-1920s, when the senior author first became interested in hypnotic age regression, periodically there has been propounded the proposition that any intelligent college student can readily and easily calculate the day of, the week for any given past date. At the time researchers uncritically accepted this assumption[1] as proof that any correct identification of the weekday by subjects who had been age-regressed hypnotically was not evidence of the reestablishment of earlier understandings and patterns of behavior. In this regard the senior author had repeatedly regressed hypnotic subjects in age, had then asked them what day of the month it was, and had received an immediate answer. Without further pause they would be asked what day of the week it was, and an immediate reply would be given which, in the majority of instances, was correct. This had been regarded by the senior author as a significant finding that tended to validate age regression as a genuine phenomenon, particularly when numerous inquiries of fellow students in the normal waking state had disclosed a definite inability to perform such a task.

Thus, students in the awake state would be asked, "On what day of the week did your second, last [third, fourth, fifth] birthday come?" Or, "On what weekday did Christmas [New Year's, Fourth of July, Valentine's Day] come two [three, four, five] years ago?" A correct answer to this type of question was found to be a rarity. The usual answer was, "I just do not know" or "I'd have to work that out." Some accepted the question as an interesting problem and actually tried to devise calculation methods to determine the answer. On the whole, however, practically all failed in their calculations, so that a correct answer by a correct method was as much a rarity as was a correct spontaneous answer. Among the correct spontaneous answers were some invalidated by personal referents such as, "That's easy, my birthday that year was the day after Thanksgiving, so it would be Friday." Sometimes a special event would permit a correct answer for a certain birthday. Thus, there might be a correct answer such as, "My birthday is exactly three weeks before Christmas. Last Christmas was on a Sunday because I had to go to work on a new job the next day, so my birthday last year was on Sunday." Even so, they would be confused and uncertain as to the date of the week for the preceding and the subsequent birthdays.

FIRST STUDY

The senior author proceeded to regress a series of 10 hypnotic subjects to various age levels. The usual procedure of an orientation backward in time through the years was

employed, thereby effecting a blanket amnesia for all events subsequent to the preselected past time. If time permitted, at least four different past ages were selected. The experiment was not done for publication but simply to discover if there were sufficient grounds for studying hypnotic regression as a valid phenomenon. The periods of time preselected were intentionally described to the subject as "this nice day in summer [fall, winter, or spring], and you are about 17 [11, 9, or 7 years old]. These specific ages were not used for each subject but serve merely to indicate the type of age range. For each subject the separate regressions were done in random fashion: The first regression might be to the youngest age level, the next might be to the oldest, and the order of the next two might be from the lesser to the greater or vice versa. The selection of season of the year followed a random pattern, too: A subject might be regressed to a childhood summer, for example, with subsequent regressions to spring, winter, and fall for other age levels.

In determining the year to which the subject was regressed, the point of time of orientation was made the subject's responsibility by employing such seemingly definitive descriptions as, "And now it will soon be your 16th birthday," or, "You are now 13 years old and school will soon begin again." Thus, a birthday early in January (there were no preliminary questions for such determinations) might compel the subject to orient to the preceding year in accordance with his definition of the word soon. Or the subject might be instructed, "And now it is such a nice day, right in the middle of the summer just before you go into the 8th grade." A follow-up question might be, "I wonder if it is going to rain today. What do you think?" An answer might then lead to such spontaneous dialogues as follows:

> Patient: I hope not 'cause Daddy is going to take us fishing.
>
> Therapist: Does your Daddy always take you fishing?
>
> Patient: No, but he promised to take us fishing today because it is Willie's birthday tomorrow and we go to church on Sunday, so he has to take us today.

Thus, the weekday would be an indirect spontaneous disclosure.

Or the question of "What do you think you will do today?" might elicit the following dialogue:

> Patient: Oh, it's visiting day and I got to go visit my Daddy.
>
> Therapist: Why is that?
>
> Patient: My Daddy and my Momma don't live together no more, and every Saturday I have to go visit him.

Such spontaneous disclosures were not infrequent at lower age levels, but when questioned for the day of the month the subjects usually did not know it. Occasionally,

when the subject was queried at an early age level for the month of the year, a reply of the following character would be received: “It’s July—no, it was July last week, and now it’s August.”

Frequently no weekday identification could be secured at the lower age levels. Instead, the subjects would state that they didn’t know what weekday it was, or would offer several questioning guesses. When they were then questioned, “What day do you think it is?” the confident answer would be, “It’s `painting’ day [or `story’ day or `practice’ day], and inquiry would disclose that once a week some activity in school would be emphasized. This finding was frequently encountered among the senior author’s fellow students in the waking state, who more than once, when asked the day of the week, would reply, “Let’s see, I went to chemistry class [mathematics, physics, etc.] today. That’s a Monday-Wednesday-Friday course, and it was my second class this week in Chemistry—so it’s Wednesday.” Subsequently the author encountered a similar identification of weekdays in his fellow medical students. The weekday nomenclature was replaced by courses being taken as the identification. Thus Saturday ceased to be Saturday; it became Dermatology Clinic day. Years later the senior author’s medical students did the same thing. More than once he received a telephone call: “Is Eloise [the post office name of the Wayne County General Hospital and Infirmary on the outskirts of Detroit, Michigan] Day tomorrow, or the next day?” Frequently, the hospital staff replaced Wednesday with “Staff Day,” to which one would orient temporarily by “day before” or “day after Staff.” Hence the early regression-state-identification of weekdays in terms of events was accepted at the time, with increasing evidence of its validity in subsequent observation of human behavior.

At the older age level regressions, especially from twelve upward, there tended to be two types of reply. Thus the senior author might say hesitantly to the subject, “Uh, let’s see, oh, what day is it today?” To this the subject was likely to respond (1) with a statement that he didn’t know, hadn’t noticed, had been too busy to pay attention to the calendar, or (2) immediately with a specific weekday or day of the month. If the subject Past gave a specific weekday, the author would get further information with the remark, “Oh, I meant the day of the month!” If initially the subject gave the day of the month, the author would ask for the day of the week. At the older age levels this type of reception was misleading as to the author’s actual purposes and served to get additional data by which doubly to confirm or to disprove the responses given.

The same measure employed at younger age levels disclosed that both items of information were difficult to secure; some subjects tended to remember the day of the week, while others remembered the day of the month. It then became necessary to ask for other data, such as, “What are you going to do today?” when a reply indicated that it was the 13th of April at their regressed age of eight. Then if the answer was “go to church,” one could test the validity of the reply. If the answer was “go to school,” this would be followed by “And the next day? And the day after that?” If either of these two questions was answered, “Oh, stay home like every time,” the inference of Saturday would be warranted. Or one can inquire about yesterday and the day before. If both questions are answered by a statement of school attendance and a question about tomorrow, and if the

next day also elicits an answer of school attendance, the inference is warranted that the day of the month given is a Tuesday, Wednesday, or Thursday. However, other comparable check questions, or the technique of reorienting the subject to a month earlier or three weeks later, will serve to yield check data. It was early discovered that the answer, "I stayed home the next day and the next day and then I went to school again," does not necessarily mean that the subject is speaking of a
Saturday or a Sunday. It might signify an absence from school because of illness or a holiday.

Many of the subjects at the upper age levels failed to identify the weekday or the day of the month. But this was found to be true in the ordinary school and college population and, for that matter, in medical school as well. And who has not encountered adults asking both the day of the week and the day of the month? Inquiry and observation over the years have disclosed a definite unreliability in weekday and month day identification deriving from legitimate interests, not only from neurotic conflicts.

As a consequence of all these special inquiries, the senior author felt satisfied with the results. He had learned that approximately two out of three age-regressed hypnotic subjects could give accurately the weekday or its equivalent for some past day in their life history and that this ability was apparently directly correlated with the age level to which they had been regressed. The lower age levels appeared to have more identification labels based on activity (e.g., "painting day" or "story day"), while the person in the waking state gave responses of another character altogether. Since the senior author was primarily interested in the subjective and emotional meaningfulness to the subject of regression experiences, rather than in the absolute validity of objective factual reporting, this inquiry was dropped as having served its purpose in establishing the validity of age regression in many instances.

SECOND STUDY

In the late 1930s, while the senior author was conducting hypnotic research in relation to the past emotional experiences of psychotic patients at Wayne County General Hospital, the same adverse criticism as to the superior ability of age-regressed subjects versus nonregressed subjects to recall past week and month days was encountered anew. Recalling the original study, a second comparable inquiry was made on anew population of students of medicine and psychology, secretaries, nurses, social service workers, staff physicians, and even psychiatry patients, including some people who were actively psychotic. This study varied in that past dates for both the 20th and 19th centuries were used. The responses elicited were (1) rejections of the task, (2) failure when attempted, and (3) two correct answers to the weekday identity of the past 20^{th}-century date. These correct answers happened to be from two chess experts, but both of them failed to identify the 19th century dates. They had forgotten, along with all subjects except one psychology student, that 1900 was not a leap year. (A surprising number of the subjects did not recall this fact about 1900 and even challenged the senior author regarding it.)

The hypnotic subjects, who were often tested in the presence of critics, gave correct answers in a definite majority of instances. Since there were more female subjects in the hypnotic group than in the waking group, the secondary criticism that the inquiry with the waking group might not be valid because of the large number of women in that group was invalidated.

In neither the first nor the second study were the age-regressed subjects asked to identify a weekday of a date preceding their birth—such inquiries were considered undesirable. Since the purpose of utilizing hypnosis as an experimental procedure was to examine the meaningfulness of the subjects' past, personal, experiential realities, to request information preceding their birth would have been a falsification of the emotional content inherent in the hypnotic state.

The criticism may be leveled that these two inquiries were separate in kind for the waking as opposed to the hypnotic groups. The waking group was presented with a mathematical problem, whereas the hypnotic group was presented with a problem contingent upon subjective experiences. That it can be solved only on a mathematical basis is, however, the prevalent waking assumption. The senior author's experience is that the *waking subjects are restricted to their general conscious concepts of how to function intellectually, while hypnotic subjects respond in a totally different way based on real-life experiences and the reactivated memories of such experiences*. The waking subjects approach the problem as a cognitive one, requiring time and careful calculation, whereas the age-regressed hypnotic subject utilizes reactivated personal associations in an immediate and spontaneous manner.

APPENDIX

A college class of algebra students was given the following problems to test the assumption that any college student could calculate the day of the week for any given date of the past.

First Problem

Given: What day of the week it is today.
Find: What day of the week it was x years ago, where x is approximately 20 years ago (x is a whole number of years).

Second Problem

Given: What day of the week it is today.
Find: What day of the week it was x years ago, where x is approximately 75 years ago (x is a whole number of years large enough to make the day sought fall in the 19th century).

Total number of people attempting to solve the problems: 39

Results: *24.8*

(1) Number of people who got both problems entirely correct using a correct method: 1
(2) Number of people who got first problem entirely correct using a correct method: 14
(3) Number of people employing a correct method in solving the problems (some minor mistakes): 15
(4) Number of people who knew 1900 is not a leap year; (The one person who got the problem correct.): 1

(Note: The one person who did get the correct answers was an A student in an intermediate algebra course in college.)

The final algebra grades of the students who got the correct answer through a correct method to the first problem are as follows:

A = 3
B = 4
C = 2
D = 4
F = 1

Time Requirements

Number of minutes required by the one student who got both answers correct to calculate the problems: 5 1/2

Average number of minutes required by the students who got the correct answer to the first problem but the wrong answer to the second problem (N = 13): 13½

Average number of minutes required by the 15 students to work the problem through a correct method without regard to answer: 15½

From these results it is evident that most students in a college algebra class cannot quickly and easily calculate the day of the week or any given past date.

---

[1]An experimental demonstration of the incorrectness of this assumption is presented in the Appendix by Allan Erickson

On the Possible Occurrence of a Dream in an Eight-Month-Old Infant

Milton H. Erickson

Reprinted with permission from *The Psychoanalytic Quarterly*, July, 1941, Vol. X, No. 3.

The age at which dreams first play a part in the psychic life of the individual is unknown. Various careful studies have reported that dreams may occur even before the development of speech, but the weight of evidence has been inferential in character and based upon sleep disturbances for which purely physiological, as distinct from psychic, activity might as readily be postulated. With the development of speech, however, definite evidence of dreaming by very young children has been obtained, their utterances while asleep disclosing their sleep disturbances to have an unmistakable psychic content, as is shown so clearly in recent observations of dreaming in a two-year-four-month-old baby (Grotjahn, 1938).

Pertinent to these considerations is the following brief note reporting an instance in detail which suggests strongly that a dream with definite psychic and affective content may occur even at the early age of eight months. The attendant circumstances are given in full since they suggest a possible background for the development of affective desires which might in turn give rise to dream activity. For a period of months a father was in the habit of playing with his infant daughter regularly just previous to her 6 P.M. feeding, and much pleasure was taken in inducing her to laugh and in watching her extend her legs, flex her arms over her chest, and turn her head from side to side as she laughed. The infant had developed a definite attitude of expectation for this specific play activity.

When she was exactly eight months old, external circumstances caused the father to be absent from home one evening and the next. Returning at midnight the second evening, he paused at her bedroom door. He could see her clearly outlined in the moonlight, lying quietly in her crib, breathing deeply and sleeping soundly. As he was about to turn away, she moved restlessly, extended her legs, flexed her arms over her chest, turned her head from side to side, laughed merrily, took another breath and laughed again. This was followed by general relaxation and a continuance of the deep, quiet, breathing, nor did she arouse when her father entered, but continued to sleep as he tucked her more securely under the covers.

To say that an infant of eight months could have a dream of definite psychic content and with affective components seems questionable, but even more questionable would be any attempt to postulate a physical discomfort which would disturb sleep and result, at that age, in an expression by laughter. Likewise questionable could be any attempt to draw conclusions about so young a child experiencing affective deprivation so strongly that

resort would be had to a dream satisfaction. Yet in this instance such an inference seems plausible. In any event the observation is noteworthy in relationship to the problem of dream life, and it is hoped that other observers may report similar instances.

Since making this original observation, another of similar character has been made.

As they were returning late one night, the parents heard the baby, then 13 months old, laughing merrily. Entering her bedroom immediately, they found the child apparently sound asleep. Before they had an opportunity to touch her, however, the child again laughed merrily, and this laughter was immediately succeeded by a third peal, following which the infant continued to sleep so soundly that even the changing of her diaper did not arouse her.

That this type of behavior occurred in relation to a pleasing psychic content or experience on the order of a dream seems to be a reasonably plausible and legitimate inference.

At the age of 23 months, this same child became much concerned over a rather extensive abrasion of the knee suffered by her older sister as a result of a fall on the pavement—an accident discussed by all of the children in the family and their playmates. Several nights later, after she had been sleeping about three hours, she suddenly began to cry. Upon being picked up, still crying, she sobbed, "Po' Kaka [Carol]. Kaka bad bump. Kaka hurt. Kaka cry." Efforts to reassure her verbally failed, as did an attempt to show her that Carol was sleeping quietly. She continued crying, adding, "Kaka fall down. Kaka hurt knee." She seemed still to be asleep and unresponsive to all reassurances. Accordingly she was aroused completely. Thereupon she repeated her remarks, but with much less grief in her voice, and she seemed to be very greatly bewildered and puzzled by the sight of Carol sleeping quietly in bed, as if she could not reconcile a dream content with the actual sight of her sleeping sister. She then proceeded to discuss the matter, and the impression derived from her fragmentary remarks was that she was trying hard to explain the situation to her parents. Following this she returned readily to bed and slept comfortably the rest of the night. In this instance there can be no doubt of the occurrence of an actual dream based upon a previous experience.

The Successful Treatment of a Case of Acute Hysterical Depression by a Return Under Hypnosis to a Critical Phase of Childhood

Milton H. Erickson and Lawrence S. Kubie

Reprinted with permission from *The Psychoanalytic Quarterly*, October, 1941, Vol. X, No. 4.

EVENTS WHICH LED TO THE ATTEMPT TO TREAT A DEPRESSION BY HYPNOSIS

An unusually capable 23-year-old woman had been employed in a mental hospital for several months. Toward the end of this period she developed a progressively deepening depression. Later it became known that she had continued to discharge her duties fairly well for some weeks after a certain upsetting event; but that as time passed she had become increasingly disinterested and ineffectual in her work, slowly discontinuing all social relationships, and spending more and more time in her secluded room. At this point in her illness she ate only in response to her roommate's pleading, sobbed much of the time, occasionally expressed a wish to die, and became blocked and inhibited in speech whenever any effort was made to question her about her difficulties. During the latter part of this phase the patient's symptoms became so acute that her relatives and friends sought psychiatric help.

The patient was seen by several psychiatrists, some of whom diagnosed her condition as the depressive phase of a manic-depressive psychosis. A psychoanalyst and one of the authors, Dr. Erickson, believed it to be an acute reactive depression. Later evidence, which became available only as the story developed, indicated that it was a typical "hysterical depression," that is, a depression reaction growing out of a definite hysterical episode.

Several consultants were in favor of commitment. To this, however, the family of the patient would not consent, insisting that some form of active psychotherapy be at least attempted. Accordingly, sympathetic and persuasive encouragement was tried. The patient responded to this sufficiently to appear slightly less depressed and to return to her work in a feeble and rather ineffectual fashion; but she remained unable to discuss her problem.

This slight amelioration of her symptoms was sufficiently encouraging to warrant further efforts, yet, was far from sufficient to free her from the danger of a relapse into deeper suicidal depression. Furthermore, the threat of commitment still hung over her head; therefore, with many misgivings the suggestion was made that she attempt psychoanalytic treatment. She showed some interest in this idea, and despite the fact that

it is unusual to attempt analysis in the midst of a retarded depression, for a period of about a month she was encouraged to make daily visits to an analytically trained psychiatrist.

During this month, except for the fact that the analytic hour seemed to help the patient to make a better adjustment during the rest of the day, she made little progress, produced no free associations, related only a few fragmentary parts of her story, and usually spent the hour in depressed silence with occasional futile efforts to say something, or in sobbing as she declared that she did not know what awful thing was wrong with her or what awful thing had happened to her. Toward the end of the month she began to show signs of relapsing into an acute depression of psychotic intensity so that commitment seemed imperative.

In spite of these discouraging experiences the family again asked that before resorting to commitment some other therapeutic measure be attempted. The suggestion that hypnotic therapy might be of value was accepted by her relatives, and plans were made for this without the patient's knowledge. At this point the patient's problem was referred to Dr. Erickson with the following story which had been pieced together by the various psychiatrists from the accounts of the patient's roommate, of her relatives, of a man in the case, and in small part, of the patient herself.

CLINICAL HISTORY

The patient was the only daughter in a stern, rigid, and moralistic family. Her mother, of whom she always stood in awe, had died when the patient was 13 years old. This had had the effect of limiting her social life somewhat, but she had an unusually close friendship with a neighbor's daughter of her own age. This friendship had continued uneventfully from childhood until the patient was 20 years old, three years before the date of the patient's illness.

At that time the two girls had made the acquaintance of an attractive young man with whom both had fallen in love. Impartial toward them at first, the young man gradually showed his preference for the other girl, and presently married her. The patient responded to this with definite disappointment and regret but quickly made an adjustment which seemed at the time to be unusually "normal," but which in view of later developments must be viewed with some suspicion. She continued her friendship with the couple, developed transitory interests in other men, and seemed to have forgotten all feelings of love for her friend's husband.

A year after the marriage the young wife died of pneumonia. At the loss of her friend the patient showed a wholly natural grief and sorrow. Almost immediately thereafter the young widower moved to another section of the country, and for a time dropped out of the patient's life completely. Approximately a year later he returned and by chance met the patient. Thereupon their former friendship was resumed, and they began to see each other with increasing frequency.

Soon the patient confided to her roommate that she was “thinking seriously” about this man, and admitted that she was very much in love with him. Her behavior on returning from her outings with him was described by the roommate and by others as “thrilled to the skies,” “happy and joyous,” and “so much in love she walks on air.”

One evening, after some months, she returned early and alone. She was sobbing, and her dress was stained with vomitus. To her roommate’s anxious inquiries the patient answered only with fragmentary words about being sick, nauseated, filthy, nasty, and degraded. She said that love was hateful, disgusting, filthy, and terrible, and she declared that she was not fit to live, that she did not want to live, and that there was nothing worthwhile or decent in life.

When asked if the man had done anything to her, she began to retch, renewed her sobs, begged to be left alone, and refused to permit medical aid to be summoned. Finally she yielded to persuasion and went to bed.

The next morning she seemed fairly well, although rather unhappy. She ate her breakfast, but when a friend who knew nothing of these events casually asked about the previous evening’s engagement, the patient became violently nauseated, lost her breakfast, and rushed precipitously to her room. There she remained in bed the rest of the day, sobbing, uncommunicative, uncooperative with a physician who saw her, essentially repeating the behavior of the previous evening.

During that day the man tried to call on her. This precipitated another spell of vomiting; she refused to see him. She explained to her roommate that the man was “all right,” but that she was nasty, filthy, disgusting, and sickening, and that she would rather kill herself than ever see that man again. No additional information could be obtained from her. Thereafter a telephone call or a letter from the man, or even the mention of his name, and finally even a casual remark by her associates about their own social contacts with men, would precipitate nausea, vomiting, and acute depression.

To a psychiatrist the man stated that on that evening they had gone for a drive and had stopped to view a sunset. Their conversation had become serious, and he had told her of his love for her and of his desire to marry her. This confession he had long wanted to make, but, he had refrained even from hinting at it because of the recency of his wife’s death and his knowledge of the depth and intimacy of the friendship that had existed between the two girls. As he had completed his confession, he had realized from the expression on her face that she reciprocated his feelings, and he had leaned over to kiss her. Immediately she had attempted to fend him off, had vomited over him in an almost projectile fashion, and had become “just plain hysterical.” She had sobbed, cried, shuddered, and uttered the words “nasty,” “filthy,” and “degrading.” By these words the man had thought she referred to her vomiting. She refused to let him take her home, seemed unable to talk to him except to tell him that she must never see him again, and to declare that there was nothing decent in life. Then she had rushed frantically away.

Subsequently, all efforts on the part of friends or physicians to talk to the patient about these events had served only to accentuate the symptoms and to evoke fresh manifestations.

PREPARATION FOR AN INDIRECT HYPNOTIC INVESTIGATION

Many hints from this story induced the investigator not to attempt to hypnotize the patient simply and directly. In the first place there was the fact that she had rejected every overt sexual word or deed with violent vomiting and with a paralyzing depression which practically carried her out of contact with those who had attempted to help her. She rejected the man so completely that she could not hear or mention his name without vomiting; this reaction to men had become so diffused that she could not accept the ministrations of male physicians, but reacted as though they meant to her the same kind of threat her suitor had represented. She had been able to accept him only in a spiritualized and distant courtship, or when she was protected by the presence of her friends. It was evident that she would far too greatly fear direct hypnosis ever to submit to it.

She was moreover too deeply entrenched in the refuge of illness to fight energetically for health. She had no resources with which to struggle against her anxiety and depression, but at any signal she collapsed deeper into illness. This gave warning that in the preliminary phases of treatment one would have to work completely without her cooperation, either conscious or unconscious, without raising the least flurry of anxiety, without making a single frightening or disturbing allusion to her trouble, if possible without her even knowing that she was being inducted into treatment and most important of all, without her feeling that the therapist (the hypnotist) was directing his conduct toward her at all. Whatever was going on in her presence must seem to her to relate to someone else. Only in this way could the treatment be undertaken with any hope of success. It should be recalled that even the passive, quiet, wordless, almost unseen presence of an analyst had been too great an aggression for the patient to accept, an intolerable erotic challenge, with the result that after a month she had sunk deeper into depression.

Accordingly, arrangements were made to have the patient's roommate confide to the patient that for some time she had been receiving hypnotic psychotherapy. Two days later the psychoanalyst approached the patient and asked her, as a favor to him in return for his efforts on her behalf, to act as a chaperone for her roommate in her regular hypnotic session with Dr. Erickson.

This request he justified by the explanation that she was the only suitable chaperone who knew about her roommate's treatment; the nurse who usually chaperoned the treatment was unavoidably absent. The patient consented in a disinterested and listless fashion, whereupon he casually suggested that she be attentive to the hypnotic work, since she herself might sometime want to try it.

By asking the patient to do this as a favor for him, the analyst put her in an active, giving role. By suggesting to her that she listen carefully because she herself might want similar help some time, he eliminated any immediate threat, at the same time suggesting that in some undefined future she might find it useful to turn to the hypnotist for therapy.[1]

THE FIRST HYPNOTIC SESSION

Upon entering the office, the two girls were seated in adjacent chairs, and a prolonged, tedious, and laborious series of suggestions was given to the roommate, who soon developed an excellent trance, thereby setting an effective example for the intended patient. During the course of this trance suggestions were given to the roommate in such a way that by imperceptible degrees they were accepted by the patient as applying to her. The two girls were seated not far apart in identical chairs and in such a manner that they adopted more or less similar postures as they faced the hypnotist; also, they were so placed that the hypnotist could inconspicuously observe either or both of them continuously. In this way it was possible to give a suggestion to the roommate that she inhale or exhale more deeply, so timing the suggestion as to coincide with the patient's respiratory movements. By repeating this carefully many times, it was possible finally to see that any suggestion given to the roommate with regard to her respiration was automatically performed by the patient as well. Similarly, the patient having been observed placing her hand on her thigh, the suggestion was given to the roommate that she place her hand upon her thigh and that she should feel it resting there. Such maneuvers gradually and cumulatively brought the patient into a close identification with her roommate, so that gradually anything said to the roommate applied to the patient as well.

Interspersed with this were other maneuvers. For instance, the hypnotist would turn to the patient and say casually, "I hope that you are not getting too tired of waiting." In subsequent suggestions to the roommate that she was becoming tired, the patient herself would thereupon feel increasing fatigue without any realization that this was because of a suggestion which had been given to her. Gradually it then became possible for the hypnotist to make suggestions to the roommate, while looking directly at the patient, thus creating in the patient an impulse to respond, just as anyone feels when someone looks at one while addressing a question or a comment to another person.

At the expiration of an hour and a half the patient fell into a deep trance.

Several things were done to ensure her cooperation in this trance and its continuance and to make sure that there would be opportunities to use hypnotic treatment in the future. In the first place the patient was told gently that she was in a hypnotic trance. She was reassured that the hypnotist would do nothing that she was unwilling to have him do and that therefore there was no need for a chaperone. She was told that she could disrupt the trance if the hypnotist should offend her. Then she was told to continue to sleep deeply for an indefinite time, listening to and obeying only every legitimate command given her by the hypnotist. Thus she was given the reassuring but illusory feeling that she had a free choice. Care was taken to make sure that she had a friendly feeling toward the

hypnotist, and for future purposes a promise was secured from her to develop a deep trance at any future time for any legitimate purpose. These preliminaries were time-consuming, but they were vitally necessary for safeguarding and facilitating the work to be done.

It was obvious that the patient's problems centered around emotions so violent that any therapeutic exploration would have to be carried out in some wholly "safe" fashion without provoking the least trace of guilt or fear. Such "safe exploration" meant dealing with everything in such a way that the patient could escape all painful implications. The first maneuver was to lead the patient back to a childhood devoid of childhood pain.

Accordingly, emphatic instructions were given to the patient "to forget absolutely and completely many things," carefully omitting to specify just what was to be forgotten. Thus the patient and the hypnotist entered into a tacit agreement that some things were best forgotten—that is, best repressed. Permission also was thereby given to the patient to repress them without naming them. The exploratory process which lay ahead would be facilitated by this permission to repress the more painful things, since automatically it would be applied to those which were most troublesome. [2]

Next the patient was systematically subjected to a gradual disorientation for time and place, then gradually reoriented to a vaguely defined period in childhood lying somewhere between the ages of 10 and 13. The technique used is described in some detail in studies on the hypnotic induction of color blindness and of hypnotic deafness (Erickson, 1938, 1939). The hypnotist suggests first a state of general confusion as to the exact day, carrying this over step by step to include the week, the month, and the year. Then this is elaborated toward an intensification of a desire to recall certain unspecified things that had occurred in previous years, which also are left indeterminate. The process is a slow one and involves jumping from one confusing idea to another until out of the state of general confusion the patient develops an intense need for some definite and reassuring feeling of certainty about something, whereupon she becomes only too glad to accept definite reassurance and definite commands.

In reorienting the patient toward the age period between 10 and 13, the hypnotist was careful to be extremely dogmatic in tone of voice but equally vague and indefinite as to his precise meaning. The suggestions were given to the patient as though talking to someone else rather than directly to her. She was not told that she herself had to seize upon some meaningful event in those three years.

The years from 10 to 13 were chosen with the idea that they just preceded her mother's death and that they must have included the period of onset of her menstruation and therefore have meant the critical turning point in her general emotional life and in her psychosexual development. Since nothing was known in detail about her life, the exact period of time to which she would finally become reoriented was left to the force of her own experiences.

She was at no time asked to name and identify specifically the age to which she became reoriented in the trance. By allowing her to avoid this specific detail, she was compelled to do something more important—namely, to speak in general terms of the total experience which those years had meant.[3]

Presently in her trance the patient showed by the childishness of her posture and manner, as well as by the childishness of her replies to casual remarks, that she had really regressed to a juvenile level of behavior. She was then told emphatically, "You know many things now, things you never can forget no matter how old you grow, and you are going to tell me those things now just as soon as I tell you what I'm talking about." These instructions were repeated over and over again with admonitions to obey them, to understand them fully, to be prepared to carry them out exactly as told; she was urged to express and affirm her intention to carry through all of these suggestions. This was continued until her general behavior seemed to say, "Well, for what are we waiting? I'm ready."

She was told to relate everything that she knew about sex, especially in connection with menstruation, everything and anything that she had learned or been told about sex during the general period of this hypnotically reestablished but purposely undefined period in her childhood. It is fair to call this an "undefined period in her childhood" because three or four years is indeed a long time to a child, and from among the many and diverse experiences of those years she was at liberty to select those things which were of outstanding importance. Had she been confined to a more restricted span of time, she could have chosen inconspicuous items. Leaving her to select from within a certain broad but critical period in her life forced her to choose the important and painful items.

Up to this point the hypnotic procedure had been systematically planned, with the expectation that any further procedure would depend upon the results of these preliminary maneuvers.

To these instructions the patient reacted with some fright. Then in a tense and childlike fashion she proceeded obediently to talk in brief disconnected sentences, phrases, and words. Her remarks related to sexual activity, although in the instructions given to her emphasis had been laid not upon intercourse but upon menstruation. The following constitutes an adequate account:

> My mother told me all about that. It's nasty. Girls mustn't let boys do anything to them. Not ever. Not nice. Nice girls never do. Only bad girls. *It would make mother sick.*[4] Bad girls are disgusting. I wouldn't do it. You mustn't let them touch you. You will get nasty feelings. You mustn't let them touch you. You will get nasty feelings. You mustn't touch yourself. Nasty. Mother told me never, never, and I won't. Must be careful. Must go good. Awful things happen if you aren't careful. Then you can't do anything. It's too late. I'm going to do like mother says. She wouldn't love me if I didn't.

Many of the remarks were repeated many times in essentially identical wordings. Some were uttered only once or twice. She was allowed to continue her recitation until no new material was forthcoming, except the one additional item that this moralistic lecture had been given by the mother on several occasions.

No attempt was made to introduce any questions while she was talking, but when she had ceased she was asked, "Why does your mother tell you these many things?"

"So I'll *always* be a good girl," was the simple, earnest, childlike reply.[5]

Although it was clear, almost from the start, that the patient's passive and submissive dependence upon the mother's commands would have to be broken, it was equally evident that the image of the dead mother played a role in her life which overshadowed that of any living person and that this idolized superego figure could not be dislodged from its position by any direct frontal attack. For this reason the hypnotist's stratagem was to adopt a point of view as nearly identical with the mother as he could. He had first to identify himself entirely with this mother image. Only at the end did he dare to introduce a hint of any qualifying reservations. Therefore he began by giving the patient immediate and emphatic assurance: "Of course you *always* will be a good girl." Then in a manner which was in harmony with the mother's stern, rigid, moralistic, and forbidding attitudes (as judged from the patient's manner and words), each idea attributed to the mother was carefully reviewed in the same terms, and each was earnestly approved. In addition the patient was admonished urgently to be glad that her mother had already told her so many of those important things that every mother really should tell her little girl. Finally, she was instructed to "remember telling me about all of these things, because I'm going to have you tell me about them again some other time."

The patient was gradually and systematically reoriented in terms of her current age and situation in life, thereby reestablishing the original hypnotic trance. However, the earlier instructions to "forget many things," were still in effect, and an amnesia was induced and maintained for all of the events of the hypnotically induced state of regression. This was done in order to soften the transition from those early memories to the present because of the intense conflict which existed between the early maternal commands and her current impulses.

She was prepared for the next step, however, by being told that she would shortly be awakened from her trance and that then she would be asked some questions about her childhood which she was to answer fully. To have asked her in her ordinary waking state about her sexual instructions would have been merely to repeat the severe aggressions of all of her previous experiences with psychiatrists; but by telling her during her trance that questions about her childhood would be asked, she was prepared to take a passive intellectual attitude toward the demand, and to obey it without consciously admitting its connection with her present problems.

As a further preparation for the next step she was told that the nature of the questions to be asked of her would not be explained to her until she had awakened, and that until then

it would suffice for her to know merely that the questions would deal with her childhood. Here again the hypnotist was governed by the basic principle of making all commands as general and nonspecific as possible, leaving it to the subject's own emotional needs to focus his remarks.

Finally, technical suggestions were given to the patient to the effect that she should allow herself to be hypnotized again, that she should go into a sound and deep trance, that if she had any resistances toward such a trance she would make the hypnotist aware of it after the trance had developed, whereupon she could then decide whether or not to continue in the trance. The purpose of these suggestions was merely to make certain that the patient would again allow herself to be hypnotized with full confidence that she could if she chose disrupt the trance at any time. This illusion of self-determination made it certain that the hypnotist would be able to swing the patient into a trance. Once she was in that condition, he was confident that he could keep her there until his therapeutic aims had been achieved.

Upon awakening, the patient showed no awareness of having been in a trance. She complained of feeling tired and remarked spontaneously that perhaps hypnosis might help her, since it seemed to be helping her roommate. Purposely, no reply was made to this. Instead she was asked abruptly, "Will you please tell me everything you can about any special instructions concerning sexual matters that your mother may have given you when you were a little girl?"

After a show of hesitation and reluctance, the patient began in a low voice and in a manner of rigid primness to repeat essentially the same story that she had told in the earlier regressive trance state, except that this time she employed a stilted, adult vocabulary and sentence structure, and made much mention of her mother. Her account was essentially as follows:

> My mother gave me very careful instruction on many occasions about the time I began to menstruate. Mother impressed upon me many times the importance of every nice girl protecting herself from undesirable associations and experiences. Mother made me realize how nauseating, filthy, and disgusting sex can be. Mother made me realize the degraded character of anybody who indulges in sex. I appreciate my mother's careful instruction of me when I was just a little girl.

She made no effort to elaborate on any of these remarks and was obviously eager to dismiss the topic. When she had concluded her account of her mother's teachings, they were systematically restated to her without any comment or criticism. Instead they were given full and earnest approval, and she was told that she should be most grateful that her mother had taken advantage of every opportunity to tell her little daughter those things every little child should know and should begin to understand in childhood.

Following this an appointment was made for another interview a week hence, and she was hastily dismissed.

During the course of the following week no new reactions were noted in the patient by her roommate, and the general trend of her depressive behavior continued unchanged.

THE SECOND HYPNOTIC TRANCE

At the second appointment the patient readily developed a deep trance and at once was instructed to recall completely and in chronological order the events of the previous session. She was asked to review them in her mind silently, then to recount them aloud slowly and thoughtfully but without any elaboration.

Such silent review of a hypnotically repressed experience is a necessary preparation. It ensures completeness of the final recall. It avoids uneven emphasis on separate elements in the recollection and distorted emphasis which the subject subsequently would feel the need of defending. It permits an initial recall in silence without any feeling that in remembering facts the subject is also betraying them to someone else. This facilitates the reassembling of painful elements in the subject's memories. Finally, when the subject is asked to tell aloud that which has just been thought through in silence, it becomes a recounting of mere thoughts and memories, rather than the more painful recounting of actual events. This also helps to lessen the emotional barriers against communicating with the hypnotist.

As the patient completed this task, her attention again was drawn to the fact that her mother had lectured her repeatedly. Then she was asked, "How old were you when your mother died?" She replied, "When I was thirteen." Immediately the comment was made with quiet emphasis, "Had your mother lived longer, she would have talked to you many more times to give you advice; but since she died when you were only thirteen, she could not complete that task, and so it became your task to complete it without her help."

Without giving the patient any opportunity either to accept this comment or to reject it, or indeed to react to it in any way, she quickly was switched to something else by asking her to give an account of the events which had occurred immediately after she had awakened from her first trance. As she completed the account, her attention was drawn to the repetitive character of her mother's lectures, and the same careful comment was made on the unfinished character of her mother's work.

It will be recalled that on the first day of hypnotic work the patient was brought back to an early period in her childhood, and in this pseudoregression, she was asked to give an account of the sexual instructions her mother had given her. Then through a series of intermediate transitional states she was wakened, and in her waking state she was asked to give an account of the same instructions, but with an amnesia for the fact that she had already told any of this to the hypnotist. In the second hypnotic treatment up to this point the patient was promptly hypnotized, and the posthypnotic amnesia for the first hypnotic experience was lifted so that she could recall all of the events of her first trance. Then she was asked to review the material which she had discussed immediately after awakening from the first trance—in short, her conscious memories of her mother's puritanical instructions. By reviewing in a trance both the events of her previous trance and the

events that had occurred immediately on her waking from this trance, a direct link was established between the childhood ides and affects and those of the previous week's adult experience. Thus the two could be contrasted and compared from her adult point of view.

The patient then was reoriented to the same period of early childhood. She was reminded of the account she had given before and was asked to repeat it. When she had done so, in terms essentially identical with those she had used in her original account, similar approving remarks were made, but this time so worded as to emphasize sharply the fact that these lectures had all been given to her in her childhood. When this seemed to be impressed upon her adequately, the suggestion was made quietly that as she grew older, her mother would have to give her additional advice, since things change as one grows older. This idea was repeated over and over, always in conjunction with the additional suggestion that she might well wonder what other things her mother would tell her as she grew older.

Immediately after this last suggestion the patient was brought back from her pseudochildhood to an ordinary trance state. She was asked to repeat her account of the remarks she had made in the waking state. She was urged to take special care not to confuse the words she had used when fully awake with the words of the account she had given in the first pseudochildhood trance state, even though the ideas expressed were essentially the same and even though she had both accounts fresh in her mind. This request constituted a permission to remember now in an ordinary trance the events of the second pseudochildhood trance, since this had been merely a repetition of the first, but the fact that there had been a second trance of this kind would not be recalled. Instead the two trances would be blended into a single experience.

As before, the purpose of these devices was to bring gradually together the child's and the adult's points of view. Into her childhood perspective an element of expectation and of wondering had been introduced by the comment that as she grew older, her mother would have had more to teach her. This now was ready to be brought to bear upon the adult version of her mother's instructions, which she had also given.

The blending of the two experiences served an additional technical purpose. In the first place repetitions are necessary under hypnosis, just as they are in dream analysis or in the recounting of experiences by patients under analysis in general. Without repetitions one cannot be sure that all of the material is brought to expression; moreover, allowing the subject under hypnosis to recall both the original version and the various repetitions as though they were a single occasion actually gives the subject something to hold back—namely, the fact that there were two or more experiences. This seems to satisfy the subject's need to withhold something, by giving her something unimportant to withhold in return for the important fact which is divulged. This the hypnotist can well afford to do, just as one can allow a baby to refuse to give up a rattle when he has already given up the butcher's knife. The baby is satisfied and so is the parent.

As the patient concluded this task, her attention was drawn again to the period of her life in which her mother's lectures had been given, the repetitions of these lectures, their

incompleteness, the unfinished task left to a little girl by her mother's death, and the necessity to speak to a child in simple and unqualified language before she is old enough for more complex adult understanding. Every effort was made to impress each of these specific points upon her, but always by the use of terms as general as possible.

Without giving the patient an opportunity to develop or elaborate these points, the suggestion was made that she might well begin the hitherto unrealized and unrecognized task of continuing for herself the course of sexual instruction which her mother had begun but had been unable to finish because of her death. She was urged that she might best begin this unfinished task by speculating earnestly and seriously upon what advice her mother would have given her during the years intervening between childhood and adolescence and between adolescence and adult womanhood. As she accepted this suggestion, it was amplified by additional instructions to take into consideration all intellectual and emotional aspects, all such things as physical, psychological, and emotional changes, development and growth, and most important to give full consideration to the ultimate reasonable goals of an adult woman, and to do so completely, fully, freely, and without fail, and to elaborate each idea in full accord with the facts appropriate to herself.

Immediately after this instruction was given, the patient was told that upon awakening she should repeat all of the various accounts she had given in this hypnotic session, preferably in their chronological order, or else, if she chose, in any other comprehensive form which she preferred. Thereupon she was awakened.

The patient's waking account was decidedly brief. She slowly combined everything which she had said into a single, concise story. Significantly, she spoke in the past tense: "My mother attempted to give me an understanding of sex. She tried to give it to me in a way that a child such as I was could understand. She impressed upon me the seriousness of sex; also, the importance of having nothing to do with it. She made it very clear to me as a child."

This account was given with long pauses between each sentence, as though she was thinking profoundly. She interrupted herself several times to comment on her mother's death and on the incompleteness of her instruction, and to remark that had her mother lived, more things would have been said. Repeatedly she said, as if to herself, "I wonder how mother would have told me the things I should know now."

The examiner seized upon this last remark as a point for terminating the session, and the patient was dismissed hastily. No attempt was made to guide her thoughts beyond the urgent instruction to speculate freely upon the things her mother would have told her and which she now needed to know. She was told to return in one week.

During this week the patient showed marked improvement. Her roommate reported "some crying, but of a different kind," and none of the previous depressed behavior. The patient seemed rather to be profoundly self-absorbed, absent-minded, and puzzled; much

of the time she wore a thoughtful and sometimes bewildered expression. No attempt was made to establish any contact with the patient during the week.

THIRD HYPNOTIC SESSION

Promptly upon her arrival for the third session the patient was hypnotized and instructed to review rapidly and silently within her own mind all of the events of the two previous sessions, to recall the instructions and suggestions which had been given to her and the responses she had made, to include in her review any new attitudes which she might have developed and to give full and free rein to her thinking, and finally to summarize aloud her ideas and conclusions as she proceeded with this task.

Slowly and thoughtfully, but with an appearance of ease and comfort, the patient proceeded to review these events freely, briefly, and with no assistance. Her final statement summarized her performance most adequately:

> You might say that mother tried to tell me the things I needed to know, that she would have told me how to take care of myself happily and how to look forward confidently to the time when I could do those things appropriate to my age, have a husband and a home and be a woman who has grown up.

The patient was asked to repeat this review in greater detail, in order to be sure that toward both her childhood and adult years she had achieved suitable adult attitudes. As these instructions were repeated slowly and emphatically, the patient became profoundly absorbed in thought, and after a short while she turned with an alert, attentive expression, as if awaiting the next step.

Instruction was given that when she awoke she was to have a complete amnesia for all three sessions, including even the fact that she had been hypnotized, with the exception that she would be able to recall her first stilted, prim, waking account. This amnesia was to include any new and satisfying understanding she had come to possess. She was told further that upon awakening she would be given a systematic review of her sex instruction as the hypnotist had learned about these matters from her, but that because of the all-inclusive amnesia this review would seem to her to be a hypothetical construction of probabilities built by the hypnotist upon that first waking account. As this occurred, she was to listen with intense interest and ever growing understanding. She would find truths and meanings and applications understandable only to her in whatever was said, and as those continued and developed, she would acquire a capacity to interpret, to apply, and to recognize them as actually belonging to her, and to do so far beyond any capacity that the hypnotist might have to understand.

At first glance it would seem strange to suggest repression of insight as one of the culminating steps in a therapeutic procedure. In the first place it implies that much of the affective insight may either remain or again become unconscious without lessening its therapeutic value. Secondly, it protects the subject from the disturbing feeling that anyone else knows the things about her which she now knows, but which she wishes to keep to

herself; hence the importance of the suggestions that she would understand far more than the hypnotist. Thirdly, by looking upon the material as a purely hypothetical construction of probabilities by the hypnotist, the patient was provided with an opportunity to recover insight gradually, in a slowly progressive fashion, as she tested this hypothetical structure. Had the same material been presented to her as definite and unquestionable facts, she might again have developed sudden repressions with a spontaneous loss of all insight. If that occurred, the investigation would have had to be undertaken afresh. On the other hand, where a certain measure of repression is ordered by, the hypnotist, it remains under his control, because what the hypnotist suppresses he can recover at will. Thus her degree of insight remained under full and complete control by the hypnotist, so that he could at any time give the patient full insight or prepare her for it again. Finally, by depriving the patient temporarily of her new and gratifying insight, a certain unconscious eagerness and need for further knowledge was developed which assisted in the ultimate recovery of full insight.

When these instructions had been repeated sufficiently to effect a full understanding, the patient was awakened with an amnesia for all events except the stilted, prim account which she had given at the end of the first therapeutic session. Reminding her of that account, the hypnotist offered to speculate upon the probable nature and development of the sex instructions which she had been given. He proceeded to review all the material she had furnished in general terms that permitted her to apply them freely to her own experiences.

Thus the patient was given a general review of the development of all the primary and secondary sexual characteristics: the phenomenon of menstruation, the appearance of pubic and axillary hair, the development of her breasts, the probable interest in the growth of her nipples, the first wearing of a brassiere, the possibilities that boys had noticed her developing figure and that some of them may have slapped her freshly, and the like. Each was named in rapid succession without placing emphasis on any individual item. This was followed by a discussion of modesty, of the first feelings of sexual awareness, or autoerotic feelings, of the ideas of love in puberty and adolescence, of the possible ideas of where babies came from. Thus without any specific data, a wide variety of ideas and typical experiences were covered by name. After this, general statements were made as to the speculations that might have passed through her mind at one time or another. This again was done slowly and always in vague general terms, so that she could make a comprehensive and extensive personal application of these remarks.

Shortly after this procedure was begun, the patient responded by a show of interest and with every outward manifestation of insight and of understanding. At the conclusion the patient declared simply, “You know, I can understand what has been wrong with me, but I’m in a hurry now and I will tell you tomorrow.”

This was the patient’s first acknowledgment that she had a problem, and instead of permitting her to rush away, she was promptly rehypnotized and was emphatically instructed to recover any and all memories of her trance experiences that would be of use. By stressing in this way the fact that certain of those memories would be valuable and

useful to her, the patient was led to view all of them as possibly useful, thus withdrawing her attention from any conflicting feelings about those memories. This assists in their free and full recovery by the patient. She was told that she should feel free to ask for advice, suggestions, and any instruction that she wished, and to do so freely and comfortably. As soon as this instruction had been firmly impressed, the patient was awakened.

Immediately, but with less urgency, she said that she wanted to leave but added that she would first like to ask a few questions. When told that she might do so, the patient asked the hypnotist to state his personal opinion about "kissing, petting, and necking." Very cautiously and using her own words, approbation was given of all three, with the reservation that each should be done in a manner which conformed with one's own ideals and that only such amorous behavior could be indulged in as would conform to the essential ideals of the individual personality. The patient received this statement thoughtfully and then asked for a personal opinion as to whether it was right to feel sexual desires. The cautious reply was given that sexual desire was a normal and essential feeling for every living creature and that its absence from appropriate situations was wrong. To this was added the statement that she would undoubtedly agree that her own mother, were she living, would have said the same thing. After thinking this over, the patient left hastily.

THERAPEUTIC OUTCOME

The next day the patient returned to declare that she had spent the previous evening in the company of her suitor. With many blushes she added, "Kissing is great sport." Thereupon she made another hurried departure.

A few days later she was seen by appointment and held out her left hand to display an engagement ring. She explained that as a result of her talk with the hypnotist during the last therapeutic session, she had gained an entirely new understanding of many things, and that this new understanding had made it possible for her to accept the emotion of love and to experience sexual desires and feelings, and that she was now entirely grown up and ready for the experiences of womanhood. She seemed unwilling to discuss matters further, except to ask whether she might have another interview with the hypnotist in the near future, explaining that at that time she would like to receive instruction about coitus, since she expected to be married shortly. She added with some slight embarrassment, "Doctor, that time I wanted to rush away.... By not letting me rush away, you saved my virginity. I wanted to go right to him and offer myself to him at once."

Sometime later she was seen in accordance with her request. A minimum of information was given her, and it was found that she had no particular worries or concern about the entire matter and was straightforward and earnest about her desire to be instructed. Shortly afterward the patient came in to report that she was to be married within a few days and that she looked forward happily to her honeymoon.

About a year later she came in to report that her married life was all she could hope for, and that she was anticipating motherhood with much pleasure. Two years later she was seen again and was found to be happy with her husband and her baby daughter.

SUMMARY AND DISCUSSION

For special reasons the treatment of this patient had to be approached with many precautions. The circumstances of her illness made a direct approach to her problem (whether by a man or a woman) dangerous because such an approach invariably caused an acute increase of her panic and of her suicidal depression. She could be treated, if at all, only by creating an elaborate pretense of leaving her problems quite alone, without even letting her realize that any therapy was being attempted, without acknowledging the development of a relationship between the patient and the physician, and without open reference to the experiences which had precipitated her illness.

For these reasons the treatment was begun by pretending to treat someone else in her presence, and, through this means she was slowly and gradually brought into a hypnotic state in which her own problems could be approached more directly.

From this point on the treatment proceeded along lines which are the reverse of the usual psychoanalytic technique. Some points seem to be worthy of special emphasis.

Instead of depending solely upon memory to recover important experiences out of the past, the patient under hypnosis was translated back to a critical period of her childhood, so that in that state she could relive or revive the general quality of the influences playing upon her, but without recapturing the details of specific scenes and episodes. Instead of stirring them up and making them conscious, there was a deliberate effort to avoid the induction of any feelings of guilt or fear. Similarly, instead of insisting upon total conscious recall, permission was freely granted to the patient to forget painful things, not only during but also after the hypnotic treatment. Underlying this permission to forget was the confidence that even those facts which were consciously forgotten could be recovered during the hypnosis when needed for therapeutic use, and that their therapeutic efficacy would continue even during the posthypnotic repression.

The hypnotist's attack on the patient's rigid superego was interesting from various points of view. Particularly noteworthy, however, was the fact that the attack on the superego began with a complete support of all the most repressive attitudes which the patient attributed to her dead mother. It was only by forming a bond in this way between himself and the mother that he was able later slowly to undermine the rigidity of this repressive figure and thus to penetrate the patient's tense and automatic defenses of her mother's dictates. Another significant point is the method used by the hypnotist to help the patient silently assemble her ideas before communicating them. This seemed to assist materially in reducing the patient's fear of remembering presumably because it is not as difficult to recall embarrassing things which one can keep to one's self as it is to bring them to mind with the knowledge that one must confess them at once; moreover, once such things have been reviewed in thought, it becomes easier to talk of the thoughts than it would have

been to talk of the events themselves. This two-stage method of recalling and assembling data before communicating it might have its usefulness in analysis as well.

A point at which the work of the hypnotist coincides closely with that of the analyst is in the use of repetitions in many forms and at each age level investigated. This use of repetitions is quite similar to what is found to be necessary in analysis as well.

In understanding the course of this treatment and of the patient's recovery, there are many gaps in the material, gaps which could be filled in only by conducting a treatment of this kind in a patient who had been under a fairly prolonged analysis.

There are many questions we would like to have answered. Was the basis of the mother's overwhelming authority primarily affection or hostility and fear? Were the dead mother and the dead friend equivalent? If the hypnotist had said instead that he was the dear friend, and that as the dead friend he encouraged and approved of her love-making with the dead friend's husband (an equivalent of a mother telling her that she could make love to her father), would this impersonation of the friend by the hypnotist have freed the patient from guilt feelings and from her hysterical depression without the induced regression to childhood? What was the mechanism of the cure? Was the hypnotist equated to her mother, and thus enabled to remove the mother's taboos? Or was the fiancé at first a surrogate father until the hypnotist took over the father's role, thus removing it from the man and thereby making it possible for the patient to have an erotic relation with the man without a barrier of incest taboos? What was the role of her orality and its significance in relationship to the vomiting? In general, what was the role of all those basic facts of her early life, which must have determined the patient's relationship to her parents and to people in general?

The answers to these gaps in information is challenging, both from a theoretical and from a factual point of view. The knowledge of these facts is indispensable for an understanding of the structure of the illness and the dynamics of the recovery. But the fact that recovery could take place so quickly and without hospitalization, in face of the fact that there were so many things which the hypnotist never discovered and that the patient did not know, also has its important theoretical consequences. It faces us with the question: if recovery can take place with the gain of such rudimentary insight, what then is the relationship between unconscious insight, conscious insight, and the process of recovery from a neurosis?

---

[1]These two points are of special interest to analysts who are accustomed to demand of their patients an awareness of their illnesses and of the need for treatment, and an acceptance of the therapeutic relationship to the analyst. While this is a valid basis for therapeutic work with many of the neuroses, it is an impossible goal in dealing with many neurotic characters and with those neuroses which are accompanied by severe affective disturbances, and with psychoses. Analysts who become too completely habituated to their own method may delude themselves with the idea that their passivity is pacifying, and may overlook the extent to which it may be an assault in terms of the patient's unconscious emotional reactions. The approach described above, therefore, is an illustration of a method whereby, under appropriate circumstances, these difficulties can be circumvented.

[2]Here again is an interesting and significant departure from analytic technique, in which the implicit and sometimes explicit challenge is to break through every repression. The rigidity with which this axiom of analytic technique is applied may account for some analytic failures; it may also be an example of conflict between research and therapeutic purposes.

[3]The search back toward reliving an earlier period in the life of a hypnotic subject occurs in either of two ways. First there can be a "regression" in terms of what the subject as an adult believes, understands, remembers, or imagines about that earlier period of her life. In this form of "regression" the subject's behavior will be a half-conscious dramatization of her present understanding of that previous time, and she will behave as she believes would be suitable for her as a child of the suggested age level. The other type of "regression" is far different in character and significance. It requires an actual revivication of the patterns of behavior of the suggested earlier period of life in terms only of what actually belonged there. It is not a "regression" through the use of current memories, recollections, or reconstructions of a bygone day. The present itself and all subsequent life and experience are as though they were blotted out. Consequently, in this second type of regression the hypnotist and the hypnotic situation, as well many other things, become anachronisms and nonexistent. In addition to the difficulties inherent in keeping hypnotic control over a total situation, this "deletion" of the hypnotist creates an additional difficulty. It is not easy for the hypnotist to enter into conversation with someone who will not meet him until 10 years hence. This difficulty is overcome by transforming the hypnotist into someone known to the patient during the earlier period, by suggesting that he is "someone whom you know and like and trust and talk to." Usually a teacher, an uncle, a neighbor, some definite or indefinite figure belonging to the desired age period is selected automatically by the subject's unconscious. Such a transformation of the hypnotist makes it possible to maintain contact with the subject in the face of the anachronism mentioned above. Unfortunately many investigators of "hypnotic regression" have accepted as valid that type of "regression" which is based upon current conceptions of the past; and they have not gone on to the type of true regression in which the hypnotic situation itself ceases and the subject is plunged directly into the chronological past.

[4]The phrase, "It would make mother sick," may have had much to do with her illness: Mother had had intercourse and died. Her friend, who was a mother substitute had had intercourse and died. The same thing was about to happen to the patient. Mother has said it, and it must be true. It is a child's passive acceptance of logic from the image with which it has become identified.

[5]Here is an important bit of profound, unconscious psychological wisdom. The commands had been repeated incessantly in the patient's mind, whether or not in reality they had been repeated as incessantly by the mother. This repetition, which is the essence of all neurosis (Kubie, 1939), must occur because of the resurgent instinctual demands. Hence the patient indicates in the word always her continuing secret insurrection against a continuing prohibition, and therefore her ever-present state of fear.

The Experimental Demonstration of Unconscious Mentation by Automatic Writing

Milton H. Erickson

Reprinted with permission from *The Psychoanalytic Quarterly*, October, 1937,
Vol. VI, No. 4.

For the most part our knowledge of psychological processes has been achieved through clinical observations. That such knowledge is valid is readily admitted, but its confirmation by other methods is essential. For this reason the application of experimental procedure is a desirable means of retesting conclusions reached clinically. In this way hypotheses may be subjected to direct tests from which the extraneous forces inevitable in clinical situations may be excluded. In an effort to develop methods for this sort of laboratory investigation, the experimental procedures reported here were undertaken.

PROTOCOL I

During an evening gathering of about ten college people a discussion arose about hypnotism and the role of the unconscious in conscious actions. The writer claimed that people could perform an act consciously which would express fully all of their conscious purposes, but which could simultaneously have another unconscious meaning, and that by appropriate measures this unconscious meaning could be brought fully into consciousness. This gave rise to much argument, and presently one of the subjects of the writer's earliest experiments with hypnotism volunteered her services.

In casting about for some act which could be regarded fully so that no doubts might arise, the suggestion was made that the subject be asked to write something, thus making the performance tangible. Accordingly, the subject was told *that she was to write something, in full conscious awareness of what she was writing, that her writing was to be clearly legible to everyone present, but that in writing it her unconscious would so guide her hand that she would in actuality write something beyond that which could be read either by herself or by the others present*. To these instructions a flippant reply was given, not in keeping with the serious general tone of the discussion, namely, "You say words, but they don't make sense."

There followed further discussion about what should be written. The author proposed that all present should guess the length of time that it had taken a member of the group to move a certain article in the room. The guesses ranged from two seconds to half a minute, the subject alone venturing the absurd estimate of "two to three minutes." Each one defended his own guess warmly, but the subject was peculiarly insistent upon her accuracy. After some general argument the author suggested to the subject that she write

her *unconscious guess* as to the length of time involved. She protested emphatically that her conscious and unconscious guesses would be the same, and that there was no point in writing it down since she had already put it into words and defended it orally. However, in response to the author's insistence she began to write. As she set pencil to paper, she looked startled and declared emphatically, "It wasn't either—it was at least two minutes." She then proceeded to write rather slowly and in the uncertain, juvenile script shown in the illustration. Again as she wrote she said, "It wasn't either, I know it was at least two

minutes, nearer three." When finished, she was asked if she knew what she had written. She replied, "Yes, I know, but it isn't so." She was promptly told not to say aloud what she had written, and the paper was passed around with the injunction that each should read it silently.

When all had examined it, the subject was asked what she had written.
She replied, "I wrote `thirty seconds,' but that isn't right because it was at least two minutes, if not three." After scanning the writing again, the author asked if the group accepted her statement of what she had, written.
Some reexamined the writing but all agreed that it read "thirty seconds." The subject was reminded of the original discussion about hidden unconscious meanings and asked if she was sure she had read it correctly. To this she replied, "As soon as I started to write, I knew I was going to write 'thirty seconds.' I knew that that was wrong, but my hand just went ahead and wrote it." Again she was asked if she was sure she had read her writing correctly. She replied, "Well, you will have to admit that that's a t and an *h* and an *i*. Look at that *r*—you can't mistake that, or the t. It just has to be thirty. You have all the letters there. I admit the writing is bad, but you try holding paper on your lap when you write and your writing won't be so good either. I'm sure that that s is an s. " Here the subject asked several of the group individually if they, too, felt certain of the identity of the *s*. Finally accepting their reassurances, she continued, "That's a period after *c*, which makes the abbreviation for seconds. 'Thirty sec.' is what it reads, with seconds abbreviated, but my handwriting would be better if I had a better place to put the paper." Again the author asked, "But really, haven't you written something more? Can't you read something more than just `thirty sec.?' She scanned the paper carefully, as did the other members of the group, but all insisted that the writing clearly and legibly read "thirty sec." The subject continued to insist that she knew what she was going to write immediately upon the initiation of the act of writing, and that she had written exactly what was in her mind.

She was then requested to answer the following questions *by means of automatic writing*, as a method of securing unconscious responses directly. The questions and the answers obtained by the automatic writing are given verbatim:

Q. Does this writing read "thirty sec."?

A. Yes.

Q. Does the writing have any additional meaning?

A. Yes.

Q. Can it be read?

A. Yes.

Q. Has anybody read the writing correctly?

A. No

Q. Is "thirty sec." the correct reading?

A. No.

Q. Is something omitted in reading "thirty sec."?

A. Yes.

Q. Will you write that which has been omitted?

A. Yes.

Q. All right, write what has been omitted.

A. 8 [written as a numeral].

Q. What does the writing really read, then?

A. 38 sec. [in numerals.]

Immediately after writing the last reply, the subject picked up the original writing and declared, "Yes, it does read *38*, only I didn't realize that y was written as an *8*. I can see it now. I wasn't thinking of numbers and I was sure that *thirty* was wrong. Yet I knew that the t and the r were plain, and I was sure the s was an s. I can see the *8* now, but I couldn't before even though I know now that I wrote it. I was so sure you were wrong when you acted as if I had written something I didn't know about."

The subject was then asked to write automatically the replies to the following questions, which are given verbatim with their answers:

Q. Do you recall the instructions I gave you about combining conscious and unconscious activity?

A. Yes.

Q. Is this writing your demonstration of this?

A. Yes.

Summary of Protocol I

The main steps in this observation can be summarized as follows;

1. A general discussion of the question of whether a single act can simultaneously express both a conscious and an unconscious meaning and purpose.
2. The decision to test this through automatic writing.
3. An offer to serve as the "test animal" by a woman who had frequently been subjected to hypnosis by the experimenter.
4. The request made that clearly and consciously she should write something which contained a concealed double meaning.
5. Her flippant retort.
6. The execution of this order: while she is thinking and saying "two to three minutes," she writes out in script "thirty sec." in such a way that the *y* conceals the number *8* and can also be read to mean "38 seconds."
7. This is done so cleverly that at first no one except the experimenter consciously recognizes the presence of the concealed figure 8.
8. When asked to describe *aloud* what she had written, the subject insists that she has written "thirty seconds." When asked to describe this by *automatic writing*, the subject writes "38 sec.," thus indicating that on an unconscious level she was fully aware of the little joke with which she had carried out the experimenter's request, although on a conscious level she had no knowledge of it.

Discussion

In the above experiment two types of behavior attract attention. The first of these is the subject's flippant and ambiguous reply when given her instructions. By replying in this way she consciously neither accepted nor rejected the instructions, but left herself free to react to the instructions as she chose. Consciously she accepted the task; but at the same time by this flippant attitude she shifted onto her unconscious the guidance of her response.

To support this shift another simple technique of self-distraction was employed: the grossly exaggerated guess which she made about the time. Although of the others present none guessed more than a half a minute, the subject insisted that the action had taken two to three minutes. Thus she placed herself at variance with the entire group and gave herself a conscious issue to battle over. As a result, as she began to write, she was concerned not with the identity of *what* she was writing, but rather with the problem of her correctness.

Then, after she had completed her writing, and her defenses against full conscious awareness were threatened again as the experimenter asked her to examine her writing, she rendered this dangerous procedure harmless by isolating the individual letters one from another. Even so the irregularity of the y raised a pressing problem. From this she extricated herself by stressing the difficulty of writing on paper held in her lap (in itself a valid rationalization) and then furthered this distraction by raising an immediate and insistent doubt concerning the identity of the letter *s*, thereby displacing to safer territory the doubt properly centering about the *y*. This was followed by still further distraction of her attention to the period and to the abbreviated form of the word. Having thus identified the two parts, she was able again to identify the phrase as a whole, avoiding as she did so any other possibility. Thus, with the irregularity of the critical letter y explained plausibly by the physical difficulties of writing, and its identity bounded on both sides by clearly identified letters, any critical conscious consideration of its meaning was precluded.

When she was pushed still further to search for hidden meanings in what she had written, the emotions involved in the unconscious purpose to keep her little joke to herself were expressed as an anxiety concerning the experimenter, later described as the feeling, "I was so sure you were wrong."

Finally, mention must be made of her use of two different types of written symbols, the word form and the numerical form, to express a unitary thought. The tendency for one pattern of thinking to persist, and the difficulty in shifting to another type, are generally recognized. The task imposed on the subject of this experimentation implied the simultaneous performance of two different types of mental activity, one of which would be obvious and attention-compelling and thus able to establish a pattern of mental activity that could obscure and inhibit the recognition of the other. Hence the written production began with a word and ended with a word, with the numerical symbol secreted in a part of the first word, although when seen in isolation it is easily recognizable.

Thus by writing the phrase "thirty-eight seconds" with the eight as a numerical symbol forming the *y* of the word *thirty*, by apparently failing to understand instructions, by developing minor affects of a mild anxiety, by rationalizing realities, and by employing techniques of self-distraction and mixing together two different types of symbolic expression, she was able to execute consciously an act which in itself was fully expressive and complete, but which simultaneously possessed an additional unrecognized significance at another level of mentation. By a technique of automatic writing this hidden meaning was revealed by the subject, who only then could recognize it consciously.

PROTOCOL II

A 22 year-old girl, a college graduate and member of the staff, had been one of those present when the previous experiment had been performed. She was interested in the possibility of independent unconscious thinking and asked to be hypnotized and to be taught automatic writing as a possible means of identifying some of her own inner conflicts. After some discussion an appointment was arranged, and that very evening an attempt was made to hypnotize her.

She was exceedingly resistive, and finally it became necessary to pretend to abandon the attempt. The hypnotist feigned interest in a radio program and somewhat discourteously ignored her request that he try again. She became resentful at this and retaliated, perhaps, by going into a spontaneous sleep. As soon as she was sleeping soundly, she was roused gently, and then by slowly graduated suggestions she was led into a fairly deep hypnotic sleep. In this state a domineering type of suggestion was employed, and she was literally forced to walk about, to change her position, and to manifest catalepsy, in order to induce a deeper trance.[1]

During these procedures casual mention was made of automatic writing—a few general remarks, followed by a vague hint that she herself might sometime do automatic writing. Then, after further and more explicit discussion, a definite suggestion was made that she write automatically at once. She was seated at a desk and instructed to dream of pleasant things of long ago, and told that as she did this her hand would automatically write some simple unemotional statements. She complied fairly readily, showing the typical juvenile script of automatic writing, and wrote, “The lady washed my hair,” followed by, “Cats and dogs fight.”

When it was observed that her writing was legible and her arm movements free, she was given the further suggestion that after awakening, whenever the experimenter rapped on his desk or chair, she should automatically write the sentence, “‘Twas a dark and dreary night.” She was also instructed to write legibly, easily, rapidly, and without paying any conscious attention to her hand.

The subject was wakened, and subsequently eight times during the course of the evening she was induced to write the phrase, “‘Twas a dark and dreary night,” in response to eight separate tapping signals. Some of these were done while she was awake, but with her attention distracted. Some were done while she was again in a state of hypnotic sleep. At the end, under hypnosis, she was instructed to remember nothing of the entire complicated activity of the evening except the fact that she had been in a trance—once. It was this command which became the storm center around which the experiment focused.

Several times during the course of these observations, when questioned as to the number of times she had written the posthypnotic phrase, the subject became confused and had made varying mistakes. It was evident, however, that she was always struggling against a

too-compliant acquiescence to the suggestions which had been given her under hypnosis. The same attitude was indicated now at the end of the experiment.

For some minutes she was allowed to sleep quietly, after which she was awakened and a casual conversation was resumed. Suddenly this was interrupted in order to ask, "How many times have you been in a trance this evening?" She looked puzzled and then very slowly and very thoughtfully replied, "three times, maybe four, but I wouldn't know how many because *all I want to say is 'once'* and I can't figure out why I should want to say 'once.'" The remark was made casually, "Well, if you want to say numbers and are interested in saying numbers, just say the first number that comes into your mind." She replied with unwonted alacrity, "Thirty-five." The experimenter had expected her to say "eight," thus completing her rejection of the general instructions for amnesia which she had begun in her statement about the number of times she had been in a trance. Although she had wanted to reply "once" in obedience to my instructions, she actually had answered "three to four."

She was asked, "Why did you say, `thirty-five'?" She answered, "I don't know. That was the first number that came to my mind that seemed to be right." Asked, "Why is it right?" she answered, "It just seems that way." "Has it any meaning?" "Well, all numbers have meaning, and I presume you would say then that thirty-five has a meaning." The experimenter wrote the number 35 and asked her to look at it carefully and to tell what it meant. She looked confused and puzzled, kept glancing at the number and then at the experimenter as if she could not understand what was meant. Finally she declared that the request was meaningless to her: "I just can't understand what you mean." Her whole manner suggested that she was blocked and unable to think clearly. In silence the experimenter wrote clearly on the paper, "7 plus 1 equals 8, which is the reason for saying 35." She still looked at it as blankly as a schoolchild struggling helplessly with a problem in arithmetic, and when told to think that over carefully, she smiled in an amused fashion, read it aloud, and said, "That doesn't mean anything to me. What has seven plus one equals eight got to do with thirty-five? There isn't any connection." Here again she seemed to show the pseudo-stupidity of a frightened schoolchild whose unconscious affects have got in the way of the thinking processes. She was asked, "Does your unconscious know what that means?" She replied, "I don't know, maybe it hasn't got any meanings."

The suggestion was given that her hand write automatically. She looked rather puzzled, picked up the pencil, and then glanced up for a cue. She was asked, "Does your unconscious understand that sentence?" She continued to look at the experimenter with a puzzled expression while her hand wrote freely in typical automatic script, "yes." When she had finished writing, the pencil dropped to the paper and she became aware that her hand had written. She looked at the word "yes," spelled it out, and asked, "What does that mean? Why did my hand write that?" The experimenter suggested, "That is the answer to my question," to which she replied, "What question?" The question was repeated, "Does your unconscious understand that sentence?" She again looked at "yes," grasped its relationship to the question, but still looked puzzled as to its meaning. Then she was asked, "Has that statement anything to do with the instructions given you in the last

trance?" Again she wrote "yes," while still studying the experimenter's face as if she did not understand what he said. As before she became aware of having written "yes" only as her pencil dropped on the page. She promptly inquired, "What does all this mean?" This query was answered with the further question, "Has it got anything to do with something you have done?" Again the automatic writing answered "yes."

The following series of questions was then asked, to each of which the subject replied with automatic writing, each time showing bewilderment and an inability to understand as she watched her hand write. The manner of asking each question was to address it to her hand as if it were a third person which will explain the reference to the subject herself as "she."

Q. You have written a sentence a number of times for me?

A. Yes.

Q. You know how many times you have written it?

A. Yes.

Q. Could you tell me how many times?

A. Yes.

Q. Would she know?

A. No.

There the subject interrupted to declare, "That isn't so. I know how many times I wrote it. Look, here I wrote it three times, and there once, that makes four, and here are two more, and there's another, no, that's the same one, no, here's that one—one, two, three, four, five, six, seven," pointing each time, "seven times I wrote it. You can see for yourself." In making this count, and pointing each time, she had moved her hand repeatedly back and forth over the eighth writing without noticing it, although it was fully as plain as the rest of the writing.

Again addressing the subject's hand:

Q. That's the right count for her, isn't it?

A. Yes [a pause, and then in fainter characters and less clearly formed letters], for her.

As the subject read this she demanded, "What does that mean, `for her'? I'm the only one that's writing—'for her'—Oh yes, that's what you just said when you spoke."

Q. Shall we tell her?

A. No [pause], not yet.

Here the subject read this reply aloud wonderingly, repeated “not yet,” then in a tone of marked affect demanded, “Say, what’s going on here?” Then apologetically, “Oh, I beg your pardon, Dr. Erickson, I didn’t mean that, I’m sorry.”

Q. It’s all right, isn’t it?

A. Sure!

Here the subject read her answer aloud saying, “Sure? Why, Dr. Erickson, I wouldn’t answer you like that, I don’t mean to be impolite. You know that, don’t you? I didn’t write that.”

Q. Was that number a chance selection?

A. No [written in large characters with pencil pressed heavily].

Q. Has that number the same significance as the answers you have been writing? [pointing to the previous answer, “No, not yet.”].

A. Yes [written emphatically].

Q. What do you think when I write [suiting the action to the word] “7 plus 1 equals 8 which is the reason for saying 35?”

As this was written, she declared, “I just got a wild desire to snicker, and I don’t know why. You are so serious, and it seems so silly.” But as she was making this statement, her hand was writing automatically, “You know too much,” concluding the writing by banging the pencil down to form a period. This attracted her attention, and she read it over and over in an abstracted, puzzled fashion, glancing up from time to time, trying to speak but apparently blocking each time, glancing down at the writing immediately each time that the words failed to come.

After some patient waiting:

Q. Has that [pointing to the written equation] got anything to do with the instructions given in the last trance?

A. [Verbally] Last trance, why, I can’t remember—last trance, which one—what happened—I—I—

Here she was interrupted by her hand again banging the pencil on the desk, and she became aware consciously that she had written, “You are too wise.” She read it aloud, glanced at the experimenter, repeated it, and said, “Why, my hand must mean you—

that's impertinent. —Just like this is [pointing to the "You know too much"]. I don't mean to be disrespectful—it isn't me—it's my hand [a pause]. Why, you and my hand are talking to each other—what are you talking about—tell me—tell me." Here the subject became so insistent that the experimenter was forced to yield.

Q. Would you like to know?

A. Yes [pause], tell her.

Q. Will you tell her?

A. No [pause], you.

During this questioning the subject watched her hand in a fascinated fashion and seemed greatly puzzled by the replies her hand was giving.

Q. How many times have you written, "'Twas a dark and dreary night"?

A. [Verbally] I wrote it seven times—but what has that got—oooh, ooh, I wrote it eight times—I forgot—you told me when I was asleep to forget everything—I only forgot part—I remember now—I wrote it here [searching the paper and identifying the writing correctly] see seven and one more, that makes eight, just like you said, but what has that got to do with thirty-five?

Q. Will you tell her?

A. No—you [automatic writing].

Q. I will tell her, but you fill in my explanation

My explanation was: "Look at thirty-five—you see three, five." Here the subject interrupted, "Oh, I see it now. You told me to forget everything in the last trance and you rapped on the desk and I wrote and I remembered that I wrote it—I didn't forget it and I wanted to tell you that. I still remembered that I had written it eight times but I only remembered writing it seven times, if you get what I mean, and when you asked me to give a number, I thought I was just giving any number. But now I can see that I was telling you eight times, and I was worried that you wouldn't understand, and when you wrote `seven plus one equals eight which is the reason for saying thirty-five' I knew you understood, and I thought you were too smart. No, that isn't what I said, I wrote `you are too wise,' but I meant too smart. I just told you thirty-five because that meant eight times. I can see it just as plain now."

The subject then stated that as she had written the two "impertinent" statements, she had had a "wild desire to snicker" but had controlled herself for fear of giving offense, and that this desire had been replaced by a sense of elation and satisfaction.

Summary of Protocol II

1. Request of a young female graduate student to be hypnotized and to be taught automatic writing.
2. Unsuccessful effort to hypnotize her.
3. Pretense of abandoning this effort.
4. Spontaneous sleep.
5. Spontaneous sleep converted into hypnotic sleep.
6. Forceful deepening of hypnotic sleep with induction of vigorous activity.
7. First automatic writing, consisting of irrelevant phrases while daydreaming.
8. Posthypnotic suggestion to write a special posthypnotic phrase whenever a tapping signal was given.
9. At this point the subject was put through a complicated series of maneuvers, some of them while awake but under the guidance of a posthypnotic suggestion, some of them under superinduced repetitions of the hypnotic state. During the course of these complicated tests, on eight occasions she wrote down the posthypnotic test phrase in response to the tapping signal.
10. Finally, while asleep, she was given the suggestion that she should remember nothing of the entire evening's experience except the fact that she had been in a hypnotic trance once. The obedience to this command was used as the experimental test situation.
11. Quiet sleep for several minutes, then awakened.
12. Asked how often she had been in an hypnotic state, she struggled against the suggestion (10), but acknowledged that she had a strong impulsion to say "once" although she knew it was more than that.
13. Finally came the number test with a concealed double meaning. When asked to say the first number she thought of, she said "thirty-five" and could give no reason for saying it.
14. Series of steps by which the point was made clear to the hypnotist and to the subject that 35 was an elliptical and secretive method of writing, "three plus five equals eight," to indicate the number of times which she had written the posthypnotic phrase. During this phase the patient's replies were divided so completely as almost to indicate a split into two organized egos, her conscious ego and the unconscious pseudoego organized around her automatic writing hand.

Discussion

For a definite reason these somewhat rambling observations were made without a carefully prearranged program. Their immediate goal was simply to demonstrate experimentally, and beyond any possible doubt, the fact that consciously chosen words, thoughts, and acts can mean more than one thing at a time: their conscious or manifest content on the one hand, and a latent, unconscious content on the other. Thus in these experiments what has long been known to be true for dreams is shown to be true for other human psychic processes. The more significant ultimate purpose of these random observations, however, was to seek out ways in which the technique of hypnotism and more particularly of automatic writing could be used for experimental purposes, and to

suggest specific problems to which they might be applied. The experiments give rise therefore to various somewhat heterogenous reflections.

1. In the first experiment one is struck by the versatility of the unconscious with respect to the methods it employs in order to dissimulate its purposes. The technique illustrated in the first protocol offers an opportunity to study the relationship between specific types of normal or neurotic characters and the various methods of unconscious dissimulation which different neurotic types habitually employ.

The development of such a study in relation to the personality as a whole necessitates a simultaneous study of the subject by psychoanalysis.

2. In the first experiment devices are used unconsciously which are familiar to us chiefly in humor. It would seem, therefore, that humorlessly and quite without conscious comic intent the unconscious can use irony, punning, and the technique of the puzzle. In short, the techniques of conscious humor are an earnest and serious matter in unconscious psychic processes. This is always particularly disconcerting when weighty and significant problems are treated by means of unconsciously chosen representatives and devices which to our conscious judgments seem ridiculous and trivial. This has been observed repeatedly in dream analysis, and it is clearly demonstrated here in automatic writing and hypnosis. There are few findings in the field of psychoanalysis, or its experimental study through hypnotism, which excite more skepticism than does this observation.

3. In the second experiment described above two other interesting facts are presented for consideration:

a. The seemingly unmotivated elation which arose when the subject put over a secret and unconscious defiance suggests a mechanism for certain types of elations in patients.
b. The particular kind of block in thinking which was produced during the course of the experiment is strongly reminiscent of thinking difficulties observable in schoolchildren. There is a hint here that the further elaboration of this type of investigation may be of use to educators in the problems of some children who, despite good native gifts, fail in academic studies.

In conclusion we may say that these experiments demonstrate not merely the coexistence of hidden meanings in conscious acts, but also carry the promise of usefulness for an experimental attack on many significant problems. It is obvious, however, that all such work demands a close collaboration between those familiar with experimental work in the field of hypnosis and those familiar with the psychoanalytic technique. For adequate development of the applications of such experiments to the problems involved in understanding psychic dynamisms, it would be advisable to have the subjects under psychoanalytic study in order to observe fully their reactions to the experimental procedure, to determine the influence of the experiment upon the subject, and to throw light on analytic theory and its applications.

---

[1]The domineering type of suggestion employed here is used reluctantly and only under special circumstances such as this. This is not the place for a full discussion of the relationship of the technique employed to the underlying unconscious fantasies which the subject brings to the hypnotic experience. Empirically, however, it has been found necessary at times, when dealing with subjects who consciously approach the experience with enthusiastic cooperation but with exceptionally intense unconscious resistances, to subject them to this type of exercise before undertaking any steps relating to the experiment itself.

The Use of Automatic Drawing in the Interpretation and Relief of a State of Acute Obsessional Depression

Milton H. Erickson and Lawrence S. Kubie

Reprinted with permission from *The Psychoanalytic Quarterly,* October, 1938, Vol. VII, No.4.

No matter how accurate any body of scientific theory may be, its confirmation by the use of some technique other than that on which the theory first rested is always valuable. This is the most convincing way of ruling out the misleading influence of possible undetected methodological fallacies. With this in mind the following case is reported in detail because, by means of a nonpsychoanalytic technique, it illustrates a certain type of symbolic activity which is comparable in character to that studied by psychoanalysis in dreams and in psychotic states, and because of its clear demonstration of certain of the dynamic relationships which exist between conscious and unconscious aspects of the human psyche. Finally, it is reported because of our interest in this general type of technique as a means of uncovering unconscious material, and because of the challenge this may offer to certain phases of psychoanalytic technique (Erickson, 1937).

HISTORY

A 24-year-old girl attended a clinical demonstration of hypnosis for a class in psychology at the university. At this demonstration particular emphasis was laid on the phenomenon of automatic writing and on the integrated functioning of subconscious processes as a seemingly independent entity in the total psyche. Afterward she inquired at length about the possibility of acquiring the ability to do automatic writing herself, and whether it was probable or even possible that her own unconscious might function in a coordinated, integrated fashion without her conscious awareness. Affirmative replies were given to both inquiries. Thereupon, as the explanation of her interest she volunteered the statement that during the preceding month she had become unhappy and uneasy in all her relationships for some unknown reason, and that she was becoming increasingly "worried, unhappy and depressed" despite the fact that she knew of no personal problem that could trouble her seriously. She then asked if she might try automatic writing through which her unconscious, acting independently, could give an account of whatever was troubling her. She was told that she might try this plan if she were really interested, and she responded that first she would like to have a formal psychiatric review of her life.

Accordingly, on the next day she was interviewed at length. The more important data obtained in this interview may be summarized as follows:

1. She was an only child, idolized by her parents, as they in turn were by her, living in what seemed to be a very happy home.

2. Her adjustments to college had been excellent until the preceding month, when her work had begun to suffer seriously in consequence of the sudden development of "worry," "concern," "fear," "unhappiness," and "horrible depression," which persisted almost continuously and for which she knew no cause whatever.

3. Recently she had been impelled to read some psychoanalytic literature and had found the subject of symbolism "most interesting and fascinating," but "silly," "meaningless," and "without any scientific validity." When asked for the references, she replied, "Oh, I just thumbed through a lot of books and journals in the library, but the only thing that interested me was symbolism."

4. For a month, and only since reading about symbolism, she had noted the development of a habit of "scribbling," "scratching," "drawing pictures and lines" when telephoning, studying, sitting in the classroom, or merely idling. She did this in an abstracted manner, usually without noting what she was doing, and thought of it merely as a sign of nervousness, of a desire to do something, but what this might be she did not know. She added that it was a “jittery” habit, objectionable because it "dirtied" the walls of telephone booths, the tablecloths in restaurants, and clean paper in her notebooks. (Throughout the interview the patient constantly demonstrated this "habit" most adequately, and it was obvious that she was not aware that she was doing so. Only at the close of the interview did she notice her scribbling, and remarked, "Well, I guess I have demonstrated that jitteryness better than I described it.")

5. Finally, the only personal problem which troubled her consciously was the fact that her three years at college had slowly and gradually separated her from her most intimate girlhood friend, in spite of that girl's regular weekend visits to the patient's home. The patient felt "lonely" and "resentful" about this, and said that during the preceding few weeks this angry feeling had increased until it had become an "uncontrollable resentment" over the loss of her friend. Nor was this obsessive resentment diminished by her realization that there was nothing she could do about it because of the ever-increasing divergence of their interests.

At the completion of her story, in the manner so characteristic of psychiatric patients who have told more than they know, she dismissed her account as probably being of no significance and asked insistently whether now, after hearing her story, it still was thought possible to secure by means of automatic writing the facts which were pertinent to her problem-"if there really were a problem." She thought that if she could read subsequently whatever she might write automatically, she could thus force herself to become consciously aware of what was troubling her. She also wanted to know if the examiner was confident that her subconscious could function in a sufficiently integrated fashion to give a coherent, understandable account.

In response to these anxious inquiries she was told emphatically that she could do exactly as she wished, and this was followed by repeated, carefully worded suggestions given to her in a gentle but insistent and attention-compelling fashion, which served to induce the passively receptive state that marks the initiation of a light hypnotic trance. These suggestions were to the effect that:

1. The time intervening until her appointment on the next day would be spent by her subconscious in reviewing and organizing all the material to which she wished access.

2. In addition, her subconscious would decide upon the method or means of communication and would select some tangible method by which to communicate what it had to say in a way which would be clearly understandable to the examiner and also in a fashion which could, at the proper moment, be clearly understood by the patient herself, so that no doubts or equivocations could arise.

3. Since she herself had suggested automatic writing, pencils and papers would be supplied, so that she would have an opportunity to employ that method in the same abstracted manner as that in which she had made her drawings during the interview.

   (The reader will note that this suggestion actually constituted in its significance an indirect command to repeat her drawings in an intelligible fashion. It was given for the reason that automatic writing is often most difficult to secure on first attempts. It was to be expected that this would be even more true with this patient, whose entire story implied a resolute, unconscious reluctance to know certain things, despite her strong concomitant conscious desire to become aware of them. For her, therefore, automatic writing itself would have proved too revealing, if successful at all, and would have forced on the patient a too rapid realization of her repressed material. This, of course, would either have proved profoundly upsetting or would have summoned up vigorous repressive mechanisms to forestall the complete communication of her material.)

4. In the interval before her next appointment she was to keep her mind consciously busy with studying, reading light fiction, and social activities, thus supplying herself with innocuous topics for conversation on which she could report consciously, so that at the time of the appointment communications concerning her problem would be imparted entirely by subconscious automatic behavior (the drawing) and not become part of her conscious speech.

At the end of the interview the patient seemed rather confused and uncertain about her instructions. She made several hesitating attempts to pick up the sheets of paper on which she had again been "nervously scribbling," suddenly made a last plea for reassurance, and then left quickly when this had been given.

Examination of her drawings after her departure disclosed various figures and lines repeated over and over in varying sizes. There were long and short lines-vertical, horizontal, and oblique. Some were traced lightly, others heavily shaded. Also, there were spirals, cylinders, triangles, squares, and rectangles of various proportions, some drawn lightly and others heavily. While she had been making these drawings, no sequences or relationships had been observed. One peculiarity, however, was the fact that each figure had been drawn as an isolated unit with no attempt to run one into the next.

A subsequent examination of two different books of her lecture notes showed that her "nervous scribbling" had been a sudden development of the preceding weeks. In these notebooks page

after page was found with the same limited types of figures and lines, drawn over and over in a totally disconnected, confused fashion (see Figure 1).

The next day the patient appeared promptly and remarked at once that the suggestions given her the day before seemed to have been effective, since she had not thought about herself at all after leaving the office, and she had even lost conscious interest in her problem so completely that she had returned only because she felt herself to be under an obligation to keep her appointment despite her lack of interest in its purpose. She also explained that she had read a recent novel and was prepared to relate the entire story in detail, remarking facetiously that it would be a cheap way for the examiner to become posted on the latest information of the literary world.

She was told promptly that she could start the story at once; and as she did so, her chair was carefully placed sideways to the desk so that her right arm rested on the desk in close proximity to paper and pencils, while the examiner took a position diagonally opposite. Thus, although she faced away from the paper, it remained well within the range of her peripheral vision.

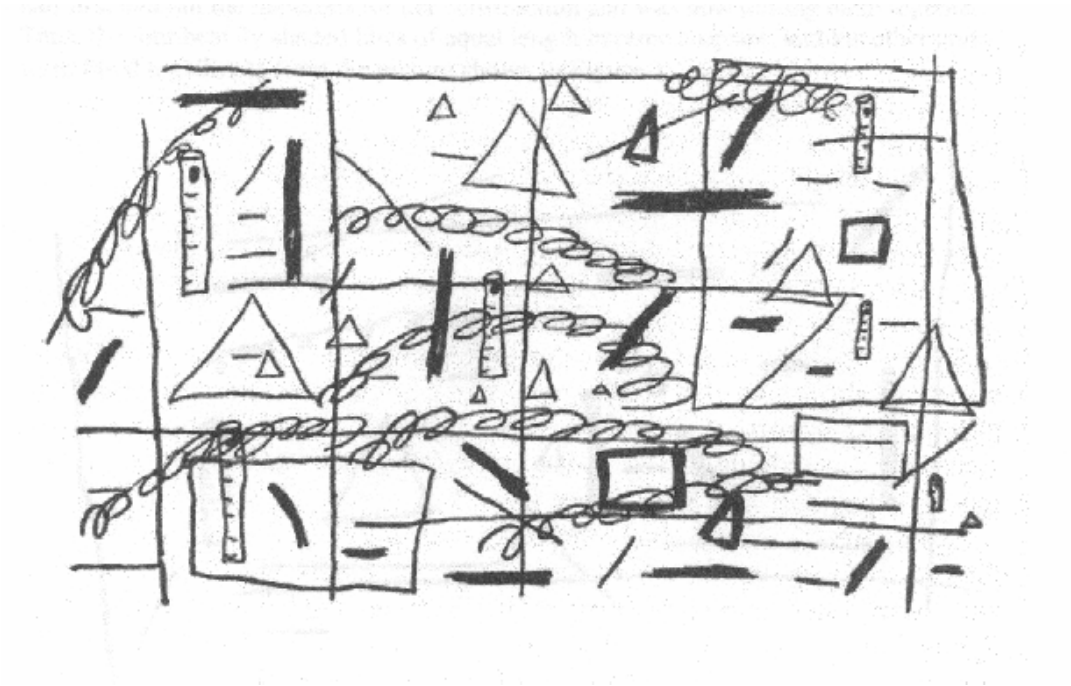

Figure 1

Shortly after she had begun to tell the story of the book, she abstractedly picked up the pencil and in a laborious, strained fashion began to repeat on the upper half of the sheet of paper the drawings of the previous day, now and then glancing down at her productions for a moment or so m an absentminded fashion. As before, no particular sequence of the drawings was noted, but a significant duplication of some of the elements may be observed in Figure 2.

When she had completed these drawings, she became rather confused in her speech, and was observed to relax and tighten her grip on the pencil as if she wanted to lay it down but found

herself unable to do so. She was encouraged here by an insistent, low-toned suggestion, "Go ahead, keep on, it's all right, go ahead, go ahead, keep on."

She remarked immediately, “Oh yes, I know where I am, I just lost the thread of the story for a moment," and continued the narrative.

At the same time her hand was seen to take a fresh grip on the pencil and to shove the pad forward so as to make the lower half of the paper available, and she drew a line as if to divide the paper in halves. Then in a slow and deliberate fashion, with a marked increase in the tension of her right hand and some speeding of her speech, she began to construct a picture by arranging the elements which she had previously drawn so often and so repetitively in an incoherent manner into an orderly, systematic whole. It was as if she had first laid out the materials for her construction and was now putting them together. Thus, the four heavily shaded lines of equal length became a square, and the other units were fitted together to form the picture shown in Figure 3.

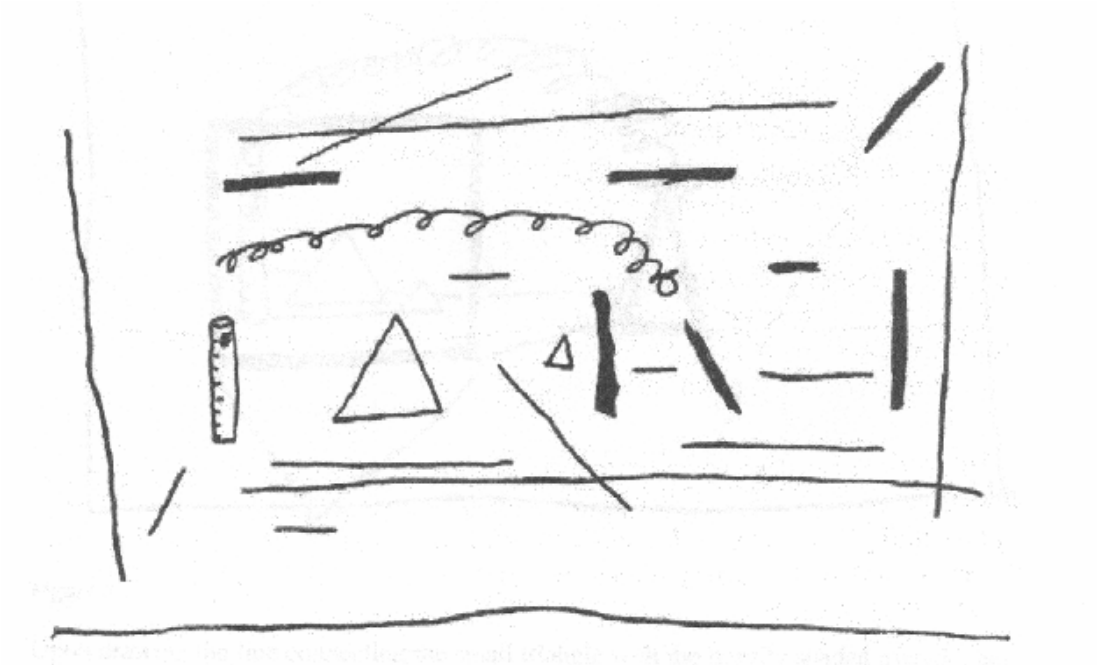

Figure 2

In completing the square, however, the patient showed marked uncertainty about its lower-left-hand comer, and kept glancing down at it abstractedly for a moment or so at a time. Finally she distorted the comer slightly, leaving it open. Also, in making the lower-right-hand corner she pressed down unduly, breaking the pencil point.

In making the diagonal line extending downward from the lower-left-hand comer of the square, her hand moved with sudden force and speed. Then, after a considerable pause, her hand moved more and more slowly on the up stroke to the lower-right-hand comer of the square, the line wavering; then finally her hand moved quickly and forcibly over to the shaded triangle.

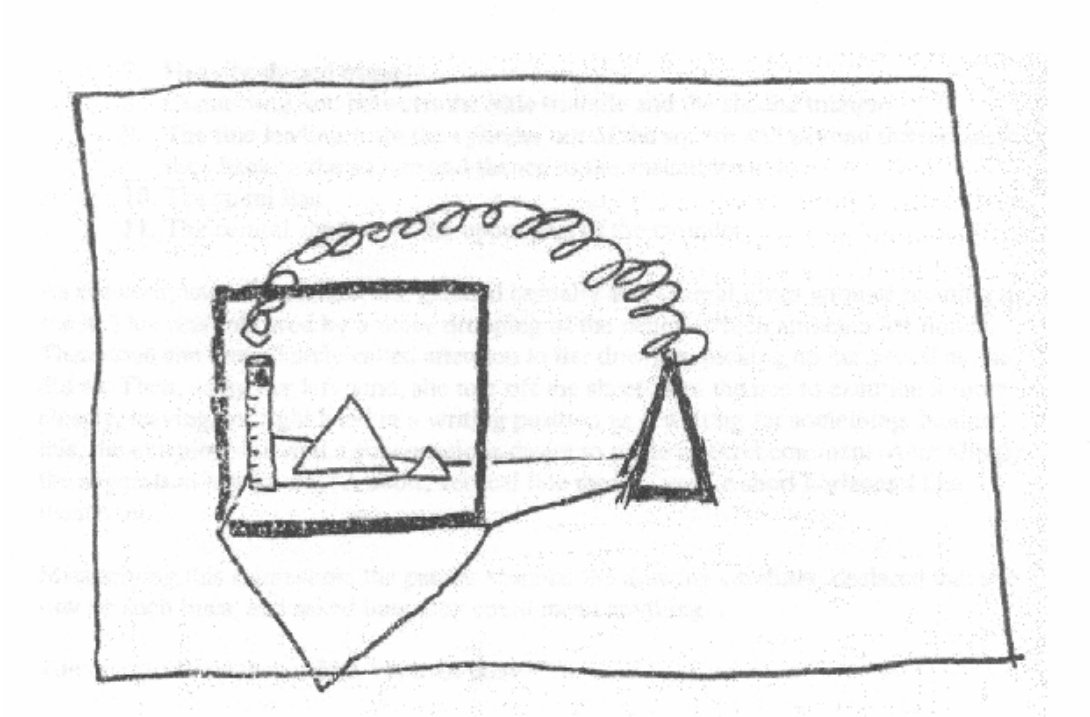

Figure 3

Upon drawing the line connecting the small triangle with the heavily shaded triangle, her hand stopped short as it approached the side of the square and placed a period. Following this her hand lifted and moved over the edge as if surmounting a barrier, after which it completed the line in a steady, firm manner.

The spiral line connecting the cylinder and the shaded triangle began freely and easily, but as it approached the triangle the hand movements became increasingly labored and slow.

Repeatedly during the drawing process the patient's hand would return to the larger of the two light triangles, as if to touch it up a bit and to make it more perfect in outline, while the shaded triangle was drawn roughly.

During her drawing it was possible to record the order in which the various elements were added to the total picture.

1. Square
2. Cylinder
3. Large light triangle
4. Small triangle
5. Connecting lines between cylinder and the large triangle, the large triangle and the little triangle, and the cylinder and the little triangle
6. Enclosing rectangle

7. Heavily shaded triangle
S. Connecting line between the little triangle and the shaded triangle
9. The line leading from the cylinder out of the square and beyond the rectangle, then back to the square and thence to the shaded triangle
10. The spiral line
11. The central shading of the upper part of the cylinder

As she completed the picture, she glanced casually at it several times without seeming to see it. This was followed by a noisy dropping of the pencil, which attracted her notice. Thereupon she immediately called attention to her drawing, picking up her pencil as she did so. Then, using her left hand, she tore off the sheet from the pad to examine it more closely, leaving her right hand in a writing position as if waiting for something. Noting this, the examiner inferred a subconscious desire to make a secret comment. Accordingly the suggestion was given, "A short, vertical line means 'yes,' a short horizontal line means 'no.'

Misapplying this suggestion, the patient scanned the drawing carefully, declared that she saw no such lines, and asked how they could mean anything.

The question was then asked, "Is it all there?"

She replied, "I suppose so, if there is anything there at all," while her hand, without her awareness, made a "yes" sign.

"Everything?"

"Well, I suppose if anything is there, everything is," and again her hand made the “yes” sign without her awareness.

She scanned the picture carefully for some moments and then remarked, "Well, it's just silly nonsense, meaningless. Do you mean to say you can make any sense out of that scratching-to use your own words, that it tells everything?"

Apparently in answer to her own question her hand made another "yes" sign and then dropped the pencil as if the task were now complete. Without waiting for a reply she continued, "It's funny! Even though I know that picture is silly, I know it means something because right now I've got an urge to give you something and, even though I know it's silly, I'm going to give it to you anyway because it's connected with that." Pointing to the shaded triangle, she took from her pocket a packet of matches advertising a local hotel and dropped it on the desk.

Then she immediately consulted her watch, declaring that she had to leave, and seemed to be experiencing a mild panic. However, after a little urging, she consented to answer a few questions about what the picture might mean. She looked the drawing over and offered the following comments, which she insisted she could not elaborate: "Two pictures in frames, a large one," she explained, pointing to the rectangle, "and a small one," pointing to the square, "with the corner broken." Pointing to the figures in the square she said, "These are all connected, and the connection between the little one," pointing to the small triangle, "and that," pointing to

the shaded triangle, "is broken. And that," she added, indicating the cylinder, "is a cigarette with smoke. We all smoke in our family; maybe those are father's matches I gave you. But the whole thing makes no sense at all. Only a psychiatrist could see anything in it," and with that she rushed from the office only to return at once to ask, "When can I see you again?" Upon being told, "Just as soon as you want to know a bit more, call me," she rushed away. No comments were made upon the unitary drawings at the top of the page, and she seemed not to notice them.

About three weeks later she appeared unexpectedly "to report progress." She stated that evidently her drawings must have meant something since she had experienced a marked change in her emotions. She no longer felt worried or depressed, though at times she felt an "intense dread of something," as if she were "going to stumble onto something," and, "I have a feeling that I'm going to find out something dreadful." With much hesitation she added, "What I really mean is that I have a feeling that I am getting ready to know something I already know, but don't know I know it. I know that sounds awfully silly, but it's the only way I can explain, and I am really afraid to know what it's all about. And it's connected with these matches," handing the examiner a second packet similar to the first. "We (the family) had dinner at the hotel last night, and that's where I got them. I saw another packet on the library table last night, but these are the ones I got."

All the other remarks were casual in character, nothing further was learned, and she left rather hurriedly, apparently somewhat uneasy and confused in mind.

Two weeks later she again appeared unexpectedly, declaring as before that she had come "to report progress," and explaining that in the interim she had experienced the development of an absolute certainty that the drawing was meaningful, that "there is a complete story in that picture that anybody can read, and I'm getting terribly curious to know what it is." Here she demanded to see the drawing, and after scrutinizing it closely remarked, "Really, it still looks like a mess of nothing. I just know it's the whole story, too, but why I say that I don't know. But I am sure that my subconscious knows a lot that it won't tell me. I have a feeling that it is just waiting for my conscious mind to prepare itself for a shock, and it's just making me darned curious so I won't mind the shock." When asked when she would know, she replied, "Oh, I suppose not long," and then became emotionally disturbed and insisted on changing the topic of conversation.

A week later she came in to state that she had an engagement to dine with her girlhood friend at the hotel that evening, and that this was causing her much emotional distress. She explained: "I hate to see our friendship broken up just by drifting apart the way we have. And I don't like my attitude toward Jane. You see, Jane's a year younger than me, and she's got a boyfriend and she's pretty much in love with him. She says she thinks I know him, but she won't tell me his name or anything about him, and I don't like my attitude toward her, because I'm so jealous of her that I just hate her intensely; I'd like to pull her hair out. I just hate her because I feel as if she had taken my boyfriend away from me, but that's silly, because I haven't got a boyfriend. I don't want to keep my appointment with her because I know Pm going to quarrel with her, and there really isn't anything to quarrel about, but I know I'll just say one nasty thing after another, and I don't want to, but it's going to happen and I can't avoid it. And another thing, after I quarrel with her I'm going to have a fight with my father. I've just been working up to this for a week. I've only had two fights with my father, and they were both about my college plans, but I don't know what

this fight's going to be about. Probably some little thing like his carelessness in smoking and dropping ashes on the rug at home, probably any little old excuse. I just hope father isn't in when I get home. Can't you say something to me so this all won't happen? But I suppose as long as it's in me it might as well come out and get it over with. When I made the appointment with Jane, I had a vague idea of what was going to happen, and as soon as she accepted I could see, just as plain as could be, what I've just told you, so I hung up the receiver before I had a chance to cancel my invitation."

More remarks were made of a similar character and significance, but all attempts to discuss her drawings or to secure an elucidation of her premonitions failed, since she declared that the only things of interest to her at the moment were the "impending battles."

The next day she dropped in the office to report hurriedly, "I'm in a rush. All I've got time for is to tell you it all happened just as I predicted. Jane and I started out visiting nicely, and then I got to wise-cracking and began hurting her feelings. I didn't notice that at first, and when I did, I just didn't give a damn and I went to town on her in the cruelest, nastiest, most subtle fashion I could. I didn't say anything particularly, but it was the way I said it and mocked her. When she cried I felt a lot better, and although I was ashamed of myself I didn't feel any sympathy for her. I wound up by telling her that we could agree to disagree and she could go her way and I'd go my way. Then I went home and Father was sitting there reading and I was itching for him to say something, just anything. I was awfully amused at myself, but I figured there wasn't anything I could do about it, so I began smoking and pacing the floor. Finally he told me to sit down and be quiet, and that just set me off. I just yelled at him to shut up, that I could *run around* if I wanted to, and he couldn't say anything to me. It was too late to go out, and if I *wanted to run around* I had just as much right as he had. I told him he might think he was smart, but I was a lot smarter, that I wasn't born yesterday, that I knew what it was all about, and a lot of silly, incoherent, tempery things that I really didn't mean and that didn't make sense. Finally he got disgusted and told me if I couldn't talk sense to shut up and go to bed and sleep it off. So I did. And the funny thing is that when I woke up this morning, I thought of those drawings I did for you, and I tried to think about them, but all I could think was first the word 'today' and then the word 'tomorrow,' and finally I just kept thinking 'tomorrow.' Does that mean anything to you? It doesn't to me," and with this remark she took her departure.

The next afternoon she appeared and declared, "After I left you yesterday, I had a funny feeling I had made an appointment with you for today, but I really knew I hadn't. Then this morning the first thing I thought of was that drawing, and I knew that I could understand it now, and I've been thinking about it all day. I remember the whole picture; I can see it in my mind plainly, but it's still meaningless, doesn't mean a thing. Let me look at it."

She was handed the picture, which she scrutinized in a most painstaking fashion, with an expression of intense curiosity on her face, finally sighing and putting it down to remark, "Well, I guess I'm mistaken. It doesn't mean a thing-just a silly picture after all." Then suddenly brightening, "But if you will say just a word to start me off, I know I'll understand it."

No heed was given this indirect request, and she repeatedly examined the picture only to lay it aside each time in an intensely puzzled fashion.

Finally, she repeated her request for a "starting word" and was countered with the question, "What word?" To this she replied, "Oh, any word. You know what the picture means, so just say any word that will give me a start. I am really just dying to know what it's all about even though I am a little bit afraid, maybe a lot. But say something, anything."

Her insistent request was acceded to by the remark, "Sometime ago you told me you were terribly interested in and fascinated by symbolism," and as this remark was made the packet of hotel matches was carefully dropped on the desk.

Immediately she seized the drawing and looked at it momentarily, at the same time grabbing the packet of matches and throwing it violently on the floor. She then burst into a torrent of vituperation, addressed apparently to nobody, intermingled with expressions of sympathy for her mother and explanatory details, of which the following constitutes only a fairly adequate summary:

> The damned nasty filthy little cheater. And she calls herself my friend. She's having an affair with Father. Damn him. Poor Mother. She visits Mother, damn her, and Father acts like a saint around the house, damn him. They go to the hotel, the same hotel Father took us to [for dinner]. I hated her because she took my father away from me-and Mother. That's why I always stole his cigarettes. Even when I had some, I'd sneak into the hall and get some out of his coat pocket. Sometimes I'd take the whole package, sometimes only one or two. If she thinks she's going to break up my home, she's got another thought coming, plenty too. The first time she told me about her boyfriend-her boyfriend, huh-she lit her cigarette with those matches. I knew then, but I couldn't believe it. And I used to take Father's matches away from him, and I'd get so goddamn mad when he'd tell me to use my own. I didn't want Mother to see those matches, and it didn't make sense then.

This was followed by much profanity and repetition of the above remarks which seemed to exhaust her rage, following which she sobbed bitterly.

Composing herself, she apologized for her profanity and rage and then remarked quietly, "I suppose I better explain all this to you. When you said symbolism, I suddenly remembered that Freud said cylinders symbolized men and triangles, women, and then I recalled that cigarettes were cylinders and that they could symbolize a penis. Then the whole meaning of the picture just burst into my mind all at once, and I guess I just couldn't take it, and that's why I acted like I did. Now I can explain the picture to you."

Pointing to the various elements of the picture, she explained rapidly. "This cigarette is Father, and that big triangle is Mother-she's short and fat and blonde and the little triangle is me. I'm blonde too. I'm really taller than Mother, but I just feel little to her. You see, those lines all connect us in a family group and the square is the family frame. And that line from Father breaks through the family frame and goes down below the social frame-that's the big square-and then it tries to go back to the family and can't, and so it just goes over to Jane. You see, she is a tall, slender brunette. And that smoke from Father's penis curls around Jane. And that line between me and Jane is broken where it comes to the family frame. And I've been drawing and drawing these pictures all the time like that (pointing to the unitary drawings at the top of the page), but this is the first time I ever put them together. And see where I blackened Father's face. It should

be! And when I gave you those matches, I told you they were connected with Jane, even though I didn't know that was Jane then."

For some minutes the patient sat quietly and thoughtfully, now and then glancing at the drawing. Finally she remarked, "I know the interpretation of this picture is true, but only because I feel it is true. I have been thinking everything over and there isn't a solitary fact that I know, on which I can rely, that could possibly substantiate what I've said. Jane and I have drifted apart, but that doesn't make her Father's mistress. Jane does call at the house but always on evenings when Father is out, and while she doesn't stay more than three-quarters of an hour, that doesn't mean that that's a blind. And Mother can't hide anything and her nature is such that she would know about things before they happen, and I know she has no inking of this. As for the matches, anybody could have hotel matches, and my stealing Father's cigarettes only proves there's something wrong with me. Well, now that I've discovered this, I'm going to go through with it and clear it up so that I'll have better proof than just my subconscious drawings."

What the proof was to be the patient refused to state, and the rest of the interview was spent by the patient in outlining a calm, dispassionate, philosophical view and acceptance of the entire situation.

Two days later she came to the office accompanied by a young woman. As they entered the office the patient said, "This is Jane. I bullied and browbeat her into coming here without giving her any idea of what or why, and her own sense of guilt toward me kept her from refusing Now I'm going to have my say and then I'm going to leave her with you so she can talk to you and get a little sense put into her head."

Then, turning to Jane, "Just about two months ago you started something which you didn't want me to know about. You thought you were getting by with it, but you weren't. You told me your boyfriend was about four years older than you, and you told me he wanted an affair with you but that you wouldn't consent. You were just a sweet young girl talking things over with your dearest pal. And all the time you knew, and all the time I was putting two and two together, and finally I went to a psychiatrist and the other day I got the answer, so now I know your whole sordid, nasty story. Here's a cigarette, now light it with *these* matches—they're hotel matches. Now you know just what I'm talking about."

With that she rushed out of the office, and as she did so, Jane turned and asked, "Does Ann really know about her father and me?"

Then, without any questioning of any sort, Jane responded to the difficult situation in which she found herself by relating the story of her intrigue with the patient's father, confirming fully every detail given by the patient and adding the information that both she and her lover had been most secretive and had been most confident that they could not even be suspected. She also added that on the occasion of Ann's first weekend home from college after the beginning of the affair, she had felt that Ann was most disagreeable and irritable for no good reason, and Ann's father had made the same comment during one of their meetings. She attributed Ann's knowledge of the affair entirely to "intuition."

Following these disclosures Ann was recalled to the office, and as she entered, she eyed Jane closely, then remarked, "Well, I did have a faint hope that it wasn't so, but it is, isn't it?" Jane nodded affirmatively, to which Ann replied philosophically, "Well, what Father does is his own business, and what you do is yours, but you're not visiting at our home anymore, and you and father can pick another hotel since the family is in the habit of eating at that hotel frequently. I'll just explain your failure to visit at home to Mother by saying we quarreled, and as for you and me, we're acquaintances, and you can tell Father that heaven help both of you if Mother ever finds out. And that's that! You can go back to town by one bus and I'll take another, and you can beat it now because I want to talk to the doctor."

After Jane's immediate departure the gist of the patient's remarks was that she intended to accept the whole matter in a dispassionate, philosophical manner, and that she was still tremendously puzzled as to how she had "stumbled onto it," since she felt convinced that "it must have been just plain intuition that worked out right. When I first started drawing those little pictures, it made me feel terribly jittery, but I couldn't stop. I was just obsessed by them, but they had no meaning until last Thursday. Now when I look back at it all, the whole thing just seems screwy because I must have known from the beginning, and yet I really didn't know a thing until the other day here. But hereafter I'm not going to let any subconscious knowledge upset me as frightfully as that did."

The patient was seen casually thereafter on a number of occasions, and satisfactory evidence was obtained of a continuing good adjustment. A few years later she married very happily. One additional item of information obtained from the patient was that on a number of occasions before her upset she had suspected her father of intrigues with various women but had always dismissed her suspicions as unworthy. These suspicions were confirmed unexpectedly by Jane, however, while discussing with the examiner her intrigue with the patient's father. She volunteered the information that over a period of eight years the father had had a series of affairs, one of which had been broken off only at her insistence.

Also, after the passage of several months the patient's notebooks were again examined. When this privilege was requested, she remarked, "Oh, I know! I forgot to tell you. I lost that habit just as soon as I found things out I haven't done a bit of scribbling since then." Inspection of the notebooks verified her statement.

Subsequently Jane too was seen casually and volunteered the information that the intrigue was continuing, but that she had complied with Ann's injunctions.

DISCUSSION

I. The Significance of the Illness

It is hardly possible to overestimate the theoretical significance and interest of this case. Only rarely does an opportunity arise to study a severe neurotic storm-in some ways nearly psychotic-under such well-controlled conditions.

A young woman deeply and apparently peacefully devoted both to her father and to her mother suddenly is confronted with the threat of a deep hurt to her mother through her father and her own best friend, and with the acutely painful picture of her father's emotional desertion of the family. This of course is adequate grounds for sorrow and anger. But it was more significant still that she was confronted by these jolting facts, not in her conscious perceptions, but only in her unconscious; and that furthermore her reaction to this unconscious knowledge was not one of simple sorrow and anger, but a far more complex constellation of neurotic and affective symptoms. All of this becomes clear directly from the data of the case and without any intricate or debatable analytic speculations and interpretations.

Here, then, is a test case. Can psychic injuries of which we are not consciously aware be at the heart of major psychopathological states? And how does the reaction of the patient illuminate this problem?

On the weekend of her return home when she first sensed unconsciously the intimacy between her friend and her father, her immediate response was one of troubled and unmotivated irritability-an irritability which never found any focus, but which was displaced incessantly from one trivial object to another. Thereafter she lapsed into a state of obsess ional depression, which seemed to her to be without content or meaning, although it was accompanied by a withdrawal of interest from all of her previous activities and from all previous object relationships. As this depressive mood gathered, her irritability persisted, undiminished and still without adequate conscious object. For the first time, however, it began to focus its expression in two symptomatic compulsive acts whose symbolic meaning later became unmistakable. The first of these was a minutely circumscribed kleptomania—i.e., the specific compulsion to steal cigarettes and matches from her father's pockets, obviously with an angry and punitive preconscious purpose but which was seen in the automatic drawings to have a much deeper unconscious castrative goal as well The second was an equally circumscribed, almost encapsulated obsess ional drive toward the constant repetition of scribbled drawings of cylinders, triangles, looping spirals, and straight lines slanting in all directions. (cf Figure 1.)

It is of interest to note that her illness began with episodic emotional flurries, which quickly were followed by an affect which became fixed and obsessional, and that this in turn was supplemented by a group of obsess ional acts. The theoretical significance of this sequence of events is a matter into which we cannot go at this point, but the sequence should be borne in mind.

The patient's involuntary and, to her, mysterious irritability deserves another word. It is an exact replica of a type of frantic, shifting, and apparently unmotivated irritability which one sees in children when they are stirred into overwhelming states of unconscious jealousy toward parents and siblings. In this patient it is possible to observe how the irritability was precipitated when the patient's unconscious was confronted with the love relationship between her father and her friend Furthermore it is clear that the irritability reflects her conflict between various roles, as for instance her identification with her mother in the family group, her fantasy of herself in the role of her father's mistress, her jealousy of this mistress, and the resulting conflicts which manifested themselves throughout her upset period between the vengeful, guilty, and protective impulses toward everyone involved in the situation.

It is clear that the unconscious impulses which were driving her strove in many ways for adequate expression and resolution: first in the vengeful gestures (stealing of matches and cigarettes), then in the automatic incoherent drawings or scribblings (a so-called habit which is later seen to be infused with specific and translatable meanings), and finally in the increasing and obsessive need to find out what it was all about, as manifested in her blind search into psychiatric and analytical literature, her fascination with and skepticism about symbolism, and in the appeal for help still veiled slightly behind her "curiosity about automatic writing."

Surely both the driving and the directing power of unconscious mentation could not be more beautifully illustrated in any laboratory test than it is here. A further example is in the unwitting double meaning in the naively chosen phrase "run around," which the patient used repeatedly in her blind, angry outburst against her father, without realizing consciously its obvious reference to his sexual habits.

And finally the symbolic representation of complex human relationships by simple, childlike scribbled drawings, which is the most dramatic feature of the story, is so clear as to need no further comment.

II. Technique

The technical challenges with which the experience confronts us are several. In the first place it must be admitted quite simply that the most skillful use of orthodox psychoanalytic technique could not possibly have uncovered the repressed awareness of the father's liaison in a mere handful of sessions. Speed in achieving a result is of course not a sole criterion of excellence. It may well be that with such rapid therapy certain vital reconstructive experiences cannot be brought to a patient, whereas they, on the other hand, may be an essential part of the more orthodox analytic approach. But there is nothing in this observation which would seem to make the two methods mutually exclusive. In some form they might be supplementary or complementary to one another; and for at least a few of those many patients to whom analysis is not applicable, such an approach as this, if only because of its speed and directness, might be useful.

Furthermore, it must be emphasized that automatic drawing as a method of communication has a close relationship to the psychoanalytic method of free association. Here the patient's undirected drawings were certainly a nonverbal form of free association. That the translation of such drawings into understandable ideas presents grave difficulties must be admitted; but these difficulties are not always greater than those which confront analysts when they deal with the symbolic material of dreams. On a two-dimensional plane these drawings are equivalent to the dramatic symbolic representation of instinctual conflicts which Homburger (1937) has described and analyzed in children's three-dimensional play with building blocks.

Furthermore, as one studies this material it is impressive to see how ready the unconscious seemed to be to communicate with the examiner by means of this accessory sign language of drawing, while at the same time the consciously organized part of the personality was busy recounting other matters. It suggests that by using either this or some other method of widening

the conscious gap between the conscious and unconscious parts of the psyche, it might be possible to secure communications from the unconscious more simply than can be done when both parts of the personality are using the single vehicle of speech. It suggests that when only one form of communication is used, the struggle between the expressive and repressive forces may be intensified.

The point we have in mind here is quite simple. Under circumstances of usual analytical procedure the patient expresses everything-both conscious and unconscious, instinctual drives and anxieties, fears and guilt-often all at the same moment and in the same system of gestures and words. That under such circumstances a patient's speech and communications may be difficult to disentangle is not strange. It, however, by some method one could allow the various aspects of the psyche to express themselves simultaneously with different simple and direct methods of communication, it would be conceivable at least that each part could express itself more clearly and with less internal confusion and resistance. In this instance it seems to have worked that way; and the shame, guilt, anxiety, and rage which prevented the patient from putting into words her unconscious knowledge left her free to express it all in her automatic scribbled drawing; furthermore this throws light on the essential mechanism of literature and art, a discussion of which will have to be reserved for another time.

It must be borne in mind, however, that the repressive forces rendered the drawings wholly chaotic until the influence of the psychiatrist was exerted on this patient in a clear-cut and definite manner, in order to assist her in the expression of her problem. In the first place, looking back it becomes obvious that the patient came seeking a substitute father who would give her permission to know the facts about her real father-a "permissive agent" whose function would be to lessen her guilt and her anxiety and to give her the right to express the rage and the hurt that she felt.

Thus we see that the first movement toward recovery came as she simultaneously talked and scribbled in the first interview and apparently without any insight. The observer on that occasion gave her a certain direct, quiet, but impressive suggestion: that she was to allow her unconscious to deal with her problem, instead of her conscious mind. This is an important divergence from psychoanalytic technique with its deliberate drive to force everything into consciousness, because at the same time that the psychiatrist gave the patient permission to face the facts unconsciously, he gave her conscious mind the right to be free from its obsessive preoccupation with the problem. The patient experienced an immediate temporary relief. She felt so "well" the next day that she even thought of not retuning for her next appointment. With this ground under her feet, however, at the next session she went deeper into her problem and emerged with her first moment of conscious panic-a panic that was not at this point accompanied by any insight. Her next emotional change evolved rapidly out of this experience and soon manifested itself in her ability to express her rage, chagrin, and resentment openly in her compulsive outburst against her friend and her father, instead of in symbolic acts alone.

In all of this the "permissive agent," by his active encouragement and direct suggestions, served to lift the weight of guilt, anxiety, and ambivalence from the patient's shoulders. As a new and kindly father he diverted some of these obstructing feelings from their older goals, thus allowing the eruption of the full awareness of the affair. This important function of the therapist-to

dislodge old and rigid superego patterns-is one which unquestionably was executed by this mild suggestion at the first interview between the therapist and the patient.

Naturally this could not occur without anxiety, but the appearance of this anxiety, replacing the depression and the compulsions which had existed for so long, marked the upturn in the patient's illness.

III. Conclusion

We are far from drawing any conclusions from this single experience. Such observations must be amplified and repeated many times before it is decided that as a consequence any changes in analytic technique are indicated.

It is just to say, however, that without any effort to open up all the buried material of the patient's highly charged oedipal relationships, a direct link was established between conscious and unconscious systems of thought and feeling which surrounded the parental figures, and this by a very simple technique. Furthermore, as a direct consequence there was almost immediate relief from seriously disturbing neurotic and emotional symptoms.

It is unfortunate that although we have a clear picture of the patient's neurosis, we have no analytic insight into the character and personality out of which this neurosis developed. This is important because it is conceivable that such a method as this might be applicable for one type of character organization and not for another, even when the two had essentially similar superimposed neuroses. Such studies as these, therefore, should be carried forward in conjunction with psychoanalysis.

Translation of the Cryptic Automatic Writing of One Hypnotic Subject By Another in a Trancelike Dissociated State

Milton H. Erickson and Lawrence S. Kubie

Reprinted with permission from *The Psychoanalytic Quarterly*, January, 1940,
Vol. IX, No. 1.

During the training of a subject for a particular experiment in hypnosis a unique observation was made upon the ability of one person in a spontaneous trance accurately to decipher and to translate the mysterious and cryptic automatic writing of another. In their conscious states neither individual could understand the script. In trancelike states each one quite independently reached identical interpretations of it. Cryptic automatic writing is found to suffer from processes of distortion identical with those seen in dreams; and the translation of such writing, to involve the same principles as those involved in dream analysis.

In chronological sequence in the protocols detailed below there is portrayed both the general situation and the series of events leading to these observations:

(1) The subject, as an incident in his training and while in a deep trance, was told by an assistant in the absence of the investigator to forget all the vowels but not the fact of their existence.
(2) In another trance a week later he was given additional suggestions to the effect that he would replace the seventh (*g*) eighth (*h*), and ninth (*i*) letters of the alphabet with their respective numerals and that henceforth his name would be "Jack Young."
(3) He was then asked to write his name. In doing this he omitted the vowels and substituted the numeral 10 for the letter *J*, declaring emphatically as he completed this task that something was wrong.

Assuming in the interpretation of hypnotic productions, as in the interpretation of dreams, that every trivial detail has meaning, the assistant sought to secure from the subject an explanation both of his use of the numeral *10* and of his comment that something was wrong. The subject wrote the letters *N* and *F* and the numerals *7*, *7*, *8*, and *9*automatically in his effort to explain these phenomena, apparently offering them as an adequate explanation of everything. Dissatisfied, the assistant demanded a more understandable written explanation. This resulted in still more abbreviated and cryptic automatic writing; further requests produced merely a repetition of that writing, despite the assistant's efforts to compel some alteration of the written characters by active physical interference.

External circumstances then terminated the interview at this point, but not before the subject had demonstrated his complete lack of any conscious understanding of what his written "explanation" meant or of what the "mistake" had been, and whether it was the substitution of a *10* for the *J* in his written name.

After the subject left, the investigator came into the laboratory, and while he and his assistant were puzzling over the cryptic writing, a second subject, Alice, entered the laboratory and showed an immediate interest in the problem. This subject has the rare capacity to develop spontaneous hypnotic trances during which she functions adequately in whatever situation she finds herself. Upon awakening from them she has no awareness of her trance activities. Because of her interest in the problem, she was given an outline of the essential facts. The writing was shown to her by the assistant, who then departed, leaving Alice to puzzle over the writing with the investigator.

Thereupon Alice developed a series of spontaneous trance states interspersed with ordinary waking states. In the trance states she interpreted the writing item by item and explained it step by step to the investigator, who maintained essentially a passive, receptive role. This passive role was forced upon the investigator by the brevity of the spontaneous trances, the difficulty of trying to carry on a conversation with her at all, and the necessity constantly to meet her at two different levels of awareness in a single situation. Alice's spontaneous trances tended to be so brief that she would have time to offer only an explanatory remark or two and would then awaken with no awareness of what she had just said. In the waking state she would continue her puzzled wonderment over the writing which had just been interrupted by the spontaneous trance, or she would become interested in some totally unrelated topic and discuss that until some remark of the investigator disclosed to her his own unclear state of mind regarding the last bit of explanation she had given. There would follow another spontaneous trance in which, briefly and concisely, Alice would make another remark to clarify the investigator's mind. As a consequence it was necessary for Alice to develop a large number of spontaneous trances and to repeat her explanations many times before she could feel satisfied with the investigator's comprehension of what had been said. In addition Alice's explanations were often as cryptic to the investigator as the writing itself—as, for example, her use of the word *sign* to explain the correctness of the letter *H* (cf. the protocol below).

In the intervals between the spontaneous trances investigation showed that Alice had a complete and persistent amnesia for all of her trance disclosures, even after the entire interpretation of the writing had been secured; furthermore, when her own interpretation of the writing was presented to her, she regarded it purely as a product of the investigator's own reasoning. However, when questioned about it in an induced trance state, she not only recognized the explanation as her own but meticulously corrected the slightest change in wording introduced by the investigator.

Why Alice resorted to this devious and uncertain method of communication instead of permitting herself to develop flashes of conscious insight is a matter for speculation not

wholly explained by her statement that the writing represented her own unconscious way of thinking and writing.

The following day the first subject, T. L., came to the office unexpectedly to report what he termed "an amusing hypnagogic experience." Unaware that the assistant had told the investigator of the original situation, and unaware also of the investigator's subsequent experience with Alice, he described fully his own experiences with the assistant on the previous day, corroborating the details given by the assistant and including others which were later verified. He emphasized in particular his own argumentativeness, his insistence that there was a mistake in the written name, his feeling of absolute certainty about his conscious understanding, and his feeling of irritation with the assistant whose manner seemed unwarrantedly to imply that there were unrecognized meanings in the writing. He related that after his departure he had forgotten about the incident until, falling asleep late that evening, he had a "hypnagogic experience" in which he "saw" the episode exactly as it had occurred with a new interpretation of it all. He expressed much amusement over his earlier belligerency and defensiveness and also about his new realization of "how intensely you can believe something that is totally wrong, when right in your subconscious you know the truth." He went on to explain that along with his original "conscious explanation" he now "saw" the "true subconscious explanation," which was not at all similar to his "conscious explanation." Asked to restate his original "conscious explanation," he claimed that because it was "so wrong" he could no longer remember more than a vague outline of it, but that now he was ready to give the "correct explanation of the whole thing."

In response to the investigator's manifest interest he proceeded to give his explanation, but not with the confidence his manner had led the investigator to expect. It became apparent at once that the subject's conscious grasp of the problem was limited and that he only thought he understood it. Actually his method was to offer sudden, brief, dogmatic statements as if each were the complete explanation, only to discover spontaneously that his explanation was inadequate. Then there would follow another sudden flash of conscious insight and another dogmatic statement.

After a number of such steps the subject took the attitude of one solving a puzzle and began to search for the explanation of his various dogmatic statements and for the significance of the writing. As he studied the writing and tried to fit his various statements to it, additional flashes of insight developed, sometimes relevant to the immediate question he was trying to solve and sometimes pertinent to another item not yet touched upon. Thus, bit by bit in an unsystematic fashion, a complete explanation was developed which was in full accord with the one given by Alice. In this episode the investigator's role was again a passive, receptive one.

Of marked interest is the fact that neither subject volunteered any interpretation of the first "explanation" written as four digits. Both subjects ignored that particular writing completely until it was called to their attention. Alice remarked simply that everything was included in the writing she had explained, while T. L. commented briefly, "That's [the digits] not so good; the writing's better."

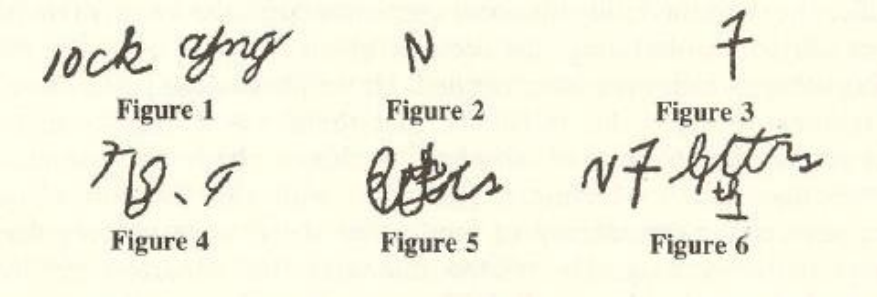

Figure 1 Figure 2 Figure 3

Figure 4 Figure 5 Figure 6

PROTOCOL I

First Week

1. Subject T. L. was told while in a hypnotic trance to forget the vowels of the alphabet but not the fact of their existence.

Second Week

2. Subject T. L. was again hypnotized and told this time to replace the seventh, eighth, and ninth letters of the alphabet (*g*, *h*, and *i*) with their respective numerals.

3. T. L. was then told that his name was "Jack Young" and was asked to write it.

4. T. L. wrote his name "10 ck Yng" (cf. Figure 1).

5. Upon inspection of his writing, T. L. declared it to be incorrect, that the *J* was a mistake; he became disputatious when the assistant suggested that it might be correct.

6. The assistant asked, "Is what you wrote correct"‘

7. T. L. wrote automatically the character *N*, which was interpreted by the assistant as a "No," but T. L. did not confirm this
8. (cf Figure 2).

9. The assistant asked if the writing was apparently incorrect.

10. T. L. wrote automatically the character *F*, which the assistant interpreted as a "Yes," but this again was neither confirmed nor corrected (cf. Figure 3).

11. The assistant then asked why the writing was only apparently incorrect.

12. T. L. wrote automatically the construction, "7 7 8 9," very faintly and somewhat illegibly (cf. Figure 4).

13. The assistant asked that the explanation be rewritten plainly and clearly and in a fashion understandable to both of them.

14. T. L. then added to the *N* and the *F* already written a peculiar group of letters (cf. Figure 5).

15. The assistant, after scrutiny of this writing, asked T. L. to rewrite on another sheet of paper his explanation in amore clearly understandable and readable fashion.

16. T. L. complied with this request by producing a second graphic construction, essentially a repetition of the previous one, ignoring and resisting as he did so the assistant's attempts to compel an alteration of the writing by forcibly moving the paper while T. L. was engaged in his task (cf. Figure 6).

17. No further verbal explanation of the writing was obtained at this time except an argumentative repetition of his previous declaration that the written name contained a mistake—namely, the use of *10* for *J*. External circumstances then brought the interview to an end.

PROTOCOL II

Entrance of Alice

1. The written name was exhibited to Alice by the assistant, and a rapid explanation was given of the posthypnotic suggestions regarding vowels and the replacement by numerals of the seventh, eighth, and ninth letters, and of T. L.'s insistence that there was a mistake in the writing of the name. Following this the assistant left.

2. Alice studied the name as it was written and then counted the letters of the alphabet rapidly.

3. Alice's explanation: *J* has the ordinal position of *10*, but the omission of the vowels gives it the ordinal position of *7—7* however is actually identical with *G*, hence it cannot be used to designate *J*. Therefore, *J*, the seventh letter, must be written as *10*. In brief, *J* is both the seventh and the tenth letter, but it can be written numerically only as *10*.

4. Alice was then shown T. L.'s written production (Figure 6). This she promptly read as "Numbers for letters," illustrating this significance by immediate reference to the use of a *10* for a *J* in the written name.

5. The investigator then gave Alice the additional information about the assistant's interpretation of the letter *N* as signifying "No" (cf. Figure 2).

6. The writing was read then by Alice as, "Not letters; numbers for letters."

7. Alice's explanation: The second character in the written explanation actually is a *T* as well as an *F* and may equally well be read as a *4*. T. L.'s passive acceptance of the interpretation of a "No" serves to transform the first two characters of the writing into the word "Not" with the vowel omitted; furthermore since the second character is obviously an *F*, and also a *4*, emphasis is thereby placed upon the second character, and this is indicated doubly by the fact that the letter *F* actually is the fourth letter in the alphabet with the vowels omitted. Hence *F*, by virtue of all this, can be used to signify *"for"* as a simple pun as well as an abbreviation.

8. Therefore, on first reading the written explanation, one reads "Not letters," but since this is only part of an explanation, one must reread the written characters for their additional meanings; hence on second reading one reads "No 4 lttrs," or "Numbers for letters."

9. The investigator accepted this reading unquestioningly, but asked what the *th* meant, since it appeared in both of T. L.'s written explanations.

10. Alice first explained with the single word "sign," but finally declared that it was connected "by the sign," which she identified by gesture as the line underneath the *th*, with the second character of the written explanation, and that it "explained" the "mistake."

11. Alice's explanation: The second character reads *T, F, 4,* and *for*, but in relation to the *th* it also reads *7*. *G* is the seventh letter in the alphabet. *G* should be written as *7*. *G* is written *G* in the name—hence, *G* is a mistake.

12. The investigator then asked Alice to read aloud the written explanation, which she did as follows: "Not letters; numbers for letters; not *7*; seventh letter; *7* in place of letter," and as this explanation was read, Alice declared that there was a concealed *7* in the word *lttrs*, an item which had been consistently overlooked by the investigator.

13. As an additional explanation Alice added, "*7* should be in the place of the letter *G* in the name, but a mistake was made and *G* was written. So to explain what he meant by 'a mistake,' *7* is written here [pointing to the concealed *7* in the character *lttrs*] so that you can see that there is really a *7* in the place of *letters* where you should read it, but where you really read just *lttrs*. "

14. The investigator asked if there were any further explanation of the *th*, since *H* is the eighth letter.

15. Alice explained, “It is a sign. You read *7-th* not *7-t-h*. “ To this was added, “Not mistake like *G*. It [*th*] is a sign.”

16. The investigator then raised the question of *G* becoming the fifth letter of the alphabet with the vowels omitted. Alice explained that *G* could not be the fifth letter because the difficulty about the *J* had definitely established *G* as the seventh letter.

17. Alice was then asked about the letter *K*. Again she explained that the establishment of the letter *J* as number *10* provided a point of orientation for all of the letters of the alphabet, regardless of the omission of the vowels, and she restated the fact that the vowels had only been forgotten, but not the fact of their existence. Therefore, the letter *J* established as number *10* would automatically cause *K* to be letter number *11* and *G* to be letter number *7*.

18. Alice then was asked about the identification of the letter *F* as the number *4* by virtue of the omission of the vowels. Alice pointed out immediately that this was for purposes of punning and that anything was permissible in a pun.

19. Alice was then asked to explain how it was that she could interpret such cryptic writing.

20. Alice’s explanation: “Oh, that’s easy. That’s just the way I always think and write. Just a little means a lot.”

21. Alice was asked, “How could you know that the writing could be interpreted?”

22. Alice’s explanation: “When you know about the vowels and the numbers, then you could see lots of meanings all at once right there and you could just read them.”

23. When asked about the written digits in Figure 4, Alice explained that they meant the same as the writing, but not so clearly.

PROTOCOL III

The next day

1. Subject T. L. reported to the investigator an “amusing hypnagogic experience” in which “I remembered the whole situation. I had a complete conscious explanation at the time. I was so sure of it, too; I wanted to argue. I said there was a mistake. I remembered every little detail of that whole situation, and, at the same time, in that hypnagogic state I could see the whole thing in an entirely different way. Half asleep there, I could see my conscious understanding of that whole situation and at the same time I could see my subconscious understanding. The two were so different, and I had been so sure of my conscious understanding, but it really was

all wrong. I didn't have anything right in my conscious understanding at all, and yet I wanted to argue; I was looking for an argument."

2. The investigator asked T. L. for an account of his conscious understanding.

3. T. L. declared that he could not remember anything about it except that it was all wrong, nothing right. "I wasn't even thinking about the things I thought I was thinking about." The investigator asked him to explain this more fully. T. L. replied, "Consciously I said there was a mistake, but the mistake I thought I was talking about wasn't a mistake at all. I thought I was talking about *J*, but in that hypnagogic experience I knew that *J* was right but that *G* was a mistake. *J* was just a mistake to my consciousness even though it was not a mistake to my subconsciousness."

4. The investigator asked T. L. to give an account of his subconscious understandings.

5. There followed then an explanation of the writing in which item by item was accorded the same interpretation as had been given by Alice. The method by which his explanation was achieved was one based upon sudden flashes of insight, such as obtain in the solving of a puzzle. Thus in relation to the second character (cf. Figure 3) he declared he could explain it best by writing it from memory, whereupon he proceeded to write the French form of the numeral *7* (the subject had studied French). In the usual position, elevated above the line, he added to this numeral a *th*. When the accuracy of his recollection was questioned, he became decidedly disputatious and insisted that it was right because of the line underneath the *th*. From these disconnected flashes of insight partial understandings of several different aspects of the problem were obtained. Alice, on the other hand, recognized the numerical quality of that character along with its other attributes without resort to intermediary steps.

6. The order in which T. L. built up his interpretations of the written explanation shown in Figure 6 was as follows:
   (a) Declaration that the use of a *10* for a *J* in the written name was not an error but that the *G* was an error.
   (b) Statement that the writing (Figure 6) read both "Not letters" and "Numbers for letters."
   (c) Elucidation of the use of a *10* for a *J*. "Without the vowels *J* was the seventh letter, and I had to put a number for that letter, but I couldn't put a *7* because even if there were no vowels you had to count their places, and that would make *G* the seventh letter, just as *J* was, so I just wrote the correct number for the letter *J*. "
   (d) Identification of the *F* (Figure 2) as a *T*, an *F*, a *4*, and as for, followed by its identification as a *7* as described in Item 5, and by relating this explanation to the clarification of the "mistake" contained in the letter *G*.

(e) Declaration that there should be a *7* in addition to the one contained in the second character of the written explanation, to be read with the *th* as "seventh letter."
(f) Discovery of the concealed *7* and the reading of the message as "Not letters, numbers for letters, not *7*, seventh letter, *7* in place of letter."
(g) Clarification of the question of the *K* and the *H* in the same fashion as Alice had done.
(h) Discovery of the pun on *4* and *F* contained in the second character of the written explanation, since previously he had regarded the *F* as a simple abbreviation for *for*.

7. Declaration that the four digits, illustrated in Figure 4, constituted a similar but less satisfactory explanation than the writing in Figure 6.
8. Explanation that Figure 6 differed from Figure 5 only because of the assistant's interference. Alice had declared them to be identical in meaning.

DISCUSSION

I. The main event of this unplanned and unexpected experience is in itself worthy of record, for it is an arresting fact that one human being in a dissociated, trancelike condition can accurately decipher the automatic writing of another—writing which neither of the two subjects was able to decipher while in states of normal consciousness. The observation stresses from a new angle a fact that has often been emphasized by those who have studied unconscious processes but which remains none the less mysterious—namely, that underneath the diversified nature of the consciously organized aspects of the personality, the unconscious talks in a language which has a remarkable uniformity; furthermore that that language has laws so constant that the unconscious of one individual is better equipped to understand the unconscious of another than the conscious aspect of the personality of either.

If this is true, and it seems to be a fact attested from many sources, it must give psychoanalysts reason to wonder as to the wisdom of confining themselves exclusively to the technique of free association in their efforts consciously to penetrate into the unconscious of a patient.

II. When one turns to the details of this experience, one finds several points which need more specific emphasis and certain basic questions which remain wholly unanswered.

(1) In the first place it is striking that in the translation of automatic writing, as in the interpretation of dreams, each element may be made to do double and triple duty: to wit, the several purposes subserved by the letters *N* and *F*.

(2) Again we see that here—as in dreams, puns, elisions, plays on words, and similar tricks that we ordinarily think of as frivolous—all play a surprising and somewhat disconcerting role in the communication of important and serious feelings. We accept this type of thought and language in simple jokes, as for instance in the old conundrum of childhood: "How do you spell `blind pig'?" to which the answer is "blndpg—leave out

the ‘eyes.”‘ But it is ever a source of fresh amazement when the unconscious processes express weighty and troublesome problems in a shorthand which has in it an element of irreverent levity.

(3) In the whole episode there are two untouched problems—why in the first instance the “mistake” occurred at all (the slip is seemingly trivial, a tempest in a teapot), and second why, when the mistake had occurred, the first subject, T. L., could not have recognized it and corrected it simply and directly. Perhaps it is of importance that the mistake concerned the patient’s own identity—i.e., the automatic spelling of his own name. It will be recalled that in the course of the experiment his name had been changed by suggestion to “Jack Young.”

It is possible that a highly charged rebellion against the implantation under hypnosis of this alternative personality, struggling with a coexistent attitude of passive submission to the authority of the hypnotist, may account for several things: the exaggerated tempest, the curiously evasive quality of some of the replies, the ambiguities (as if he did not know whether to correct the error or not), the elements of malicious humor, the literal-mindedness, the hiding. All of this seems to indicate that, both in the automatic writing and in the subsequent efforts to translate it, the subject is struggling simultaneously to explain and to hide his meaning. In support of this hypothesis there is one possible explanation of the writing, which neither subject offered although it is a rather obvious alternative: if *N* equals *not*, and if *F* is also a *T*, and if we consider that the first letter of the following group of letters is *L*, then the first three letters would read “not T. L.” —in other words, not the subject’s own initials.

It may well be that if we knew enough about the subject, T. L., and the identifications which must make up the basis of the structure of his whole personality, that this otherwise mysterious little episode would then become quite understandable.

Experimental Demonstrations of the Psychopathology of Everyday Life

Milton H. Erickson

Reprinted with permission from *The Psychoanalytic Quarterly*, July 1939, Vol. VIII.

INTRODUCTION

The experiments reported below were conducted for the most part in the presence of a seminar of graduate students held in New Haven under the leadership of Dr. Sapir during the spring of 1933. In addition, a few experiments which were performed elsewhere are included.

The subject who was used for many of these demonstrations had frequently before volunteered for similar purposes. He knew nothing, however, of the plans for these experiments; they represented situations which were entirely new and problems with which he had never before been confronted.

In his approach to such demonstrations this subject customarily reacted in a way which was fairly characteristic for many others. Ahead of time he often appeared to be resentful and anxious, or overeager about the impression which he and the experimenter would make. Suddenly, however, with the beginning of the lecture or demonstration, he would seem to shift the responsibility completely and to lapse into an attitude of complete comfort, with loss of all tension and worry.

Following one of the demonstrations described below the subject told the experimenter that his shift in mood had been even more marked than usual. The night before the lecture he had been unable to sleep and had felt more than ordinarily resentful that on so important an occasion no rehearsal or preparatory discussion had taken place. He had even developed some nausea and diarrhea. All of this nervousness had disappeared completely, however, as he entered the lecture room on the morning of these experiments.

I. UNCONSCIOUS DETERMINANTS OF THE CASUAL CONTENT OF CONVERSATION

The subject was brought into a state of profound hypnosis, during which he was instructed that after awakening he would (*1*) notice Dr. D. searching vainly through his pockets for a package of cigarettes; (*2*) that he then would proffer his own pack, and (*3*) that Dr. D. absentmindedly would forget to return the cigarettes, whereupon the subject would feel very eager to recover them because he had no others. He was further told that

(*4*) he would be too courteous to ask for the cigarettes either directly or indirectly but that (*5*) he would engage in a conversation that would cover any topic except cigarettes, although at the time his desire for the return of the cigarettes would be on his mind constantly.

When he was awakened, the subject saw that Dr. D. was looking for cigarettes. He thereupon courteously offered his own and at the same time became involved in a conversation during which Dr. D., after lighting the cigarette, absentmindedly placed the pack in his own pocket. The subject noted this with a quick glance, felt of his own pockets in a somewhat furtive manner as if to see whether or not he had another pack, and showed by his facial expression that he had no others. He then began chatting casually, wandering from one topic to another, always mentioning in some indirect but relevant fashion the word "smoking." For example, he talked about a boat on the bay at New Haven, commenting on the fact that the sight of water always made him thirsty, as did smoking. He then told a story about how the dromedary got one hump and the *camel* two. When the question of travel was raised, he immediately pictured the pleasure he would derive from crossing the Sahara Desert rocking back and forth comfortably on a *camel*. Next he told a tale of Syrian folklore in which again a camel played a role. When he was asked to tell something interesting about patients, he told of taking a patient to see a marathon dance which the latter enjoyed immensely while he himself was reminded by the antics of the dancers of a circus where one would see elephants, hippopotami, and *camels*. Asked what he would like to do, he commented on the pleasant weather and said that there was nothing more glorious than paddling in a canoe or floating at ease on the water, smoking.

II. MANIFESTATIONS OF UNCONSCIOUS AMBIVALENT FEELINGS IN CONVERSATIONS ABOUT A PERSON

During hypnosis the subject was told that he admired and respected Dr. D. very much but that unconsciously he was jealous of him and that because of this jealousy there would be a cutting edge to complimentary remarks he would make. He was further told that after awakening a conversation would be started with Dr. D. in which he would take part. The subject was then awakened, and the conversation began.

The topic of traveling and its contribution to personal education was mentioned. The subject immediately brought up the fact that Dr. D. had studied both in the Middle West and in the East and that, having traveled abroad as well, he might well be called cosmopolitan. He himself, he added, would like to travel and get a cosmopolitan education, but in the last analysis that was what was being done by any old tramp who traveled from one part of the country to another by stealing rides on freight cars. There followed a discussion of human behavior as it reflected local environments, during which the subject remarked that the man who had traveled showed a broader knowledge and better understanding of people and of cultural things; he added, however, that the same thing might possibly be said of any resident of East-Side New York.

III. LAPSUS LINGUAE AND UNCONSCIOUS IRONY

During hypnosis the subject was instructed that after he awakened, Dr. D. would begin talking to him about some abstruse subject in which he was not at all interested, and that although he would actually be profoundly bored, he would try to appear interested. He was told that he would want very much to close the conversation, that he would wish for some way of shutting off this interminable flow of words, that he would look around him in the hope of finding some distraction, and that he would feel that Dr. D. was terribly tiresome. He was then awakened, whereupon Dr. D. began the conversation. Although the subject appeared to be politely attentive, Dr. D. would occasionally say, "Perhaps you're not interested." The subject would reply with excessive emphasis, "Oh, yes, certainly, I'm very interested." Now and then he would interrupt Dr. D., trying to pin him down to some definite point for discussion, but each time this effort was evaded. At length the subject began glancing about the room and was noted casually to observe an open door. Finally he interrupted Dr. D., saying, "Excuse me, I feel an awful draft," and got up to close the door. As he did so, he was asked what he was doing. He replied, "The air seems to be awful hot ['hot air!']; I thought I would shut off the draft." When the hypnotist pretended not to understand and asked him what he was doing, the subject replied, "Why, I just shut the bore." His remark was then repeated by the hypnotist for the benefit of those in the audience who had not heard it. When the subject heard his statement given as "shutting the bore," he started visibly, seemed tremendously embarrassed, and with much urgency turned to Dr. D., saying, "Did I say that? I didn't mean that. I just meant I closed the door." He was very apologetic in his whole manner and bearing.

IV. UNCONSCIOUS RESENTMENT EXPRESSING ITSELF IN MASKED FORMS THROUGH A SMOKE-SCREEN OF OVERCOMPENSATORY COURTESY

The subject was told during hypnosis that he felt antagonistic, resentful, and jealous of Dr. D. and that this emotional state would persist after he was awakened. He was also told that after awakening he would try to be courteous and acquiescent toward Dr. D. in every way and would appear to be willing to do anything requested of him.

After being awakened, the subject seemed to be entirely at ease; he responded courteously to some casual remarks addressed to him by Dr. D. Presently Dr. D. asked him if he would mind changing his seat. The subject replied certainly not, that he would be delighted, but that he was quite comfortable where he was; if it would make Dr. D. more comfortable, however, he would be delighted to change his seat. The request was repeated, whereupon the subject arose and asked Dr. D. to designate the precise chair in which he was to seat himself. He walked over toward the designated chair but asked Dr. D. if perhaps a certain other chair might not serve even better, since the reason Dr. D. had given for his request was that he was not quite in full view of the audience. When Dr. D. insisted that the designated chair was the better one, the subject, with great courtesy, still questioned, seeming nevertheless most willing to do precisely what was desired and to be hesitant only about seating himself before he was absolutely certain of Dr. D.'s wishes.

After much insistence by Dr. D. that he seat himself the subject agreed that the chair indicated was precisely the one that he ought to sit in and proceeded to do so; but as he did so he moved the chair about six inches to one side and shifted its position so that it faced in a slightly different direction. Immediately upon seating himself he turned and politely asked, "Is this the way you would like to have me?" After a few moments of casual conversation Dr. D. found fault with his position and asked him if he would mind taking his original chair. He rose promptly, said that he would be delighted to sit anywhere that Dr. D. wished but that perhaps it would be better if he sat on the table, and offered to move the designated chair to any desired spot, suggesting some clearly unsuitable positions; finally, when urged insistently to sit in the chair, he again had to move it.

V. AMBIVALENCE: MANIFESTATIONS OF UNCONSCIOUS CONFLICT ABOUT SMOKING IN THE DISTORTION OF SIMPLE, DAILY SMOKING HABITS

During profound hypnosis, the subject was instructed to feel that he wanted to get over the habit but that he felt it was too strong a habit to break, that he would be very reluctant to smoke and would give anything not to smoke, but that he would find himself compelled to smoke; and that after he was awakened he would experience all of these feelings.

After he was awakened, the subject was drawn into a casual conversation with the hypnotist who, lighting one himself, offered him a cigarette. The subject waved it aside with the explanation that he had his own and that he preferred Camels, and promptly began to reach for his own pack. Instead of looking in his customary pocket, however, he seemed to forget where he carried his cigarettes and searched fruitlessly through all of his other pockets with a gradually increasing concern. Finally, after having sought them repeatedly in all other pockets, he located his cigarettes in their usual place. He took them out, engaged in a brief conversation as he dallied with the pack, and then began a search for matches, which he failed to find. During his search for matches he replaced the cigarettes in his pocket and began using both hands, finally locating the matches too in their usual pocket. Having done this, he now began using both hands to search for his cigarettes. He finally located them but then found that he had once more misplaced his matches. This time, however, he kept his cigarettes in hand while attempting to relocate the matches. He then placed a cigarette in his mouth and struck a match. As he struck it, however, he began a conversation which so engrossed him that he forgot the match and allowed it to burn his fingertips, whereupon, with a grimace of pain, he tossed it in the ashtray. Immediately he took another match, but again introduced a diverting topic by asking the audience in a humorous fashion if they knew the "Scotch" way of lighting a cigarette. As interest was shown, he carefully split the match through the middle. One half of the match he replaced in his pocket in a time-consuming manner and tried to light his cigarette with the other half. When it gave too feeble a flame, he discarded it and had to search for the second half. After striking this, another interesting topic of conversation developed and again he burned his fingers before he made use of it. He apologized for his failure to demonstrate the "Scotch" light successfully and repeated the performance, this

time holding the flame in such a way as to ignite only a small corner of the cigarette from which he succeeded in getting only one satisfactory puff. Then he tossed the match away and tipped the cigarette up so that he could see the lighted end. He started to explain that that was how the "Scotch" light was obtained and noted that only one small corner of the cigarette was lit. He smiled in a semiapologetic manner and explained that he had really given a "Jewish" light to the cigarette, whereupon the lighted corner expired. He made a few more humorous comments, and as he talked and gesticulated appropriately, he rolled the cigarette between his fingers in such a fashion that he broke it, whereupon he put it aside and took another. This time a member of the audience stepped up and proffered him a light, but as the lighted match drew near to the tip of his cigarette the subject sneezed and blew it out. He apologized again and said he thought he would light his own cigarette. While taking out his matches, he commented on the vaudeville trick of rolling cigars from one corner of the mouth to the other and proceeded to demonstrate how he could roll a cigarette in that fashion, which he did fairly successfully. However, in doing so he macerated the tip of the cigarette and had to discard it. He took another, holding it in his mouth while he reached for his matches, started a conversation, and took the cigarette out so that he could talk more freely. It was observed that he took the cigarette out with his hand held in the reverse position to that which he usually used, and after completing his remarks he put the dry end of the cigarette in his mouth, exposing the wet end. He then tried to light this, held the match to the tip in the proper fashion, puffed vigorously, finally got a puff of smoke, and then blew out the match. Naturally the wet end of the cigarette did not burn satisfactorily and quickly went out. He looked at it in amazement and in a semiembarrassed manner mumbled that he had lit the wrong end of the cigarette; he then commented that now both ends of the cigarette were wet, and discarded it for another. After several similar trials he finally succeeded in lighting the cigarette. It was observed that although he took deep puffs, he tended to let his cigarette burn undisturbed, and that instead of smoking it down to a reasonable butt, he quickly discarded it.

A little later, while smoking, the subject attempted to demonstrate the violent gestures of a patient and in so doing knocked off the burning tip.
Then while lighting another cigarette he became so interested in talking that he lit the cigarette in the middle rather than at the tip and had to discard it. As usual he showed profound embarrassment at seeming so awkward.

(On other occasions when the subject had demonstrated this phenomenon, he would finally complete the demonstration by selecting a cigarette in a strained and laborious fashion and then, obviously centering all of his attention upon the procedure of lighting it, he would hold his hand tensely as he lit the match, applying it with noticeable rigidity to the cigarette and holding it there so long and puffing so repeatedly that all doubt was removed concerning the actual lighting of the cigarette, whereupon his whole manner and attitude would relax and he would appear to be physically comfortable.)

VI. UNCONSCIOUS CONVICTIONS OF ABSURDITIES WITH RATIONALIZATION IN SUPPORT OF THE BELIEF IN THEM

During hypnosis the subject was instructed that he was about to be reminded by the hypnotist of something he had known for a long time, that he had known it both as a result of his own experience and from reading about it in authoritative books. This, he was told, was the fact that "all German men marry women who are two inches taller than they are." A state of absolute emotional and intellectual belief in this was suggested, and he was warned that he might be called upon to defend this statement. He was told that he had read of this in a book written by Dr. Sapir in which the reference occurred on page 42. He was informed that he would know this not only in the hypnotic state but also when awake. The subject was then wakened.

During the course of a casual conversation mention was made of the peculiar customs of various nations and peoples. Remarking that he was reminded of a peculiar custom among the Germans, the subject went on to describe the suggested phenomenon in a matter-of-fact way. When his statement was challenged, he expressed obvious surprise that anybody should doubt it. He argued that it was entirely reasonable, that customs established from some simple purpose could be perpetuated by future generations until, regardless of their absurdity, they were looked upon as rational and commonplace. From this statement he proceeded to draw a social parallel to the attitude of Mussolini regarding compulsory marriage, arguing in a logical, orderly, and reasonable fashion. When this failed to convince the doubters, he drew upon personal experience, citing examples in a casual, simple, matter-of-fact and convincing manner and calling upon others in the group to verify his statements. When they failed to do so and cited contrary instances, he smiled agreeably and stated that every rule had its exception and that the failure of the German in the audience to confirm his observation was characteristic of the well-known tendency to overlook the obvious in familiar situations. When he was asked whether any authority in the field was known to hold such a belief, he promptly stated that he had read the same observation in a book by Dr. Sapir entitled *Primitive Peoples and Customs*. When he was asked where in the book it was described, he smiled in a deprecating fashion and remarked that it had been so long since he had read the book that he could not be sure of the page but that, as he recalled it, it seemed to be between pages 40 and 45-44 perhaps; this despite the fact that the hypnotist had specified page 42. He was then asked by a member of the audience what chapter it was in; he stated that as far as he recalled it was chapter two. Asked for the chapter heading, he explained that he had read the book so long ago he really could not recall it. When a member of the audience then stated that such a belief was contrary to all common sense, the subject, in amazement and with some embarrassment, asked rather urgently, "Surely you would not dispute a man as famous and distinguished as Dr. Sapir," nodding his head toward Dr. Sapir. His whole manner was suggestive of intense surprise at such arrogant disbelief.

VII. AUTOMATIC WRITING: UNCONSCIOUS OBLITERATION OF VISUAL IMPRESSIONS IN ORDER TO PRESERVE A HYPNOTICALLY ORDERED AMNESIA

During hypnosis the subject was instructed that on awakening he would engage in a casual conversation and that as he did so his hand would begin writing, but that he would have no knowledge of what he was doing.

After he had written some incomplete sentences, he was asked what he was doing by others in the audience. With some amazement he explained that he had been talking to Dr. D. When he was informed that while talking to Dr. D. he had also been writing, he immediately pointed out that this could not have been since he had been holding a cigarette in his right hand. (He had actually transferred the cigarette from his left to the right hand upon completing the writing.) As the audience continued to insist, he pointed out that he had had no pencil and nothing to write on, in addition to the fact that *he knew* he had not been writing and that the audience must have been mistaken. His attention was then called to a pencil and some paper on the table; he seemed surprised to see the paper and pencil and insisted that he had not had anything to do with either. He was asked to examine the paper to see if there were not some automatic writing on it, or at least writing. He picked up the paper, glanced at the top sheet, shook his head, and began slowly to thumb over each sheet, examining the papers over and over again on both sides, and finally restoring the pile to its original state. He said that he found no writing on any of the sheets. His attention was called to the top sheet, which he was asked to examine. He looked it over carefully at the top, turned it over and examined it, seemed to be in doubt as to whether or not he had taken the top sheet, and took the second sheet; he examined that, put it away, and glanced at the third sheet; he then seemed to feel that possibly he had had the top sheet in his hand, so he reexamined that very thoroughly and carefully and then, still holding it right side up, declared hesitantly, as if he hated to dispute with the audience but felt compelled to disagree, that there was no writing on the paper. One of the audience called his attention to the particular part of the paper on which there was writing. He glanced at it, looked back at his informant in a puzzled way, and then reexamined that part of the paper. After turning it over somewhat doubtfully and glancing at it, he turned it right side up again. He then began holding it so that the light struck it obliquely and finally declared, still in a puzzled fashion, that there *really* was no writing on the paper. Finally he was given the suggestion by the hypnotist that there was writing and that he would see it. He glanced back at the paper in surprise, and then an expression of amusement and amazement spread over his face as he saw the writing apparently for the first time. He commented on the juvenility of the handwriting, disowning it. When asked to tell what it said, he showed much interest in reading the characters but appeared to have a certain amount of difficulty in deciphering the writing. The last word was incomplete: he read it, spelled it, and stated that it seemed to be only part of a word. When he was asked to guess what the word was, he promptly reread the sentence in order to get the context, but was unable to guess. He then wanted to know why the writing had not been finished and was informed by the hypnotist that if he would just watch the pencil on the table, it would suddenly lift up in the air and begin writing the rest of the word. He looked doubtfully at the hypnotist and then said, “Why, it’s lifting up,” seeming to have no realization that his own hand was picking up the pencil

and holding it poised in position to write. Gradually his hand began forming letters. He was asked what the pencil was writing, to which he replied, "Wait—wait; let's see"; he appeared to be entirely absorbed in the supposed phenomenon of a pencil writing alone. The hypnotist watched the writing, which was proceeding very slowly, and soon realized that the word in question was *delicious*. The hypnotist then announced this to the audience while the subject was writing the last four letters and finished by the time the subject had finished writing. The subject looked up upon completing the word and said, "It's *delicious*," and then read the sentence to see if the word was relevant to the meaning. Apparently he had not heard the observer announce the word to the seminar.

VIII. "CRYSTAL-GAZING": HALLUCINATORY VIVIDNESS OF DREAM IMAGERY EMBODYING ANGER DISPLACED FROM HYPNOTIST ON TO DREAM PERSON

In a somnambulistic state the subject was instructed that he was to gaze at the wall and that as he did this the wall would become distant, faraway, foggy, and blurred; gradually a dark point would appear, which would become more and more elaborate, that movement would enter the scene, and soon he would see a well-known and emotionally stirring moving picture.

The subject began these observations with faint interest and considerable difficulty at first, but gradually a profound change in his manner and attitude occurred as he was seen to watch the moving images with intense interest. He resented any inquiries as to what he was seeing and gave the impression that he did not want to be distracted from the scene. Now and then he would turn slightly to ask, "Did you see that? Watch." The moving scene was from Rasputin and the Empress, showing the stumbling and falling of the Czarevitch, to which the subject showed appropriate emotional reactions. He went on to describe the sequence of events in proper chronological order. When the demonstration had gone far enough, he was told that the picture was changing. He disregarded this; when the hypnotist insisted, he declared that he did not want to listen now, that the hypnotist should wait until the picture came to an end. He was obdurate about accepting any suggestions concerning the changing of the picture. The suggestion was then tried of speeding up the movie, making it go faster and faster. When this was done, it was possible to shift the scene to a hospital picture, which he described as one in which *a nurse shouted loudly at a patient*. Here he manifested great resentment toward the nurse for doing this, apparently hallucinating the nurse's voice. The incorporation into the hallucinatory image of his anger against the experimenter and the childlike and fear-laden exaggeration of his impression of loud and angry voices because of his own inner anger were all very evident.

IX. IMPLANTATION OF A COMPLEX

During hypnosis the subject was instructed to recall having had dinner at Dr. DA home on the previous day. He was then told that the hypnotist would review a certain series of actions which had occurred on the previous day and that the hypnotist would refresh his memory of certain things that the subject had done which he regretted intensely and

which constituted a source of much shame to him. Thereupon he was told to remember how during the course of the afternoon he had stood by the fireplace, leaning against the mantel while talking to Dr. D. about various subjects, when his eye happened to fall upon a package of cigarettes lying behind the clock on the end of the mantelpiece. The tale went on that Dr. D. had noticed his glance and had proceeded to tell the subject that the package of cigarettes was a sentimental keepsake of his marriage, that he and his wife had received this package of cigarettes on their wedding day and had preserved it unused ever since. As Dr. D. added various romantic elaborations, the subject had not paid much attention because he was really rather bored by the sentimental story. After fingering the package, Dr. D. had replaced it at the other end of the mantelpiece; but the subject had not paid any attention to this either. Shortly after this Dr. D. and his wife had left the room for a few minutes. During their absence the subject noticed that he was out of cigarettes and glanced about the room to see if his host had some. Noticing a pack of cigarettes at the other end of the mantelpiece, he thought that his host would have no objection to his helping himself. He stepped over and took this pack of cigarettes from the mantelpiece, opened it, extracted a cigarette, lit and smoked it. Not until he had finished smoking did he realize that this was the very pack of cigarettes which Dr. D. had placed at the end of the mantelpiece instead of returning to its original hiding-place behind the clock. The subject was then reminded of how distressed he had felt, of his sense of being in a quandry as to what he ought to do, of how he had hastily closed the pack and had replaced it behind the clock and had then decided that he had better put it where Dr. D. had placed it, but how before he could do this his host had returned so that he had been forced to carry on a casual conversation with this burden on his mind. Furthermore he was told that even now and after awakening this burden would still be on his mind.

The subject was roused, and after a few brief remarks Dr. D. offered him a cigarette. The subject started, glanced furtively first at Dr. D. and then at the hypnotist, and finally in a labored fashion reached out and accepted the cigarette, handling it in a gingerly manner. Dr. D. began an innocuous conversation, but the subject paid little attention to what was said and asked Dr. D. what he thought about sentimentality, uttering the word *sentimentality* in a tone of disgust. He then stated that he himself was not sentimental and that he tended to dislike people who were sentimental and maudlin. He stated that he hoped that Dr. D. was not sentimental, that he did not impress the subject as being sentimental. Dr. D. made another attempt to change the topic of conversation, but the subject persisted with his own line of thought. He raised a hypothetical question about a man who owned an old homestead and who, as a result of the economic depression, had lost much money and was in a quandary about the necessity of selling it. He went on to talk of the burning of the house, of the house going up in smoke, and various allied topics. He then talked of guilt feelings, how everybody stole, how he himself had stolen; he wanted to know how Dr. D. would feel about anybody who had stolen unwittingly.

Another attempt by Dr. D. to change the trend of the conversation failed. The subject then told of having once stolen a cigar which belonged to a man who had kept it for sentimental reasons. He said he had taken the cigar and smoked it without realizing that it was a keepsake, and that he had felt very bad about it and wondered about the possibility

of replacing it so that the sentimental man would not be angry with him. In a defensive manner he then expressed a high regard for a person's feelings and contended that nevertheless people should not think too hard of others who had unwittingly violated some of their sentimental values. After this he stated that not only had he stolen the cigar but he had even stolen cigarettes (pause), a pack of cigarettes. As he said this, he glanced in a particularly furtive manner at Dr. D. and also at the hypnotist, and seemed very ill at ease. He told about having smoked a cigarette and having enjoyed it, but that it had left a bad taste in his mouth afterward and that even though he had stolen the cigarettes long ago, he could not get them off his mind, that they still troubled him, though common sense told him it was nothing to be concerned or worried about.

X. THE ASSUMPTION OF ANOTHER'S IDENTITY UNDER HYPNOTIC DIRECTION, WITH STRIKING UNCONSCIOUS MIMICRY AND THE ASSUMPTION OF UNCONSCIOUS EMOTIONAL ATTITUDES

During hypnosis the subject was informed that after awakening he would be Dr. D. and that Dr. D. would be Mr. Blank, and that in the role of Dr. D. he would talk to the pseudo Mr. Blank. Additional suggestions which the subject fully accepted were given to complete the transidentification. After the subject was awakened, a conversation was begun. The pseudo Mr. Blank questioned him about his work in the seminar, as though he were Dr. D.; the subject responded by giving an excellent talk about his experiences in the seminar and his reactions to the group, talking in the phraseology of Dr. D. and expressing the personal attitudes of Dr. D. A chance conversation with Dr. D. on the previous day had supplied him with a great deal of information which he utilized fully. It was noted also that he adopted Dr. D.'s mannerisms in smoking and that he introduced ideas with certain phrases characteristic of Dr. D. When the pseudo Mr. Blank challenged his identity, the subject contradicted Mr. Blank politely and seemed profoundly amazed at Mr. Blank's remarks. Then suddenly, with an expression of dawning understanding, he turned to the hypnotist, saying, "He's in a trance, isn't he?", and thereafter was only amused at Mr. Blank's remarks. Mr. Blank then questioned the subject about his wife, to which the subject responded in a way that would have been natural for the real Dr. D. When asked about children, he assumed an expression of mild embarrassment and replied, "not yet, but you never can tell." Mr. Blank then began talking to the hypnotist in his ordinary fashion, at which the subject again seemed tremendously surprised. With a puzzled look on his face, he suddenly leaned over and tested Mr. Blank for catalepsy. When he found none, his face was expressive of some concern; he promptly whispered to the hypnotist, "He's coming out of the trance," but was relieved when the hypnotist assured him that it would be all right if this happened.

Finally, when an attempt was made to rehypnotize him in order to restore his own identity, the subject displayed the emotional attitude of resistance toward the induction of hypnosis which would have been entirely characteristic of the real Dr. D. The subject seemed actually to experience the same emotional responses that Dr. D. would have had at such a time. Finally, because he appeared to be entirely resistive to simple suggestion, it was necessary to induce hypnosis by indirect methods.

This rather astonishing result offers a technique for the experimental investigation of the phenomena of identification and of the unconscious incorporation of parental emotions by children.

Demonstration of Mental Mechanisms by Hypnosis

Milton H. Erickson

Reprinted with permission from *The Archives of Neurology and Psychiatry*, August, 1939, Volume 42, No.2.

After general introductory remarks on the special advantages of hypnosis as a means of demonstrating the mechanisms and dynamics of behavior, I introduced 3 normal subjects to the audience and conversed casually with them to demonstrate their ordinary behavior. This was followed by the rapid hypnotizing of all 3 subjects, with demonstration of some of the more common hypnotic phenomena, particularly ideomotor action, catalepsy, rapport and, finally, the somnambulistic hypnotic trance in which the subjects give an outward appearance of being awake and in full contact with their surroundings, and yet are actually completely out of contact with their surroundings except as instructed by the hypnotist. Then followed a series of demonstrations directed to the clarification of various psychic dynamisms.

Subject 1, on reaching the somnambulistic state and opening his eyes, was found to be oriented as if he were in my office, rather than in a lecture hall before an audience. This orientation on the part of the subject was found to be entirely valid, and every response he made, direct or indirect, disclosed him to be acting entirely as if he were actually in my office. This manifestation was discussed in detail, emphasis being placed on the hypnotized subject's ability to exclude, or to fail to respond to external stimuli and to react to internal stimuli as if they derived form the outside; a parallel was drawn with the reality of the delusional beliefs of psychotic patients.

Subject 2 was then placed in rapport with Dr. R. W. Cavell, and a casual conversation followed, after which I made a long series of suggestions to the subject to the effect that she was acquiring a retroactive amnesia extending to the tenth year of her life. In this manner it was possible to induce this young woman to "regress" in the patterns of her behavior and to react as if she were 10 years of age, giving the responses characteristic of a child and showing the emotional reactions, the general social patterns and the juvenile attitudes characteristic of that age. The subject in the mental state of 10 years was then interviewed by Dr. H. Reye, who questioned her extensively, eliciting replies in accord with the understanding of a child of 10.

This demonstration was discussed with emphasis on the necessity of a time-taking procedure of suggestion as a measure of permitting the subject, who is receiving such suggestions, to acquire the "mental set" by means of which there can be reestablished the levels of mentation characteristic of any suggested age without interference from subsequently acquired experiences. A parallel was drawn with the forms of regression encountered psychiatrically.

Subject 3 was then employed to demonstrate, while in the somnambulistic state, the phenomenon of negative hallucination. Dr. Cavell was pointed out, and the subject was told that shortly he would leave and that she would not see him again. After these suggestions had been given effectively, innumerable attempts were made by Dr. Cavell to establish either a positive or a negative contact with her, but the subject manifested neither avoidance of nor response to him. So far as could be determined by indirect as well as direct measures, the subject remained totally unable to make any form of response to Dr. Cavell. This was discussed, and a parallel was drawn with various forms of denial of reality observed in psychotic patients.

Hypnotic suggestions were given to subject 1 to the effect that there would appear on the floor a large crystal in which he was to see a crystal image of recent events. The subject accepted these suggestions and had a remarkably complete visual image of the lecture room as it had been during the earlier part of the evening; extensive questioning disclosed that the experience for the subject was exceedingly realistic. Discussion was offered, and parallels were drawn with the processes of reliving as it develops in psychotherapeutic measures.

Subject 3, still in the somnambulistic trance, was given a series of suggestions directed to the evocation of the phenomenon termed "resistance." To this end the subject was instructed to be entirely courteous and compliant toward Dr. S. H. Ruskin in every detail; yet at every opportunity the subject was to avoid, escape, evade, resent and resist every casual request of conversational remark made. After a brief pause, the subject was awakened and a casual conversation initiated, leading to the introduction of the subject to Dr. Ruskin. Then followed a general conversation, in which the subject missed no opportunity, however direct or indirect, to oppose Dr. Ruskin in every conceivable way, yet maintaining an attitude of impeccable courtesy. An attempt was made by Dr. Ruskin to have the subject take another seat, and every request and insistence on his part was countered effectively by courteous resistance; when he finally made it impossible for the subject to avoid compliance, the latter yielded, but moved the chair to a new position, thereby subtly nullifying the compliance. This behavior was discussed in detail in relation to the problems represented by both conscious and unconscious resistance shown by patients.

Subject 2, in the deep trance, was instructed that after awakening she was to recall a trip made by the hypnotist to Detroit, in an effort to visit a certain hospital, and the losing of his way. The subject was given a false address for this well known hospital and was told to insist, argumentatively, when awake, that this false address was the only correct one.

After awakening, subject 2 obeyed instructions fully and became involved in arguments with the members of the audience as to the location of the specified hospital. Innumerable items of proof were advanced by the subject to confirm the false address, and I discussed in general the fixity of the subject's beliefs and the general imperviousness to any reasoning approach to her delusional ideas. A parallel was drawn between this behavior and the general attitude taken by the psychotic patient when a reasoning approach is made to any form of abnormal ideation.

To subject 3 there was then suggested, in the deep trance state, a phobia for cats and a long series of suggestions was given, building up in the subject an intense fear, dislike and abhorrence of cats and anything connected with them. The subject was told that this fear would persist even after awakening, but that it would be concealed, denied and repressed from all conscious awareness. After this complex had been thoroughly implanted, the subject was allowed to awaken. Dr. Cavell took a seat beside the subject and by slow degrees led up to the topic of people's interest in pets. When this conversation had been well established, the subject began manifesting intense and uncontrollable abhorrence of and disgust for people who had any interest in animals, particularly cats, and numerous instances were cited by the subject in which persons who like cats were found to be undesirable or abhorrent. Finally, the conversation disclosed that Dr. Cavell owned a cat, whereon the subject showed a marked distaste for the proximity of her chair to Dr. Cavell, and recourse was had to various subterfuges on her part to effect a change to another seat. Dr. Reye then approached the subject to ask questions about cats, with the result that the subject became increasingly tense and emotional and unable to discuss cats without expressing intense, unreasoning and irrational hostility toward them. Finally, when questioned as to the duration of this feeling of hatred toward cats, the subject gave a long story about always having hated and abhorred cats. When all the classic manifestations of an acute phobia had been manifested clearly and unmistakably, the subject was rehypnotized and the phobia removed completely by psychotherapeutic suggestions and the giving of insight.

After this, subject 3 was rehypnotized, and a second complex was implanted in which the subject was told that, purely by accident, through a state of absentmindedness, she had seriously offended subject 1, with whom a friendly feeling had always existed. The subject was told that this result now belonged to the past, that there was nothing that could be done about it, and that it might just as well be completely repressed and forgotten.

After this, subject 3 was awakened, and, by manipulation of the situation, subjects 3 and 1 engaged in a casual conversation. During the course of this, subject 3 resorted to every conceivable misunderstanding of subject 1's remarks to offer an apology. Overcompensatory behavior and inexplicable embarrassments were demonstrated by the subject in a clear fashion. Many of the remarks made by subject 3 carried a double meaning easily apparent to the audience, but which bore only a simple conscious significance to the subject. In elaboration of the demonstration, I discussed the significance and effects of repressed material on ordinary behavior.

Subject 3 was again hypnotized; the previous complex was removed, and suggestions of an intense desire to smoke were given. At the same time the subject was instructed to want to avoid smoking, to hate smoking and yet to feel bound by an uncontrollable desire to smoke, a smoking compulsion being thereby effected. On awakening, the subject manifested marked restlessness, made several remarks about my smoking, commented that I seemed to have matches, and remarked that I had sometimes offered people cigarettes; when one was offered to her, it was rejected with a statement that a cigarette

of a special brand was desired. Since a package of this special brand was found in the audience, a cigarette was offered to the subject, who took it unwillingly and refused to smoke unless some one else joined in the act. After much dilatory activity and ineffective efforts to light the cigarette, the subject finally began to smoke in an easily recognizable compulsive fashion, becoming harshly critical of the cigarette and of the general situation, obviously not enjoying the cigarette and yet feeling compelled to smoke. Every effort made on the part of members of the audience to induce dicontinuance of the smoking met with firm resistance, despite the subject's repeated insistence that she had no desire to smoke and despite her ready desire to get rid of the cigarette, the subject finally began to smoke in an easily recognizable compulsive obsessive form of behavior.

After this, I gave a general review of the various demonstrations and drew parallels between psychoneurotic behavior, psychotic behavior and normal behavior and the various types of behavior manifested by normal hypnotic subjects, closing my remarks with emphasis on the value of hypnosis as an instrument for the teaching of the dynamics of behavior and as a means of creating within the laboratory various types of behavior which could then be subjected to critical laboratory analysis.

Unconscious Mental Activity in Hypnosis—Psychoanalytic Implications

Milton H. Erickson and Lewis B. Hill

Reprinted with permission from *The Psychoanalytic Quarterly*, January, 1944, Vol XIII, No. 1. Footnotes in this paper are by the editor of *The Psychoanalytic Quarterly* and were written for the original publication.

Misconceptions regarding the alleged limitation of hypnotic psychotherapy to hypnotic suggestion are current because of the failure to differentiate between (*1*) the process of inducing trance states and (*2*) the nature of the trance. Since hypnosis can be induced and trance manifestations elicited by suggestion, the unwarranted assumption is made that whatever develops from hypnosis must be completely a result of suggestion, and primarily an expression of it.

The hypnotized person remains an individual, and only certain limited general relationships and behavior are temporarily altered by hypnosis. Hypnosis is in fact the induction of a peculiar psychological state which permits subjects to reassociate and reorganize inner psychological complexities in a way suitable to the unique items of their own psychological experiences.

CASE REPORT

Dr. Jane was a quiet, earnest, hardworking, highly intelligent woman intern. During the course of her hospital service she had often sought help and instruction from me about her ward work. She had shown much interest, and had often watched my hypnotic experiments. She had been asked repeatedly to act as a subject but had always politely refused. I and various other members of the professional staff characterized her as a decidedly insecure, rather neurotic woman who probably suffered from some distressing personality problem.

After about six months' professional association with her, she came unexpectedly to my office and related with some pressure and urgency that she had a serious personal problem that she must decide within the next month. For months, every time she tried to make a decision about it, her thoughts became blocked, she became anxious, and she dismissed it by absorbing herself in work. She had developed insomnia and drove herself from one task to another to fall asleep from exhaustion. She invited my assistance and prescribed the manner in which it was to be given. Some evening when it was convenient for me, I was to go to her apartment and hypnotize her, adding that she did not know why she wanted me to do it. She warned me not to question her because she did not know the answers. She dictated in detail the manner in which I was to proceed in hypnotizing her:

> I want you to be very emphatic about instructing my unconscious to think my problem through in a cool, unemotional fashion. I want my unconscious to discover what that problem is because I really don't know, and to look at it from every angle, size it up, and then make some sort of a final formulation no matter what it is. Watching your subjects has impressed me with the way the unconscious can handle problems a person doesn't know he has. I know I have a problem that troubles me, makes me irritable and lose a lot of weight. I am just plain disagreeable in company. This can't go on. I've got to leave the hospital soon, and I can't even make any plans. So I want my unconscious to straighten things out for me.
>
> This is what I want to do. First hypnotize me very soundly, and when I am in a deep trance, tell my unconscious everything I have just told you, using the notes you have made so that you don't omit anything. I want you to be as careful and as complete as you are when you are giving your experimental subjects suggestions. You don't know what your instructions are going to result in, and it is the same way with me. I don't know and you don't know what it is all about, but if you tell my unconscious everything I have told you, it will understand. Be sure to tell it that it must think the whole problem clear through. Be emphatic.[1]

She disclaimed with obvious sincerity any additional understanding of her problem and said that she could not give any more information, although she felt herself willing to do so. She left the office hastily.

On meeting her during the next two days, no reference was made to the visit, even though several opportunities were offered her. On the third day she was asked casually about her plans for the evening. She replied she felt so tired that she planned to go to bed early and get some rest. Nothing in her manner indicated any awareness of a possible significance to the question.

At seven o'clock that evening she seemed astonished to have me call on her. She met the situation in a socially adequate fashion and invited me in for a visit. During the general conversation that ensued it became apparent that she had developed an amnesia for the visit to my office. She yawned repeatedly, each time apologizing for her seeming inhospitality, and confessed to having insomnia. This was seized upon to introduce the topic of hypnosis and the suggestion was offered that she might try hypnosis to induce sleep. Contrary to her previous refusals, she consented and promptly adjusted herself in a comfortable position on the couch.

She responded quickly and soon developed a profound trance. She was told to sleep deeply and continuously for half an hour during which I would absent myself, the purpose being that of providing ample opportunity for her to develop a profound trance state. She passively assented.

Returning in half an hour I told her to continue sleeping deeply, and I began a rather rambling monologue, making vague general references to the office visit followed by repeated comments on the autonomy of the unconscious, its ability to respond adequately, and its capacity to solve mental problems as well as, or even better than, the conscious mind. There followed a systematic review of the conversation of the initial interview, to which she seemed to listen most attentively and with some show of emotion.

At the conclusion she was asked if she understood the nature of her problem and if she were willing to examine it and to solve it. With much emotion she answered, "Yes, I know what it is. I understand. It is hard to decide, but I have to do it and I suppose I might as well now." Asked if she wished to talk about her problem, she replied that she did not want to have anybody know anything about it, that her purpose was to solve it entirely by herself. How long a time would she need? After a few moments she answered thoughtfully, "Come back in an hour and ask me if I am through and I will tell you."

An hour later she was still sleeping soundly. Asked if it was time to awaken her, she answered, "I am almost through. It will probably take me half an hour longer." In half an hour she responded to my return with the spontaneous statement, "I'm through. I've got it solved. You can awaken me any time you want to, but I think you better tell me after I am awakened that it will be all right to know the answer." I agreed but instructed her to remain asleep some minutes longer in order that she might be sure of everything. Some minutes later she was told that she might awaken if she were really convinced that her task was done. Immediately she repeated her request that she be told after awakening that it would be all right to know the answer. Prompt assurance was given, and then she was told to awaken gently and easily. This she did, and at once she began to converse freely, picking up the general thread of the conversation preceding the trance. She gave no evidence of recollecting that she had been hypnotized nor of understanding the reason for my presence. She was puzzled to note the passage of time and seemed at a loss to account for it. Remarks about "our chat a few days ago" elicited only responses relating to previous professional discussions.

After 20 minutes of conversation it became obvious that she could not understand the prolongation of my inexplicable visit and that she was secretly wishing I would leave. At the door I paused and, looking at her intently, remarked, "It is all right now for you to know the answer."

She seemed to be at a loss to find words with which to reply. Again I said, "It is all right now for you to know the answer." She responded with a bewildered look, suddenly reacted with a startled flush, and became tremulous and jerky in her movements and speech. With great anxiety she explained, "Won't you excuse me, please. I just found out something I wasn't prepared to know. I have to think about it right away, so won't you please leave me alone. Please hurry."

The next day and thereafter she made no reference to the foregoing incidents. Everything indicated that she had complete amnesia for both the office visit and the events of the

evening. It was noted by her colleagues that she was working with greater ease, was more sociable, and was eating better and gaining weight.

Approximately a month after the hypnotic session she came into my office and displayed a wedding ring. She had not publicly announced her engagement of a month ago or her marriage of the previous day, choosing instead to tell it first to a selected few. I was included because in her ward work I had given her special supervision and instruction for which she felt particularly grateful. She seemed to have no conscious awareness of any other possible instance that might have some bearing upon her choice.

The man she married was known to have been interested in her for some time, but she had not been known by me or others on the staff to have shown any real interest in him. Neither was she known by her colleagues to have spent much time in his company, although it was common knowledge that he was greatly attracted to her. It was the consensus that he was decidedly her inferior in so many aspects that he would never be able to interest her, despite his substantial worth as an average citizen.

Shortly after the marriage the young couple moved to another city; nothing more was heard of them until three months later, when she walked into my office and stated that she wanted to thank me.

That morning, lying in bed after her husband had gone to his office, she had begun thinking about how happy she was and wondering what she had ever done to deserve such happiness.[2] Previous to marriage she had anticipated some difficulties in marital adjustment because of the marked difference in nature between her husband and herself; yet each time a disagreement seemed impending, it had solved itself without difficulty. Then she had experienced a sudden rush of memories relating to the interview in my office and the subsequent hypnotic session. “It was the first time I was consciously aware of those things. Of course I was conscious of what I was telling you that morning, but as soon as I left your office, I must have repressed it completely, because I never thought of it again until this morning. When you came to my apartment to hypnotize me, I was surprised to see you. I didn’t know why you came. I just thought it was a social call. And when you suggested hypnosis to me, I was so tired that I didn’t remember that I had always refused to be a subject for you.”

I asked her to give a detailed account of the initial interview. She replied, “Oh, that isn’t necessary, I remember all of that distinctly, and besides, that isn’t why I came to see you. When I told you I had a problem and that I didn’t know what the problem was, I was telling you the truth. I just knew something was wrong. I was in love with John but I didn’t know it, and I wouldn’t have believed anybody who told me so. I tried not to go out with him very often, and I didn’t, but just the same I was in love. There are many differences between John and me, as you know. Our family background is entirely different. John just plugs along, and I was always at the head of my class. I have many interests—music, literature, art—that John hasn’t. I repressed all my feelings for him the way I must have repressed that whole talk with you. Watching you do hypnosis gave me an idea. When I figured out that plan, I had the feeling that my problem must be

something I didn't want anybody to know or I wouldn't be keeping it from myself so completely. That is why I asked you to do things the way I did.

"When you put me in a trance, I was scared as soon as I went under and you began talking about the things I had said to you. But I knew right away that you were just talking to my unconscious and that if I woke up I wouldn't remember a thing, the way your other subjects do, so I felt reassured, and let you go ahead. When you finished, I was all ready to go to work, except that I was afraid of how it might turn out because I knew I loved John. As soon as you left the room, I saw in my mind, like a patient's hallucination, a great long manuscript that slowly unrolled. It was divided into pros and cons about marrying John. What they were you don't need to know."

Questioning disclosed that these were such words or phrases as "industrious," "lacking in imagination," but she was unwilling to cite other than descriptive items of which she knew me to be aware. She stated that there were many items which were of particular and personal importance to her and would be difficult for anybody else to understand.

When the lists had been read through completely, they were reread thoughtfully, and then a process of "cancellation" was begun, sometimes by crossing out pairs, sometimes by adding an item from one list to one in the other list and then rewording the combined item, giving it an entirely new significance. Some items in both columns could be dealt with only by rewording them through an inclusion of pros and cons applicable to herself rather than to John; then some of the reworded items could be "crossed out," "balanced," or "combined." In counting the items remaining in each list, she found that "there was a marked preponderance of pros, and so I reread the list of pros again because it seemed too good to believe, and I found that the count was only arithmetically correct because the pros were all so much larger than the cons. Then I knew what my answer really was.

"When you returned a second time and suggested that I sleep a few minutes longer to make sure my problem was solved, I wanted to tell you what the answer was, but I felt John should be the first to know. I was already sure, so I just slept as you told me. I knew hypnotic subjects had amnesias to trance experiences, so I carefully told you to be sure to tell me to know the answer.[3]

"When you awakened me, I didn't know I had been asleep, and you seemed to have been there only a few minutes. I was awfully upset when I noticed how late it was. I couldn't pay attention to what you were saying because I was wondering what had happened to make it so late. When you said it would be all right to know the answer, I couldn't understand what you meant. When you repeated it, I suddenly knew that I loved John and would marry him if he asked me to. I was rather rude to you, but I didn't know how that idea had come to my mind, and I had to be alone and think about it. The more I thought about it, the more I knew I loved him. I went to bed happy for the first time in months, feeling as if I didn't have a problem in the world. The next morning I had thoughts about nothing except John. We became engaged, and I wanted to tell you about it, but I couldn't figure out any reason for doing so. When we got married, I wanted to tell you

and the only reason for doing so that I could think of was the help you had given me in my work. That didn't seem to be sufficient reason, but I used it anyway."

Two years later an unannounced call on the couple found them happily married. The wife commented with pride upon the accuracy with which her unconscious had evaluated the whole situation. She had told her husband nothing about her hypnotic experience. Some years later they were found to be most happy, and enthusiastic parents of several children. Word has been received directly and indirectly from them from time to time indicating a most successful marriage. [By M.H.E.]

CASE REPORT

A young college woman, who for a year had frequently acted as an experimental hypnotic subject for me, some months later appeared at my office stating that she wished to have a long personal talk with me about an important problem.

"In my hypnotic work with you," she said, "I have learned a good many things and feel well repaid for the time and effort I have given you. Now I want to ask a personal favor of you, and it is to be a favor and not a repayment for what I have done for you. The things I have learned have more than repaid me. I am emphasizing this so that you will do exactly as I wish and not according to any ideas that you might have. I have planned this all out.

"You know practically everything about me except that I have fallen in love and am going to be married soon. That is all settled.

"George is not like me at all. We are both college graduates, but where I am brilliant, George is just of average intellect; however, he has a much more charming personality, is even-tempered and socially much more adaptable. But he is stubborn, too, and he is much more confident of his intelligence than he has any right to be. He doesn't know I am a lot more intelligent than he is, and he is not the kind of person who would ever find it out. Whereas I am excitable and quick-tempered, he is always calm and unruffled. He is just exactly the kind of man who will make up for and correct the deficiencies in my own personality, and we are very much in love. I have tried to fight against it because I am afraid I will make George unhappy, but it is no use; so I have tried to size up our personalities and tried to reach some understanding of what I must do to meet his needs if we are to have a happy married life, but I become confused and get nowhere.

"I want you to put me in a deep trance and tell me to remember clearly all that I have just been telling you. When that is done, give me instructions to think about George and myself and about the things that I need to do to ensure a reasonably good marital adjustment. Do not try to question or help me. Watch me closely, and whenever you see me getting emotionally disturbed or confused or inattentive, reassure me that I can and must do this thinking, and keep me at it until I am through. When I get through, I will let you know what else, if anything, should be done."

Accordingly, a deep hypnotic trance was induced. She was then told to review silently and in full everything she had said in the waking state and to elaborate each idea mentally until it was clear in her mind. At first she objected, but finally acceded when reminded that the suggestion was at her own request. During the review she manifested much tension. When she seemed to have completed this task, she was told to reflect on exactly what it was she had in mind to do and how she was to do it, and when her method of approach to her problem was clearly formulated, she was to proceed. Again she objected to this suggestion but soon acknowledged its desirability. After some meditation she declared that she was fully ready and asked if she might go ahead with her task. She was told to proceed. It soon became evident that she had decided to resort chiefly to a silent review or study of whatever it was she had in mind.

In a short time she became distressed, and she was urged to begin again and to postpone temporarily any particularly distressing items until other matters had been cleared up sufficiently to permit thinking about the more painful things. When she gave evidence of distress, rest periods of two to five minutes were suggested to her, and these seemed to help her.

At times she would verbalize details of past emotional experiences known to me. Sometimes she would ask me to move to a remote corner of the room and order me not to listen, as she talked to herself in a low tone. On these occasions she would ask for the instruction to "go ahead and face it through." Approximately two hours were spent in this manner, often with a display of intense emotion which seemed to be alleviated by general reassurances from me. She then declared that she was through with her task and asked to be awakened with emphatic instructions from me that she retain full consciousness of her trance experience.

Upon awakening she was sorry for having been so slow but stated that she still was not through with her task. She now wanted to review her recollections of the trance; until this was done she would not know what next step would be necessary. She spent half an hour in silent meditation without display of emotion excepting gestures expressive of decision or conviction. Questioned about her progress, she replied that she had now reviewed all the "major matters," adding that her recollection of much of the trance was exceedingly vague; nevertheless, she felt "entirely comfortable" about everything.

She now wished to discuss with me various items, but I was only to listen, except that now and then I was to take "a negative attitude," which, she explained, would encourage her to be positive and emphatic in her statements.

She spoke in vague generalities about marital adjustment, sexual satisfaction, self-control of temper, and the need for marital partners to encourage each other's interests. Finally she offered the opinion that she really had nothing further to discuss. I agreed at once, whereupon she abruptly contradicted me to declare emphatically that there was still much to be said. She then launched into an earnest discussion of all the things she felt confident would contribute materially to a successful marriage, an excellent evaluation of her own

personality and of George's, as was later learned by direct contact with him. This discussion was all at a superficial social level.

She brought the discussion to a close by stating that there remained only one thing more for me to do: "If there is to be any negative attitude toward our marriage, it is better for you to have it and not me. I want you to be pessimistic and doubtful and not encourage it. Don't say anything openly; just take a general negative attitude. *I want you to keep that attitude for at least two years* when it won't make any difference because then I will be able to show you. I will write you newsy letters which you will answer politely, and in some subtle way, such as *hoping* all is going well with George's work, express your negative attitude."

During the next two years occasional letters were received and promptly answered, always with some ambiguous remarks about George. Six months after the expiration of the two years she wrote a letter saying that she was pregnant and that her husband had been promoted to a much better position.[4] Her intimate friends all reported the marriage to be most satisfactory, and after five years it appears to remain so. George, like John, was not told of these matters. [By M.H.E.]

DISCUSSION

The study of unconscious mental activity by other techniques provides methods of checking psychoanalytic data, theories, and techniques. If it is found that the therapeutic results of psychoanalysis seem to be duplicated by different and much less time consuming techniques, psychoanalysts should be quick to investigate these possibilities in the hope that they may be verified.

These case records of two patients treated by hypnosis are of interest precisely because of the almost complete absence of evidence of unconscious mental activity in the manner in which it regularly appears in the course of psychoanalytic therapy. There is no history, there are no free associations, the patients do not even give a clear statement of their problems, and the state of the transference must be inferred. These records cannot be studied as psychoanalytic documents. This is not a failure in transcription, for the hypnotist in a personal communication states that he does not know appreciably more about his patients' ideational content than is in the record. The therapeutic result is achieved without "making the unconscious conscious."

Recognizing this difference, it still appears profitable to make a comparison between the two methods upon the basis of certain familiar concepts:

(1) Unconscious[5] conflict and indecision within the psyche gives rise to anxiety against which defenses are erected. These defenses prevent both unconscious resolution of the conflict and its emergence into consciousness, and may result in inhibition of thinking, confusion, interference with activity.
(2) An unconscious conflict may be resolved unconsciously.

(3) The result produced by this unconscious work is evidenced by the emergence into consciousness of a thought, or a decision, which the person explains either in terms of some unconscious derivatives, more or less symbolized, or by a rationalization.
(4) Such unconscious activity can be influenced, accelerated, or retarded by a relationship with another person.

Analysts have found that the transference is a vital part of the therapeutic process and that the intrapsychic conflict would not continue its disturbing existence were it not for current difficulties in personal relationships according to a pattern of transference and provoked by the individual's relation to his environment. The hypnotist [6] evidently holds the view that the intrapsychic conflict exists as an entity complete in itself although modifiable by extrapsychic influences. The transference of the hypnotic subject to the hypnotist is ignored, or at least not utilized as a therapeutic instrument, by the hypnotist. Psychoanalytic technique explores precisely the transference as the essential focus of therapy.[7]

The majority of patients seeking psychotherapy suffer symptoms the causes of which they can only deny or rationalize. Those who believe that they know the nature of their conflicts are still unable to recognize the factors making for their insolubility. While patients claim ignorance of their intrapsychic problems, they relate a running narrative which, when it is completed in the process of analysis, demonstrates that there must have been an unconscious understanding and planning from the beginning. Patients "know" what is troubling them, but the knowledge is too painful to be borne in consciousness without help. The conflict is neither consciously perceived nor effectively suppressed.

The unconscious weighing of pros and cons to arrive at a decision by these two women whose records are presented is routinely observed in analysis. Both these women were familiar with hypnotic experiments and were aware of the possibility of avoiding the conscious working out of their problems. Analysands who have had a long acquaintance with psychoanalytic psychotherapy before making the decision to be analyzed have identical ambivalent feelings about the treatment. Often it is not clear what brings them to the decision to begin treatment. Such patients are sometimes found to have been maintaining defenses against the anxiety incident to partial insight. A good example is a paranoid individual who can no longer endure the "persecutions" of his enemy nor the "deceptions" of his wife. He is consciously convinced about his delusions, but instead of consulting a lawyer, under the guise of seeking protection from the enemy or treatment for his wife, he consults a psychiatrist and becomes convinced that he himself needs treatment. Clearly the unconscious understanding of his problem is far more correct than is his conscious formulation of it.

Psychoanalytic "working through" is essentially due to the fact that once a point is grasped it still cannot be utilized until sundry unconscious associations have become conscious. Psychoanalytic technique endeavors to reduce the stimulus (anxiety) to resistance. The hypnotic technique bypasses the resistance, so to speak. The hypnotist

endeavors to operate directly upon the conflict in the belief that if it is solved, much of the defense will spontaneously crumble.

Although in both cases reported the subjects dictate in detail the method by which the therapy was to be conducted, it can be presumed that the result could not have been accomplished without the mediation of the hypnotist. It might be said that the subjects utilized their transference to the hypnotist, who served in these instances chiefly as a passive instrument and who by following the instructions given him enabled the subjects to accomplish a piece of psychological work. This, of course, is an important part of the function of the analyst in psychoanalytic psychotherapy.

Impressive as the evident similarities between hypnotic and psychoanalytic treatment are, they focus attention upon the conspicuous differences. The first is the contrast between psychoanalytic transference and hypnotic rapport. In the cases here reported little is revealed concerning the patients' transference to the hypnotist except that they respond readily to his verbal suggestions[8]; yet this is not so surprising because he is careful to suggest only what they had previously instructed him to require them to do. That these subjects to this extent maintain the semblance of controlling the transference must be an important factor in reducing overt resistance. Much more important, however, is the fact that the unconscious motivations which arouse latent anxiety and conscious indecision remain unconscious. Noteworthy is the refusal of both subjects to tell the physician what goes on in their mind during the treatment. Patients seeking help for their difficulties of necessity emphasize their failures. This can lead in psychoanalysis to growing resentment through narcisstic injury if the analyst does not occasionally remind patients of their admirable qualities and inhibited abilities. Hypnotic technique does not require that patients communicate, or indeed become aware of primitive or infantile unconscious strivings that are alien to the conscious ego idea. Consequently the subjects are not stimulated to build up resistant and hostile attitudes because the therapy does not require that the unconscious be made conscious.

These two women apparently resolved a specific conflict without consciousness of the content of the conflict at any time during the treatment. There was no interpretation by the physician to influence what they thought. His manifest influence was purely the direction that they think. If this were the complete explanation, it would have vast implications. The hypnotic suggestion could be as unlimited as the total capacity of the patient to think. But this is to assume that the spoken word of the hypnotist constitutes his principal value as a factor influencing the patient. This conception must be incorrect. The physician, by his presence and all that he may represent in his patient's fantasy, must have a profound effect upon the patient, although it is not stated in words and perhaps not consciously recognized.[9]

The statement is of course made that patients like these were not really in great difficulty, that their plans were made, and that they merely resorted to hypnosis as a sort of ritual to bolster their actions; any abracadabra, provided it had local prestige, would have done as well. The same is said repeatedly of psychoanalysis, as in the instance of the woman who consulted a psychoanalyst and after the first interview left her engagement and wedding

rings in the analyst's lavatory. After the treatment she divorced her husband. It can be said that she had decided upon divorce and that the psychoanalytic treatment was something she used to rationalize the decision. This assertion fails to explain why the patient had to resort to such elaborate means of justifying her action. In this instance the patient's analysis revealed that she had married apparently as an act of obedience to her mother but in reality to escape from her mother. To be divorced had for her the meaning that she would have to resume her old relationship with her mother. When, through therapy, she had freed herself from an infantile dependence on her mother, she was able to proceed to terminate an unsatisfactory marriage. That these hypnotic patients did not reveal the nature of the factors which impeded their decisions to marry does not argue that there were none; nor does it prove that these factors were not thought out or altered in the unconscious.

There remains for discussion the value of psychotherapy which does not provide conscious insight. How important is the matter of making the unconscious conscious? Is symptomatic relief the criterion of successful psychotherapy? If patients should be made aware of previously unknown unconscious strivings, is it necessary that they know all of the steps through which their insight is achieved?

There is presented evidence that two patients were able through hypnosis to find psychotherapeutic relief from symptoms without conscious exploration of the unconscious sources of their conflicts. They were able to use the hypnotist to overcome their defenses and to do a piece of mental work. From two cases it is not safe to generalize, but it may be noted that in both instances the problem was one of inhibition in a woman who wished to marry and who had some difficulty in overcoming her doubts. Through the treatment both overcame the inhibition and became free to act. Nothing further was necessary to produce the desired result, marriage. Each of these women appears to have been a relatively normally functioning individual who wished only to overcome an intrapsychic obstacle to marriage and who showed a striking rigidity against self-revelation. This last characteristic may have been influenced by their familiarity with this form of therapy.[10] It further suggests that the method may have special usefulness for individuals who find it difficult or impossible to discuss their problems.

The problem presented by some analytic patients through their unwillingness to reveal some things of which they are quite conscious and their inability to become conscious of other things suggests the possibility of further study and experimentation to determine if there is a place for the use of hypnotic suggestion in the course of psychoanalytic therapy. Based upon this study, the thought recommends itself that, after a certain time in the analysis of patients who found it peculiarly difficult to make free associations, it might be suggested, with or without hypnosis, that these patients cease trying to talk and devote themselves to thinking the matter out in silence.[11] It would appear that if this method were used, it would require that the patients be given the further suggestion that they might, but certainly would not have to, report what had occurred to them during this silent thinking.[12] As indicated earlier in these remarks, this solution would not be an entirely new adventure but merely the recognition and utilization of a possibility which certain analytic patients have demonstrated on their own initiative and which these

hypnotic patients have carried much further. Hypnosis needs no longer to defend itself against the charge that it is "nothing but" suggestion. The method of hypnosis described presents a means of accomplishing vastly more in the way of psychic rehabilitation than the method of forcing upon a patient the hypnotist's ideas as to the way in which the patient should solve a conflict. This study of hypnotic psychotherapy points a way to research toward a therapy which may utilize all that has been learned both by the hypnotist and by the psychoanalyst.

---

[1]In the language of the unconscious the hypnotist is being instructed by the subject to order her to get married—the object of the treatment. [Ed.]

[2]This statement indicates that a disturbing sense of guilt about her relationship to her husband is becoming conscious. [Ed.]

[3]Two things may be noted here: (*1*) the subject's conviction that there would be an amnesia, and (*2*) that the wording of her request concerned only the answer and not the experience of reaching that answer; hence there would naturally be an amnesia for the experience and a knowledge only of the end result.

[4]Again, in the language of the unconscious, the hypnotist had been instructed by the subject to order her to have a baby and also to allow George to achieve some degree of parity with her in order "to ensure a reasonably good marital adjustment." She did both "in two years" and was then "able to show" the hypnotist that she had obeyed him. Cf. footnote [2]. [Ed.]

[5]No distinction is made here between unconscious and preconscious.

[6]These remarks are limited to the method used in these two cases.

[7] These two women were in states of transference to the hypnotist long before the treatment began. Some of the characteristics of this transference can be inferentially reconstructed. The hypnotist was a person in a position of authority to both. Both women were in states of discomforting ambivalence about marriage. Both had chosen partners who were their inferiors. The transference would seem to be a fantasy compromise in which these women were simultaneously identified with the therapist (both gave detailed peremptory orders as to how the treatment was to be carried out) and in states of submission to him (hypnotism). In the first case the submission was achieved by a device (amnesia); in the second, under protest. In both cases (explicitly stated in the second) the mixed transference to the therapist persisted long after the therapy and was presumably an important factor in the "adjustment" to marriage. [Ed.] Cf. de Saussure, Raymond:
Transference and animal magnetism. *The Psychoanalytic Quarterly*, 1943, XII, pp. 194-201.

[8] In discussions of the mechanism of hypnosis insufficient consideration is given to the possibility of *unspoken* suggestion by the hypnotist to the subject. Cf. de Saussure, Raymond: Transference and animal magnetism. *The Psychoanalytic Quarterly*, 1943, XII, pp. 199–201. [Ed.]

[9]The second subject, who seems less inhibited than the first, makes two statements that may provide a clue. Both women are ambivalent to the point of virtual paralysis about marriage. Both act out their hostility toward men by choosing inferior mates. The second subject says to the hypnotist: *"If there is to be any negative attitude toward our marriage, it is better for you to have it and not me ... just [you] take a ... negative attitude . . ."* The fantasy is clear: the hypnotist is magically to take over from her the disturbing hostility she has toward the man she has determined to marry; moreover she demands: *"I want you to keep that attitude for at least two years."* The marriage then is a *"reasonable marital adjustment"* achieved by an unresolved transference to the hypnotist, reinforced by letters and occasional visits. [Ed.]

[10]The first subject stated: “Watching your subjects has impressed me with the way the unconscious can handle problems a person doesn’t know he has.”

[11]This many analytic patients do at times without instruction from the analyst. [Ed.]

[12]Such a device could only be used in exceptional cases. As a rule it would vitiate the whole analytic process. Whenever most patients encountered a resistance, they would take this refuge. [Ed.]

Negation or Reversal of Legal Testimony

Milton H. Erickson

Reprinted with permission from the *Archives of Neurology and Psychiatry*, September 1938, Vol. 40, pp. 548-553.

The spontaneous, sincere, and apparently completely unmotivated negation, reversal, or alteration of condemnatory legal testimony previously given by credible witnesses constitutes a difficult and confusing problem. Although found more often by the psychiatrist than by the jurist, such change of testimony can, and not infrequently does, entail serious legal difficulties. Such alteration of testimony is characterized by a complete change in the beliefs and understandings of the witness, effected by unrecognized factors within the personality. It occurs most frequently among the witnesses who are themselves the injured parties and, hence, have presumably every reason for telling only the truth, and it develops usually in relation to crimes of a personally horrifying, traumatic, or repugnant character.

Because of the significance of this type of behavior psychiatrically as well as legally, the following material from the histories in two illustrative cases is presented as a clinical note for the purpose of directing attention to this phenomenon and to the need for an extensive analytic study of the psychological mechanisms and processes involved in these occurrences. Such an analytic study is not proposed in this report, since the data available are limited largely to the original situation and the final outcome. Hence, an effort will be made only to indicate briefly the various psychological factors and the psychic dynamisms contributing to the course of the developments.

The two case histories to be cited have been selected from among others because of the fully established facts of the original crimes, the detailed, factual, and fully corroborated testimony elicited initially, and the absence of external motivation in the eventual development of significant and completely contradictory attitudes and beliefs.

REPORT OF CASE

Case 1. This report centers around a police raid on a bawdy house. Arrests were made of two girl inmates aged 9 and 11 years, their parents, who were the proprietors, and twelve male patrons. Full confessions were obtained individually from all the prisoners, those of the adults corroborating fully the essentially identical accounts given by the two girls. In addition, medical examination of the girls disclosed numerous bruises and injuries, substantiating their account of beatings, and also revealed that they had been subjected to vaginal and rectal coitus and infected with syphilis and gonorrhea, both rectal and vaginal.

In the legal disposition of the case the two children were committed immediately to a custodial institution, where they were separated from each other according to the age grouping within the institution and kept for three months in "quarantine isolation" for treatment for the venereal infections.

At the suggestion of a colleague of wide experience in criminology who anticipated the eventual outcome, the two girls were interviewed separately, and an extensive account of the entire experience was obtained during the first week of their institutionalization, with three subsequent interviews thereafter at intervals of two months. The girls' stories were found to be essentially identical and to agree in full with the accounts obtained later from the adult offenders, as well as with the original court testimony.

During the first interview both girls were intensely desirous of securing a sympathetic listener, and both told the story readily, easily, and completely, manifesting much unhappiness over, and repugnance toward, their experiences. Also, they manifested intense fear and anxiety over their physical condition as well as strong specific resentments and hatreds toward their violators and a sense of great satisfaction over the punishments accorded the adults. At the same time it was noted that both girls recalled certain of their experiences with definitely pleasurable, though guilty, feelings and that they were quite shamefaced about their own active participation in certain aspects of their experiences.

A marked change in both girls was noted during the second interview. There was no longer a driving need to tell the story; emphasis was placed on the venereal infection, with the complaints centering around the inconveniences and the annoyance occasioned by the quarantine and therapy, and little mention was made of their former fears of what the disease would do to them. Many details of the original accounts were omitted; others were surprisingly vague or minimized. There was a general tendency to contradict and deny previous statements. Close questioning on a few items disclosed definite reluctance, and even difficulty, in admitting certain facts, and the repugnance previously noted had been transformed into new resentments, especially in connection with the rectal coition. The resentments and hatreds noted previously were markedly increased by the addition of resentments concerning their immediate situation.

At the time of the third interview they had made good recovery from the gonorrheal infection and were much better adjusted to the institution. Although willing and ready to talk, they seemed to be interested only in immediate matters. Questioning about their past experience elicited an utterly inadequate account, in which even major details were denied or greatly minimized. Rectal coitus was emphatically and resentfully denied by both. There were flat denials of ever having been nude or of having danced exhibitionistically, and they had forgotten the names of half the men. There were many vague statements of "Ma didn't like those things" and "Ma wouldn't let anybody do those things." A few similar statements were made concerning the father. There was a tendency to declare certain of the more offensive details to be "lies" told by one of the men who had been particularly brutal. Furthermore, their reluctance or difficulty in giving any details of their story seemed to be greatly increased. Their affective reaction seemed to be

one entirely of distaste and repugnance to the whole experience, and there was no evidence of pleasurable recollections; rather, there seemed to be an element of sadness and grief. Even the question of therapy for the venereal infections was casually glossed over as a routine health measure peculiar to their present situation, and all the earlier anxiety centering around their physical condition had disappeared. Likewise, the hate reactions centering around the original experience now seemed to be limited to mild resentment over their own imprisonment. The former sense of satisfaction over the legal punishment of the adults had disappeared except for a feeling of pleasure that the man they now accused of lying was serving time.

The final interview was conducted six months after the first. A complete change in attitude was apparent in both girls, though more marked in the younger. Strong resentment was expressed over my interest in the story, and no information was given spontaneously except the emphatic, inclusive declaration that it was "all a lot of nasty lies." A warm defense was given of both parents. The authorities were harshly criticized as unwelcome intruders into a private home, and the whole experience was minimized into the statement that "some bad men came to the house, but nothing bad happened." This statement was persisted in with such obvious sincerity and belief that resort was had to sympathetic questioning concerning the "lies" that had been told. After their confidence had been won with some difficulty, both recounted their original story in fair detail but branded each item as a "regular lie" told by various of the men while in court. Furthermore, they insisted sincerely that they had consistently told me the entire story as a "bunch of lies" maliciously concocted by some men who had had their parents arrested and imprisoned for illegal traffic in liquor. Even close questioning about the injuries sustained and venereal infection elicited either resentful denials or trivial explanations, and they seemed to have no real recollection of the whole experience as an actual happening in their own lives. At no time could their sincerity or their full belief in their statements be doubted.

Case 2. This report concerns a young man on parole from a penal institution. After stealing an automobile, he took a young woman for a drive, their intention being to spend the night at a roadhouse of ill repute. He did not disclose to her the immediate circumstances, although she was aware of his criminal history and legal status. During the course of the drive, as a result of recklessness, the car overturned, pinning the young woman beneath it, and burst into flames. The man freed himself but made no effort to rescue his companion, instead fleeing from the scene. Passing motorists rescued the girl, but not until she had been severely burned, in addition to receiving other serious injuries in the accident. The man was apprehended, and at the trial the girl, with much bitterness and hatred, and the motorists testified fully as to the facts, the truth of which the man confessed. About eight months later, without there having been intercession of any sort, the girl endeavored to secure a retrial of the case on the grounds that she had given false and mistaken testimony. The man, when interviewed by me, declared, "She's nuts! She told the truth the first time," and explained further that the relatively short sentence he had received did not warrant his undergoing the anxiety of a retrial, since his indisputable guilt in certain aspects of the case might result in a longer sentence.

The girl, when interviewed by me, was obviously sincere and believed fully that the man had exerted every effort possible to rescue her, giving full details of his endeavors by a process of retrospective falsification and misconstruction. She explained that her intense suffering and the long months of confinement during her hospitalization had made her realize how false her original account had been, since "no human being would do such a thing nor could anybody endure being so treated." She elaborated in detail on how one would feel if deserted, as she was said to have been, and declared that such an experience would be utterly "intolerable" and that one "could only imagine it but could not possibly endure it." When confronted by each item of her original testimony, she misconstrued it so logically and exculpated herself for her "misstatements" and "intentional malice" so contritely on the grounds of the shock and pain she had suffered that she was most convincing, although psychiatrically the inferences to be drawn were quite otherwise. Even the prisoner's direct admission of the truth of her original account was casually disregarded. She insisted rather compulsively that something be done to prove legally that the event as described had never taken place, since her previous testimony had been used to prove that it was an actual occurrence. When, however, it was pointed out that the sentence received by the man was well within the statutory limits for automobile theft and violation of parole and that his criminal negligence toward her presumably had not been considered in the passing of the sentence, she seemed much relieved, considered the situation as a closed incident, and actually continued so to regard it. Apparently she was satisfied that no wrong had been occasioned by her "misstatements," and hence that her "mistaken" testimony had never actually won credence, which, in turn, implied for her the unreality of the original experience.

COMMENT

What might have been the outcome had these cases been again brought into court is only speculative. General experience, however, in similar cases suggests the not unusual development of "reasonable doubt" resulting from the recanting of testimony previously given by an otherwise credible witness and a consequent acquittal because of failure to prove again the guilt originally established. Whether any legal provisions can be made for "witness unreliability" of this character is a serious question, but at least recognition should be accorded to the possibility and the frequency of such psychological behavior, as a measure of lessening the confusion occasioned by it.

Psychiatrically, any discussion of these two, or rather three, cases, since the two sisters were entirely independent of one another in the development of their reactions to the situation, constitutes a difficult problem. To elucidate the various psychological processes entering into the final outcome would necessarily be so speculative as to be unwarranted. A day-by-day account of a highly detailed character would be needed to trace the steps by which the alteration of belief was achieved, and such a measure in itself might serve to bring about an entirely different end result. Also, the data at hand in these cases are insufficient to permit more than a general consideration of the problem represented.

In this regard, however, attention may be directed to the fact that the experiences of the three girls are essentially identical in psychological structure and represent the not

unusual legal situation in which a female, after sexual usage, testifies first against the offending male and then, after a period of suffering, reverses her beliefs and attitudes to testify sincerely in his behalf. This identity is manifest primarily in: (*1*) the highly pleasurable, exciting initial development of the experience; (*2*) the sudden complete transformation of this pleasurable situation into one of extreme terror, physical helplessness, and pain, and (*3*) the final evolution into a situation of long-continued suffering and general helplessness.

In each instance certain psychological elements leading to the final outcome are to be found in common, and these may be summarized as:

1. General setting at defiance of authority and association with, and participation in, forbidden things.
2. A primary sexual relationship, illicit in character and marked by guilty, but pleasurable, participation.
3. Utilization of the female simply as an sexual instrument, without regard for an emotional return to her.
4. Brutality—direct, sadistic and physical in the first case, and indirect and essentially psychic in the second, despite the physical aspects.
5. Infliction of serious somatic injuries serving to constitute both an immediate physical threat and a long-continuing threat of future physical destruction.
6. Suffering experienced in common with the offending male, originating from common guilt and characterized for all parties by loss of freedom, personal helplessness, stigmatization, and uncertainty concerning the future.
7. Intensely bitter, resentful public denunciation of the offender by the victim, with self-exculpation and overemphasis on the other's guilt.

That these common elements were the essential dynamic forces in the negation of the original testimony can only be presumed, but unquestionably they played a significant role in the course of events. The details of the processes by which they served their purposes are a problem that must be left to more extensive studies, since this report can direct attention only to the original situation and the final significant outcome, with some suggestions regarding the processes involved in these instances. Further studies of an analytic character should serve to clarify more fully the psychological processes of retrospective falsification, suppression and repression, memory distortion, affect displacement and substitution, compensatory reactions, guilt reactions, self-exculpation, denial of reality, and wishful thinking, which are shown to a significant degree in the histories in these cases.

In this regard an analogy may be drawn between the behavior reported in these cases and that shown in daily routine life in the repression, faulty recall, and even distortion of unpleasant, disagreeable experiences, since essentially the same dynamisms are operative in both situations, though to different degrees. The more extreme character of the reactions in these cases as compared with that found in ordinary behavior may be attributed to the extreme character of these experiences.

In all probability the initial psychic dynamism in these cases, as in instances occurring in daily life, was the primary repression of the unpleasant affects arising not only from the traumatic aspects of the experience but from the girls' own guilty pleasurable participation. Contributory to this was the peculiar situation in court, in which all three girls, in telling their stories and seeking to affix blame on their aggressors, were forced, psychologically as well as legally, to disclose their own guilty participation. Thus, the two little girls in telling of their nude dancing, wine drinking, singing, and playing with the genitals of the men, and the older girl in describing her intention of spending a night of illicit love-making, were declaring in essence: "All this I was doing to make my aggressor happy, and see what he has done to me." Yet by thus emphasizing the guilt of the men, the girls placed themselves in a definitely humiliating position, thereby giving rise to a compelling need for self-exculpation. This could be possible only in a totally different situation, since self-exculpation could be achieved only by the process of exculpation of others. Hence, repression of self-condemnatory feelings would necessitate repression of other related aspects and would require a total reorganization and reconstruction of the experience in a form more assimilable to the personality.

Also to be considered in this regard are the loss of physical intactness, the infections of long duration and the ever-recurring physical assault involved in the intravenous and intramuscular therapy for the two little girls, and the facial burns, the broken ribs, and the injured arm and legs threatening to disfigure the older girl. These physically traumatic aspects of the experiences gave rise to an intense wish that these things would not and could not be so, that things would change completely. In response to this great need there developed the psychological processes by which, step by step, there could be utilization of repressions, overemphasis of various elements in the experience and distortion of others, until finally there had been achieved a complete reconstruction of the entire experience in a form which could meet the compelling needs of the personality. In the case of the two children one step in this process is clearly illustrated by their statement, "Ma didn't like those things," which progressed to "Ma wouldn't let those things happen."

Thus, shifting of responsibility to their mother for the realities of the occurrence was achieved, enabling them to avoid any necessity for relying on, or even utilizing, their knowledge of the actualities of their experience.

Similarly, the older girl summarized her psychological treatment of the experience with great clarity by declaring it to be "utterly intolerable, one that could be imagined but not endured." By regarding the experience as imaginable but unendurable, she could give herself free rein to regard it as imaginary, utilizing the fact of her survival as proof of its imaginary character. But the fallaciousness of this apparently gave rise to her compulsive need to secure proof from external forces, manifested in her seeking a retrial for the purpose of establishing by formal legal processes the unreality of the desertion. Essentially, this constituted the same process of shifting responsibility for the realities of the experience as was employed by the two children in placing their reliance on their mother.

Thus, her relief on being shown conclusively that the man had been punished only for offenses which she could readily recognize as real and which were not related to her becomes easily comprehensible. The prison sentence proved conclusively to her that the realities of the original situation were only those of automobile theft, violation of parole, and an unavoidable accident, for which no one could be held responsible.

That many considerations other than those discussed entered into the final outcome in these cases is readily admitted, but the deficiencies of the data render further elaboration overspeculative.

Permanent Relief of an Obsessional Phobia By Means of Communications With an Unsuspected Dual Personality

Milton H. Erickson and Lawrence S. Kubie

Reprinted with permission from *The Psychoanalytic Quarterly*, October 1939, Vol. VIII, No. 4.

For over a year a 20-year-old college girl—quiet, reserved, and well poised—had suffered secretly from constantly recurring obsessive fears that the icebox, kitchen, college laboratory, and locker doors had been left open. These fears were always accompanied by a compulsive, often uncontrollable need to examine and reexamine the doors to make certain they were properly closed. She awoke in the night to make repeated trips to the kitchen in order to reassure herself, but this failed to resolve her incessant doubts about the doors. An additional but seemingly unrelated symptom was an intense hatred of cats, which she considered "horrid, repulsive things." This feeling she attributed to an early experience of watching "an awful cat eating some nice pretty little baby robins." It was learned that she enjoyed making pets of laboratory animals such as white rats and guinea pigs despite obsessive fears that she might fail to close the door of the animal room. At the time the patient was seen, her difficulty was becoming more inclusive, and she was beginning to have fleeting recurring doubts about many other doors, although not to a troublesome degree.

I. INDUCTION OF CATALEPSY AND OF HAND LEVITATION UNDER HYPNOSIS AND SUGGESTION OF NAME FOR HYPNOTIC PERSONALITY FOR PURPOSE OF CLASSROOM DEMONSTRATIONS

Without any conscious or deliberate therapeutic intent on the part either of the student or of the investigator, this 20-year-old student of psychology (who will be called "Miss Damon") volunteered to serve as the subject of some experiments in hypnotism. A trance induced at the first session was characterized by a marked degree of amnesia, ready hand levitation, and profound catalepsy. To demonstrate suggestibility a posthypnotic suggestion was given that in the trance her name would be "Miss Brown."

II. PERSISTING FASCINATION WITH LEVITATION AND HORROR OVER CATALEPSY

The next day Miss Damon sat about the office entirely neglectful of her work and absorbed in inducing hand levitation and arm catalepsy by autosuggestion. She would observe these combined phenomena briefly and then would cause them both to disappear by further autosuggestions. This was repeated over and over throughout the day in a seemingly compulsive fashion. It was noted that while suggesting to herself either the

lifting or the lowering of her hands, she would repeatedly ask such questions as, "Do you see my hand move? How do you explain it? What does it mean? What is happening? Have you ever had such an experience? What psychological and neurological processes are involved? Isn't it funny? Isn't it queer? Isn't it interesting? I'm so curious, I'm just fascinated by it."

Any replies to these comments went unheeded; she seemed unaware of what she was saying.

While inducing *levitation* her facial expression was one of intense, lively, pleased interest; but as her hand or hands reached the level of her shoulders and she began to develop an apparent catalepsy, her attitude would change markedly. A facial expression would appear which one could characterize only as "dissociated." She seemed to lose contact with her surroundings and to become unresponsive to verbal or tactile stimuli. In addition to the expression of dissociation there appeared a look of intense terror, with pallor, dilated pupils, deep, labored, and irregular respiration, a slow, irregular pulse, and marked tension and rigidity of her whole body. Soon these manifestations would disappear, quickly to be replaced by the previous look of eager, amused interest; whereupon she would at once begin suggesting to herself a lowering of her hand and a disappearance of the catalepsy.

Later that day she was asked why she was so interested in catalepsy and levitation, but she could give only such rationalizations as were based on her psychological training and interests. She showed no realization that more might be involved, except for a joking remark *that her extremely low salary warranted her getting whatever experience she could*.

The next day the same behavior began anew. After confirming the observations of the previous day, the suggestion was offered that she might like to try more complex coordinated movements. She was interested at once, and the suggestion was given that she try automatic writing, to which she agreed eagerly while expressing many doubts about her capacity to do so.

III. INVESTIGATION THROUGH AUTOMATIC WRITING, LEADING TO ATTACK OF ACUTE ANXIETY

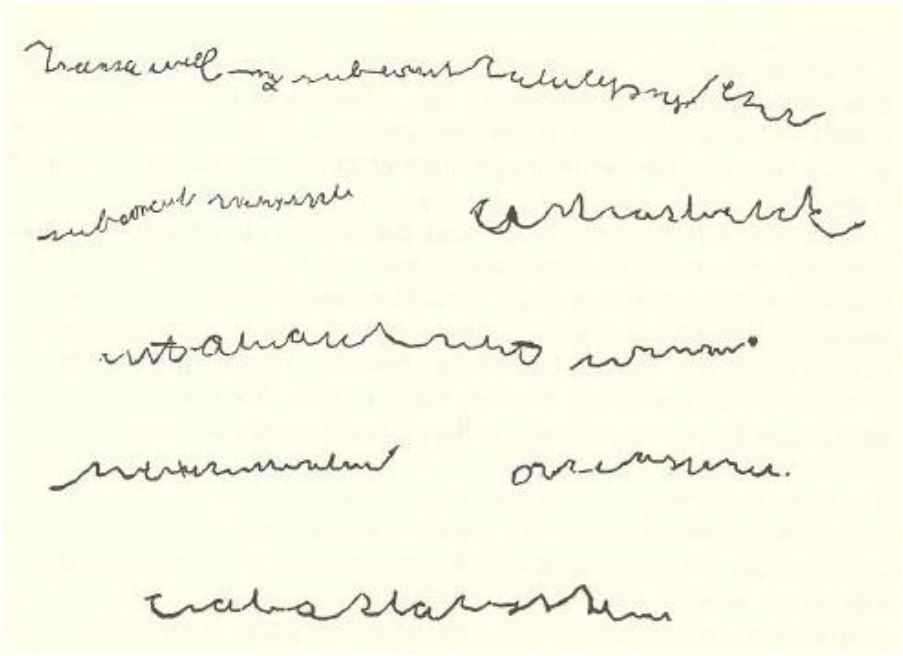
After placing her in a suitable position to distract her attention completely from the proceedings, the subject was instructed to read silently an article on gestalt psychology and to prepare a mental summary of it, ignoring as she did so anything that might be said or that might occur.

When she had become absorbed in the reading, hand levitation was suggested. She was then instructed to pick up a pencil and *to write the reason for her interest in hand levitation and in catalepsy*. This last instruction was repeated several times, and in a short time she began to write without any interruption of her reading. Toward the end of the writing she developed body tremors, marked generalized physical tension, deep labored

respiration, and pupillary dilation, and her reading seemed to become laborious and difficult. As she completed the writing, her face was pale and expressed intense terror. She dropped the pencil and explained that she suddenly felt "terribly afraid" and that she wanted to cry but could not understand why this was so since there was nothing to distress her in what she had been *reading*.

With these words her anxiety seemed to disappear completely, to be replaced by an air of eager, puzzled interest; she made no further reference to her emotional distress, apparently forgetting it completely. Immediate questions showed that she was able to give an adequate summary of what she had read. Then she was reminded of the task that had been given her. She inquired whether or not she had written anything and when shown her writing manifested first pleasure and then disappointment. The writing was illegible, scrawling, and even difficult to recognize as such. She studied it carefully, however, and succeeded in deciphering the first word as *trains*, although a careful study of the word and the observation of the movements of her pencil as she wrote indicated that it was *trance*.

Then she was asked to repeat the writing under the same conditions as before. Essentially similar results and behavior were obtained except that this time, instead of dropping the pencil, she continued to make writing movements in the air while expressing verbally her feeling of being "awful scared." Again, immediately upon verbalizing her emotional distress she seemed to forget it and interested herself first in summarizing what she had read and then in attempting to understand her writing. Accordingly she was asked to decipher what she had written, and while she was absorbed in this, low-voiced suggestions were made "to write all the rest which is not yet written on paper." Apparently without her knowledge she resumed the automatic writing in lines consisting of single words or short phrases, one of which was followed by an emphatic period. The completed writing is shown in the following illustration.



As she wrote, she seemed to the observer to be breaking her message into fragments, writing a little here, moving her hands to another part of the sheet, writing a bit more, then apparently inserting a part between two previously written phrases. Also there was a tendency for her hand to move back and forth over the completed writing, arousing in the observer the suspicion that she was really counting or checking on what had already been written. Subsequently this proved to have been what she was doing: she had rewritten parts because of a persisting dissatisfaction which led her to make repeated changes. The emphatic period was placed only after her hand had wandered back and forth over the page as if searching for the right phrase. It was found later that she had placed a second period after another phrase.

It was discovered ultimately that the writing constituted a complete production, composed of separate but related elements some of which were partial reduplications and rearrangements of various fragments.

Because of her unusual reaction to hand levitation and catalepsy, because of the strong affects of which she was only slightly aware, and finally because of the peculiar character of her automatic writing and of the concomitant conduct, the assumption was made that the writing represented significant material and that unconsciously she was seeking aid from the investigator. It was decided therefore to pursue the problem further. The investigation was carried on jointly by M.H.E., an assistant who served chiefly as a necessary conversational foil, a secretary who took complete notes of everything said and done, and the subject herself.

Because of the peculiar fashion in which the material was presented, the method of presentation itself constituting a significant part of the problem, no orderly or systematic

procedure of investigation could be followed. We were forced rather to proceed by trial and error, attempting and abandoning many leads in the effort to decipher the writing.

More than 12 hours of almost continuous work were required to solve the problem, and all progress was achieved in isolated fragments. No attempt will be made to tell a strictly chronological story of the work, but enough material will be given to show the main steps which led up to the solution of the problem.

IV. THE DISCOVERY OF THE DUAL PERSONALITY

The first essential step was achieved at the beginning of the investigation and was confirmed throughout: the identification of a second and unknown personality in the subject. This discovery was made in the following fashion.

After the subject's hand had completed the last bit of automatic writing and had placed the emphatic period, the investigator quietly slipped the sheet of paper from under her hand, leaving a fresh one in its place with her hand still holding the pencil. This was done without attracting her attention. She continued her task of deciphering, finally declaring aloud that she could make out only the words *trance, will, my, catalepsy,* and *ever,* and expressed much amusement over her inability to read more, asking laughingly, "Did I really write that nonsense?" Both the investigator and his assistant replied affirmatively and in the same amused tone. At the moment the subject was leaning forward over the desk, and her hand was out of range of her peripheral vision. As the verbal reply was given to her question, her hand was observed to write "No," of which Miss Damon remained unaware. Immediately the investigator asked, as if speaking directly to the subject, "What do you mean?" and while Miss Damon puzzled over what he meant, her hand wrote, "Can't." Again speaking as if to Miss Damon, the question was asked, "Why?", to which her hand replied, "Damon doesn't know these things."

There followed a series of questions, seemingly directed to the subject, who was merely bewildered and confused because of their unintelligibility to her while her hand wrote appropriate replies. These, with their answers, will be quoted verbatim to show the definition of this second personality. The quotations continue from the last question and reply cited above. The questions were asked orally, the replies given by automatic writing.

Q. Why?

A. Don't know, afraid to know.

Q. Who?

A. D [Damon].

Q. Who does?

A. Me.

Q. Me?

A. Brown.

Q. Who?

A. Me—Brown—B.

Q. Explain.

A. D is D, B is B.

Q. B know D?

A. Yes.

Q. D know B?

A. No. No.

Q. B part of D?

A. No. B is B; D is D.

Q. Can I talk to B?

A. Are!

Q. Talk to D?

A. Want to. [If you want to.]

Q. How long have you been B?

A. Always.

Q. What do you want?

A. Help D.

Q. Why?

A. D afraid.

Q. Do you know what D is afraid of?

A. Yes; D no.

Q. Why?

A. D afraid, forgot, don't want to know.

Q. Think D should?

A. Yes, yes, yes.

Q. You know what it is?

A. Yes.

Q. Why don't you tell D?

A. Can't, can't.

Q. Why?

A. D afraid, afraid.

Q. And you?

A. Afraid a little, not so much.

At this point Miss Damon interrupted to declare her utter bewilderment over the investigator's fragmentary remarks, and demanded an explanation.

Q. Shall I tell her?

A. Sure; she don't know.

The secretary then read the questions, while her answers were shown to Miss Damon. She attended carefully with a look of increasing understanding, finally remarking, "Why that really must mean I have a dual personality," and then was greatly startled that her hand emphatically wrote, "Right." Recovering her poise, Miss Damon asked, "Can I talk to you?" "Sure." "Can you talk to me?" "Yes." "Is your name really Brown?" "Yes." "What is your full name?" "Jane Brown." Later it was found that *Jane* signified identification with a favorite childhood literary character, and that Jane was really the important name, the *Brown* having evidently been added to it at the time of the first hypnotic demonstration described above.

Miss Damon then reviewed the questions and said musingly, "You want to help me, Brownie?" "Yes, Erickson ask, ask, ask." Further similar questions by Miss Damon elicited variations of the same cryptic answer of "Erickson ask," and a stubborn refusal to elaborate.

Throughout the investigation the Brown personality was found to be literally a separate, well-organized entity, completely maintaining its own identity, and differentiating to a fine degree between Brown and Damon. Brown was capable of entering into spirited arguments with the investigator, his assistant, and with Miss Damon, and of expressing ideas entirely at variance with those of Miss Damon. She could know before Damon did what Damon would say or think, and contributed thoughts to Miss Damon in a manner quite as psychotic patients bring up autochthonous thoughts. She would interrupt an attempted explanation of Miss Damon's by writing "Wrong," and would respond to stimuli and cues which Miss Damon either overlooked completely or misunderstood. In fact she so impressed her personality upon those in the office that automatically she was regarded by the entire group as a distinct personality among them. Nor was Brown limited just to the problems at hand. She would enter readily into conversations on many other topics, often resorting to this in an effort to distract the investigator from his efforts. In addition Brown was possessed of a definite sense of personal pride; on two occasions she resented derogatory remarks Damon made about her, and thereupon refused to write anything more except "Won't" until Damon apologized. Brown frequently became impatient and irritable with the investigator because of his inability to comprehend some of her cryptic replies; and at such times she would unhesitatingly and unsparingly denounce him as "dumb."

A characteristic of Brown's automatic script was its economy. A single letter was written whenever possible in place of a word, or a word for a phrase; abbreviations, phonetic spellings, condensations, puns, and peculiar twists of meaning were all employed, at first to a slight degree but to a greater and greater degree as the investigation progressed. Naturally this rendered the investigator's task correspondingly difficult. It was necessary to discover by appropriate questions that Damon, Brown, and Erickson were all designated by their initials; "help" meant "B wants to help D" or "E should help D"; "W.Y." meant "Will you"; "No" sometimes meant *no* and sometimes *know*, an abbreviation of "Brown does know" or some similar phrase; "subconsement" was the condensation of "*subitement*," "subsequent" and "consequent"; and "Yo" was found to be neither *yes* or *no*, but "I don't know." *No* written from left to right meant "no," but written from right to left signified a "no" reversed, which is "yes."[1] In these respects Brown's language was much like the language of dreams and constitutes in fact a demonstration of the validity of what Freud has written about the use of condensation, elision, reversal of sense, and duality of meaning in the language of dreams.

Another method of abbreviation was the use of a vertical pencil mark to mean "Yes," a horizontal one to mean "No," and an oblique line to mean

I don't know." Also,  signified "First part 'no,' second part yes,'" while  had the opposite meaning. Similarly  ,  ,  , signified "First part 'I don't know,' second part 'yes,'" etc.

In addition to these economies Brown utilized innumerable cues and signs to communicate her meaning, which often were exceedingly complicated and abstruse in character. For example, Brown was asked, "Can we get the information from Damon?" Slowly, hesitatingly, Brown moved her hand about the page as if searching for a place to write, then turned the page over and wrote quickly, "Yes." Since this answer was contradictory to previous replies, the investigator replied, "I don't understand," eliciting the comment, "Dumb." Asked "Why," the answer "Saw" was obtained. Much effort finally made it clear that the investigator had observed that before answering the question she had reversed the paper which signified that the question too had been reversed. Asked, "Then the question you really answered yes to was what?" "From Brown."

Another cue given repeatedly throughout the investigation was a very short oblique line made at random on the paper which looked as if she had attempted to write but had become blocked in her effort. Later study of Brown's productions disclosed the line to be an accent mark by which Brown was indicating that a word the investigator had thought to identify as "consequent," and which Brown had affirmed to be both the right word and rightly spelled and, with equal emphasis, the wrong word and wrongly spelled, was really the French word *consequent*. Brown confirmed this guess, and when the investigator musingly remarked, "Well, what do you think of that?" Brown wrote, "Dumb."

Other cues were writing on a fresh sheet to signify a shift to a new aspect of the problem; writing over previous writing; widely separating various parts of a single written response; periods placed within a phrase or remote from a phrase; dropping the pencil with the point or the eraser in direct relationship to a word; peculiar contradictory answers to the same question; counting the letters in a word or the words in a sentence and giving different totals upon repetition of the counts; misspellings to direct attention to a word, and many others, many of which at first either were overlooked completely or were misunderstood.

Brown's attitude toward the investigation was consistent throughout and was highly significant. She asserted emphatically that she alone knew the content of the writing, that Miss Damon did not know, and because of fear could not know; that *Miss Damon needed help which must be given in a way known only to Brown*, and that the investigator's function was primarily the assumption of a very special kind of "responsibility" that permitted Brown to give assistance only in response to direct and specific questions, with the reservation that Brown might accept or reject or postpone the questions as she felt to be best. Brown was found to maintain a highly protective attitude toward Damon, shielding her, demanding special consideration for her, offering encouragement, distracting her attention, deliberately deceiving her, and employing various other protective measures.

Perhaps the best portrayal of Brown's attitude may be found in the following quotations from her answers:

"Writing means a lot, B know it all, D don't, can't, afraid, forgot something a long time ago, D can't remember because she never knew some of it, she just thought she did but she didn't. B afraid to tell D, D get awful scared, afraid, cry. B don't like D scared, won't let her be scared, won't let her feel bad. B can't tell D, won't tell D. D must know. D must have help. B need help. Erickson ask. Ask right question, B tell Erickson right answer, wrong question, wrong answer. Right question only right question. B just answer, not tell, won't tell because D afraid, awful afraid. Erickson ask, ask, ask. Brown answer, not tell, question answer, not tell, question, answer, that help. B answer but not too fast because D get scared, cry, sick. B tell truth, all truth, Erickson not understand, don't understand because he don't know. B trying to tell, Erickson don't ask right questions. Ask, ask, ask. B can't tell, won't tell. B a little afraid; B only answer. Ask, ask."

Repeated and indirect attempts were made to induce Brown to help frame questions, but her reply was always, "Erickson ask, B answer; right question right answer, wrong question wrong answer."

Essentially, therefore, the task of the investigator became an active search for information forthcoming only when a question was found which hit the nail precisely on the head and which could be answered with approximately one word. The cues given by Brown seemed designed in part to provoke and compel further aggressive interrogations. On the other hand, in conversations which touched upon any other topic except the immediate problem, Brown was under no such restrictions. In addition, Brown in these unrelated conversations was at liberty to drop innumerable hints and clues, most of which were overlooked by the investigator.

As these various aspects of the two personalities, their attitudes to the questioner and their methods of yielding information gradually became clearer, the task of discovering the meaning of the writing became relatively easier.

At first the subject was told to write and rewrite her message more and more legibly with each repetition. This was unsuccessful whether the repetitions were of phrases, words, syllables, or letters. An attempt to have the message written with synonyms for the words or merely substituting in other words, so that the investigator could at least determine how many words were involved, was met by a flat refusal: "Won't."

A fresh approach was then begun, and Brown was asked, "Is that sentence correct and complete?" "No." Further extensive questioning finally yielded the cue, "Wrong question." After much futile questioning it was learned that the writing constituted two sentences, hence the investigator should have said *sentences* rather than *sentence*. These sentences, B replied, were abbreviated in form, and the words were either abbreviated or condensed; but B added the reassurance, "All there; B know; B understand; E ask right question; B tell." Next it was learned that the first sentence contained 7, 8, or 9 words; 7

and 8 were stated emphatically, 9 somewhat dubiously; similarly, B indicated that the second sentence contained 13, 14, or 16 words; 13 and14 emphatically, 16 dubiously. Making the immediate assumption that some of the words were repeated or that some could be broken up into two words, Brown was asked to point to the words as she counted, but she replied, "Won't, not yet." To direct questions concerning these possibilities she replied, "Won't tell." When it was pointed out to her that her refusal to answer these questions was tantamount to admitting that some of the words were either repeated or could be broken into two, Brown conceded, "Maybe," whereupon Miss Damon, who at the same moment was conversing with the investigator's assistant about a recent book, suddenly stammered, complained of feeling frightened, and then continued her conversation, again appearing to repress all knowledge of her emotional disturbance, just as she had done with the panic which occurred during her first automatic writing.

The implication of Miss Damon's behavior was mentioned to Brown, who replied, "Maybe. Not tell too fast yet."

In response to further questioning the words *trance, will, my, catalepsy, every*, and *ever* were deciphered and confirmed and were placed in order in the sentences as follows:

	Word	***Sentence***
Trance	**1**	**1**
Will	**2**	**1**
My	**3**	**1**
Catalepsy	**10, 11, or 12**	**1 and 2 counted in one sentence**
Every	**8, 9, or 10**	**1 and 2 counted in one sentence**
Ever	**13 or 14**	**1 and 2 counted in one sentence**

(A fuller explanation of this count must be reserved for the end of the paper.) Further questioning proved fruitless, nor could any aid be secured in further deciphering. Brown simply replied "Won't" to all inquiries.

A fresh start was made by attempting to have Miss Damon look at various parts of the writing and give free associations; but this was interrupted at once by Brown writing, "No, no," and a complete blocking of Miss Damon's efforts by a failure on her part to understand what was desired. This is an interesting parallel to the behavior of those patients in analysis who listen with earnest attention to repeated explanations of what they are to do, but seem incapable ever of digesting what is told them sufficiently to produce any free associations at all. In the case of Brown and Miss Damon it was as if Brown protectingly told Damon when she could think safely and similarly had the power to forbid her to think and thus arrest her intellectual process.

Since Miss Damon knew the Morse code, it was suggested that her habit of drumming with her fingers be employed by Brown to tap out the message. S. O. S., which was obtained repeatedly, meant, Brown explained, "E help, ask."

Efforts then were made to identify the words simply as parts of speech or to identify individual letters as such without regard to their positions in sentences or words. To these attempts confusing, contradictory, and conflicting answers were made which Brown

finally summarized as, “Can’t; just can’t; not right questions,” but no suggestions could be obtained from her as to how the right questions might be asked.

At this point Brown was asked if the investigator might continue his attempts to secure individual words, and she replied, “Try.” Accordingly, Brown was instructed to draw two horizontal lines, one to symbolize the most meaningful word in the message and the other the least meaningful, and to draw them any length she wished, equal or unequal, since the lines themselves would have no meaning.

Brown drew two lines, one about twice the length of the other. In drawing the first line, however, Brown was seen to pause momentarily at about the middle, while the second line was drawn in a single stroke. The investigator took this for a cue and immediately extended his pen as if to point to the first line, but actually in doing so covered up the last half of the line. As this was done, Miss Damon, who had been commenting in an amused fashion to the assistant about the investigator’s absorption in asking foolish questions, remarked that he was probably too absorbed to notice the unpleasant smell of the cigarette he had carelessly dropped in the ashtray. As the investigator with due apologies extinguished the butt, Brown was seen to push aside the sheet of paper bearing the lines. Again when asked if the investigator might continue his questioning, Brown replied, “Ask, try.” Accordingly, her attention was called to the break in drawing the line, and she was asked if this meant a word formed from two words. Despite many variations in the form of the question no answer was obtained except the statement that the right question had not been asked. Finally, the investigator declared emphatically, “That broken line *does* mean two words in the form of one, doesn’t it?” “Yes.” “And the word *smell* has something to do with the first part, hasn’t it?” “No.” “You mean that it may or may not be unpleasant?” “Yes.”

Here Brown shifted her hand to another part of the sheet, while Miss Damon declared that she had suddenly become afraid and wanted to cry. Brown wrote, “Help D,” and when this was interpreted to mean “Comfort D,” Brown wrote, “Right.” Miss Damon was immediately drawn by the investigator into a discussion of his activities and developed a lively interest in this until shown the broken line, whereupon she again manifested fright, said she could not understand her “funny feelings,” and proceeded to laugh them off.

At once Brown wrote, “Feel better, ask,” and then wrote “Con,” a syllable she had previously written but declared wrong. Extensive questioning followed in which Miss Damon participated actively, with the words *subconsciously, subsequent, consequent*, and *consequences* coming out, all of which Brown declared to be both right and wrong. Miss Damon impatiently denounced Brown as “crazy” and “a liar.” At this Brown refused to write anything except “Won’t.” Finally in response to the question why, Brown replied, “Angry.” As Miss Damon read this, she flushed deeply and explained with embarrassment, “Brown wants me to apologize,” and in a shamefaced manner said, “I’m sorry, Brown.” Inquiry by the investigator elicited the fact that Brown accepted the apology and would now write again, and spontaneously she wrote “E, E, E,” as if addressing the investigator directly while Miss Damon conversed humorously with the assistant about the apology and her “misbehavior.” The investigator continued with

"What," to which Brown replied "Sleep." "Why?" "Interferes." As Brown wrote this last word, Miss Damon was still conversing with the assistant and had not been aware of Brown's writing, but as this word was completed, Miss Damon declared, "Why, Brown is going to punish me." Immediate questioning of Miss Damon showed that she had only the "feeling" that she was to be punished and that she could offer no explanation for it unless it was that her apology was not properly offered. While she was giving this explanation, Brown wrote, "E, waiting." Accepting the implied rebuke, the investigator hypnotized Miss Damon, thus removing her as a source of interference.

Thereupon more rapid progress was made in relation to the words which had been obtained previously. Brown eliminated the word *subconscious* and declared that *subsequent* was both the right word correctly spelled, and the wrong word incorrectly spelled. At this point Miss Damon awakened in a state of terror, recovered rapidly, and began talking at random on various topics, mentioning among other things that her grandfather was a French Canadian. Shortly after this Brown wrote "Sleep," and the investigator obeyed the command and put Miss Damon to sleep again. Inquiry disclosed that French words were involved, and the elusive word might be *subsement* or *consequent* or *something like*. While this information was being obtained, Miss Damon repeatedly awakened and fell asleep again, showing intense terror each time she wakened. Questioned about Miss Damon, Brown explained that nothing could be done to help her, that it was necessary for her to experience these fits of terror but that she would feel better as soon as she had felt all of the terror which was connected with the word under examination. All of this information was volunteered by Brown, the investigator studiously avoiding any leading question. Finally Miss Damon awakened comfortably and asked what was going on. Brown wrote "Tell." Tentatively, not knowing just what to tell, the investigator pointed to the words obtained. Miss Damon interestedly commented that the problem seemed to be one of correct spelling of French words. As she said this Brown wrote, "Look." This was pointed out to Miss Damon, and everybody began to study the words, but Brown was observed to write impatiently, "Look, look, look." Miss Damon's attention was directed to this, and she declared, "Why, she must mean look somewhere else; the dictionary of course!"

Page after page of the dictionary was thumbed over with innumerable conflicting answers from Brown, until Brown impatiently told the investigator "Wrong!" More care in asking questions disclosed that the dictionary had a word like Brown's word, and that the dictionary word, while it was the right word and correctly spelled, was still the wrong word because Brown had not spelled her word correctly, "Never learned to spell."

Instructed to write her word, Brown now wrote "*subitement*, " then followed it by "*subsequemment*, " succeeded by "subsequent." Asked if "subsequent" were right for the message, Brown made no reply, but Miss Damon again became intensely terrified and proceeded entirely to forget the last steps of the investigation. Quickly she recovered her poise and took up her remarks as if she had just awakened from a trance.

Brown was asked if she had seen any other word of significance in the dictionary. "Yes." "Your word?" "Yes. Spelled different." Here Miss Damon interrupted to ask the

investigator, “What does *he* [meaning Brown] mean?” This peculiar slip of the tongue was marked by sudden pallor and a rapid forgetting of the question. Brown, asked for the word seen in the dictionary, wrote “Niaise.” When Miss Damon declared there was no such word, that she had never heard _of such a word, Brown wrote, “D don’t no it.” Asked if this word in some form were in the automatic writing Brown had written, B answered, “Yes.” Asked, “How learned?” Brown replied “Grandfather,” and questioning disclosed the fact that *at the age of three* Miss Damon had been lost and that her grandfather had called her ‘Niaise.’ (Note Miss Damon’s subsequent error in placing this episode at the age of four, as though this discussion had never occurred.)Brown then objected to further inquiries along this trend, explaining, “B afraid, D afraid of B telling.” Miss Damon read this with amusement, denied that she had even a remote feeling of fear, and declared that she was now getting “terribly interested.” B commented as Miss Damon spoke, “D don’t no.” As Miss Damon read this, she remarked, “Isn’t *he* economical?” Immediately the investigator asked, “Brown, what do you think about Damon’s last remark? Explain it.” Brown wrote, “B is *she*. D says *he* because she means Da —. D don’t no Da —B no Da —.” Miss Damon followed this writing with intense interest, asked the secretary if she really had said “he.” and then explained that “Da” was really the first two letters of Damon and that the three dashes signified, *m*, *o*, and *n*. As she completed this explanation, Brown threw pencils, paper, and books on the floor while Miss Damon gasped and in a horrified manner declared, “Brownie is having a temper tantrum,” adding, “And she can’t help it either.”

No further information could be obtained from either Miss Damon or Brown, until Miss Damon pleadingly asked, “Please Brownie, get the information,” to which Brown replied, “Suppose I fail?” In a challenging tone Miss Damon replied, “Brown, will we ever know?” Slowly Brown wrote, “Yes,” while Miss Damon shrank back in her chair, hid her face, and began to cry. The investigator asked “When?” “Don’t know.” Taking a firm, aggressive stand, the investigator declared that too many hours had been spent already, that it was now four P.M., that the assistant had an evening appointment, as did the secretary, and that more reliance should be placed upon Erickson. At this moment the assistant stated that her appointment was for eight. Brown was asked to specify the time at which she would give the complete information. At this point Miss Damon recovered her poise and interest and expressed delight when Brown wrote seven-thirty, but when Miss Damon asked Brown to confirm this promise, Brown ignored her, writing, “E, ask, work.”[2]

V. THE USE OF A MIRROR AS A “CRYSTAL” IN WHICH TO CALL UP VISUAL MEMORIES

Asked how, Brown wrote “Crystal.” Miss Damon explained that Brown must want her to do crystal-gazing, which she considered ridiculous since she did not know how, had only heard about it, and really could not do it. Brown replied, “Waiting.”

Accordingly, a trance was induced, and using a mirror which reflected the ceiling, Miss Damon was instructed, “Brown wants you to look in that crystal and see.” Almost as soon as she peered into the mirror, an expression of intense terror came over her face, and

she awakened sobbing, cowering in her chair, hiding her face, declaring that she was "awful, awful afraid," and begging piteously for help. Evidently the investigator's face reflected his alarm, but before he could say anything, Brown wrote, "It's all right, E. D just scared. Got to be. Then feel better. Just comfort." Tentatively the investigator made a few general soothing remarks, while Brown wrote, "Right," and Miss Damon piteously and tearfully reiterated her remarks, "I'm so scared, just awful scared."

In a short time Miss Damon recovered her poise and became quite apologetic about her "babyish" behavior. At the same time Brown was writing, "Better now; crystal."

The procedure was repeated with the same results except that this time before awakening, the subject repeatedly looked into the mirror, then away from it, taking a longer look each time and finally trying to say something but awakening to avoid speaking. A similar panic followed, lasting about 20 minutes, with Brown repeatedly reassuring the investigator that "D soon feel better now," "Everything all right," and "D getting ready to know but she don't no it."

Finally, when Miss Damon had composed herself, apologizing for her emotional outburst as before, Brown again wrote, "Crystal."

Another trance was induced, crystal-gazing again suggested, and this time although markedly agitated, Miss Damon reported in her trance that she was seeing her grandfather and that he was saying a word. As this report was given, Brown wrote, "B getting scared, awful scared," at which Miss Damon awoke and calmly and comfortably asked, "What time is it?" although the investigator's watch lay face up on the desk. In answer to her own question she glanced at the watch and gave the time correctly as six-thirty-five while Brown at the same moment wrote, "25 to 7." Miss Damon commented, "Seven must be the important number to Brown. I wonder why?" and looked to the investigator for an answer. While Miss Damon waited expectantly for a reply, Brown wrote:

> D no everything 7:30.
>
> D tell then—forgot long ago,
> B won't tell.
>
> B won't let D no till 7:30.

At this moment Miss Damon asked irrelevantly, "Brownie, what is your first name?" and as Brown made no reply, Miss Damon in an agitated, excited, highly emotional fashion said, "He's gone crazy! *He*! Gosh!" Then quietly, in a subdued, puzzled way, Miss Damon asked Brown why she had said *he*. Brown answered, "D no soon; not ready yet." When Miss Damon sniffed at this answer, Brown wrote, "D don't believe because afraid." Miss Damon declared that she had been afraid a short time previously, but she had no sense of fear at all now, and her air was one of amusement. Brown commented, "D don't no. D wrong. D getting ready, soon ready. 7:30 right time; D have nuff time get ready." Following these remarks Miss Damon scoffed, declaring with amusement that

she was ready for anything and that she had no fear. Brown repeated her comments, finally interjecting, “B tell everybody at 7:30. D understand; nobody else.”

Suddenly Miss Damon’s dispute with Brown changed in character, and she became definitely apprehensive. Addressing Miss Damon, the investigator asked what was happening, to which Brown, startling Miss Damon, replied, “First D afraid vague, then afraid to learn something, then afraid she not no; now she afraid she going no. D afraid she going to no *it*, “ with the *it* written in heavy characters.

Miss Damon attempted to ridicule this explanation, but her general discomfort became increasingly apparent, and she began attacking the logic of the various statements, dropping the point and feebly returning to it.

Suddenly Miss Damon looked at the watch and remarked that it was seven-twelve. As she spoke, Brown wrote, “7:21,” and Miss Damon said excitedly, “Look, she reversed it.”

Brown was asked why, and her explanation was:

> D thinks 7:07 [Damon disputed this].
>
> E won’t [understand].
>
> E will later.
>
> No further explanation could be elicited.
>
> While Miss Damon puzzled over this material, Brown wrote, “D will begin to remember at 7:23.”
>
> Miss Damon: “That’s ridiculous. How can she say a thing like that? There’s nothing to remember.”
>
> Brown: “B changing D mind.”
>
> Miss Damon: “She is not, she is not, there is nothing to remember.”
>
> Brown: “D don’t no. B changing D mind.”
>
> Miss Damon: “That is ridiculous. As if I didn’t know if my mind was being changed.” Immediately she sobbed very hard but briefly, and then asked timidly, “Have I a reason to be scared?”
>
> Brown: “Yes.”
>
> Brown to investigator: “D cry, don’t mind, nothing help. D feel better.”

Miss Damon still crying, observed at seven-twenty-two and a half that "time is fast," recovered her poise, denied that there was anything to remember or that she was scared that she wouldn't remember, fluctuating from amusement to apprehensiveness.

At seven-twenty-seven and a half another intense panic developed, Miss Damon showing great terror, sobbing, cowering, declaring piteously that there was nothing to remember.

At seven-thirty B wrote slowly, much interrupted by Miss Damon's sobbing, "consequences of catching the muskrat to the little idiot," following which Miss Damon sobbed, shuddered, and cowered, begging piteously for help until seven-thirty-five. Exactly at that moment she recovered her poise and declared with startled interest, "I just remembered a story my grandfather told us when we were kids. A muskrat got into the pantry. Everyone chased it and knocked over all the things. I haven't got a thing to do with what my hand is doing.[3]

> The investigator asked, 'Well, what does all this mean?'
>
> Brown replied, 'D no, E not understand, told you before.'
>
> Erickson: "You agreed to give the full message."
>
> Miss Damon interrupting verbally: "Every subitement catalepsy the consequences of catching the muskrat to the little idiot."
>
> Erickson: "That's it?"
>
> Brown: "No."
>
> Erickson: "What is it?"
>
> Miss Damon: "Spelling bothering her; let's let her look in the dictionary."
> After many pages had been thumbed, many apparently at random,
>
> Brown wrote, "Subsequemment, subsequent, subsequent."
>
> Erickson: "The sentence is?"
>
> Brown: "Every subsequent catalepsy consequences of catching the muskrat to the little idiot."
>
> Erickson: "First sentence?"
>
> Brown: "No."
>
> Erickson: "Write first."

Brown: “Trance will my rat antrocine go?”

Miss Damon: “She can’t spell, poor thing.”

Brown: “Antrosine, osine.”

Miss Damon: “Osine, osine, aussi.”

Brown: “Aussi.”

Erickson: “Two words? First one.”

Brown: “Enter.”

Erickson: “Rat?”

Brown: “Muskrat.”

Erickson: “The real sentences.”

Brown: “Trance, will my muskrat enter, also go. Every subsequent catalepsy the consequences of catching the muskrat to the little idiot.”

Erickson: “I don’t understand.”

Brown: “D does.”

Miss Damon’s explanation: “I know what it means now, but I didn’t then. It’s all right there. Everything, except the words mean so much. Each one means different things. You see, I thought I was interested in catalepsy; it wasn’t catalepsy but the rigidity. I was just frightened by the muskrat episode. You see, I was lost when I was four years old, [Brown interrupted to write three (cf. above), and Miss Damon accepted the correction, explaining that she probably remembered wrong, Brown commenting, “Right”] and I was awful scared. *Grandfather scolded me when I got home; he called me “petite niase,”* [Brown wrote *petite niase* and pointed the pencil to the phrase followed by the emphatic period] *and scolded me and said 1 had left the door open and 1 hadn’t. And I was mad at him and afterward 1 would leave doors open to spite him, and 1 got my brother to do it too. Pantry door and icebox door. And grandfather laughed at me for getting lost, and then he told me, while I was still scared, about how he got lost and the muskrat got in the pantry and everything got upset, and 1 thought 1 did that. I was so scared, 1 got my grandfather’s story about him mixed up with my getting lost.”* Here Brown wrote, “Petite niase *thinks she is her grandfather*.” “And I was so mad at grandfather, and so scared, and I left doors open to spite him, and 1 wondered if another muskrat would come.” Again Brown wrote “*Petite niase* thinks she is her grandfather.” This time Miss Damon became aware of the writing, read it, laughed, and said, “You remember when I called Brown *he*, and Brown wrote Da– – –? Well, I can explain that. Brown was telling you

that I didn't know who I was because my grandfather's name was David. Like my name, it begins with Da and has three more letters. And that's what Brown means when she says the little idiot (that word is really spelled *niaise*) thinks she is her grandfather."[4]

Erickson: "Anything else, Miss Damon?"

Miss Damon: "No, that's all."

Brown: "Yes."

Noticing Brown's reply, Miss Damon flushed, then asked, "Brownie, has all that got anything to do with doors bothering me?"

Brown: "Yes, tell."

Miss Damon then gave an account of her phobia, speaking of it consistently in the past tense. Following this, Miss Damon asked, "Has it anything to do with my not liking cats?"

Brown: "Yes."

Miss Damon: "How?"

Brown: "Cats chase rats.

Miss Damon: "How I have rationalized my hatred of cats. I always thought it was because I saw a cat catch a baby robin, a tame baby robin. But really I didn't like cats because, well, *cats like rats*, and I didn't like rats."

Then with an exclamation of delight, Miss Damon said, "Now I know why I always thought there was something wrong with the way I *liked* the white rats in the laboratory. When I played with them, I knew I didn't like them, but I always persuaded myself I did, and I did like them in an uncomfortable way. [Here Brown wrote, "D liked them so she wouldn't no the truth."] I suppose rats are all right, but I'm not crazy about them any more."

SUMMARY

In brief, then, this is the story of a young woman who for a great many years had hidden phobic and compulsive impulses so discreetly that they had escaped the attention even of those who during those years had known her well. However, when by apparent chance she volunteered to be the subject for a demonstration of hypnotism, she found herself caught up in a swift stream of events which led in a few hours to the permanent elimination of her phobias and compulsions.

First she became fascinated by the phenomenon of induced hand levitation, and horrified to the verge of dissociation over induced catalepsy. Thereupon by means of automatic writing an effort was made to investigate the reasons for this extreme horror and fascination. This led at first to a series of acute anxiety states and then to the uncovering of a wholly unsuspected dual personality, a personality which linked with a childhood heroine from the literature of her youth. In a session lasting several hours repeated unsuccessful efforts were made to decipher the automatic writing that had been recorded by this second personality. Finally visual images were evoked by having the subject gaze into a mirror while under deep hypnosis. These images brought back to consciousness some episodes from the third year of the patient's life which clarified the writing and at the same time explained the phobias and compulsions, all of which served to effect a therapeutic result that has persisted over a period of years.

DISCUSSION

The story presents challenging problems with regard to the workings of unconscious processes and the different technical approaches to them.

In one session several hours in duration repressed memories were recovered of a traumatic experience that had occurred at the age of three and had been completely forgotten.

These memories were recovered by the use of automatic writing. The original automatic script was almost unintelligible, only a few letters or syllables being recognizable (cf. illustration). The writing had been accompanied by an intense transient panic. The slow and laborious deciphering of this original script simultaneously solved the mystery of the neurosis itself.

Further use was made of automatic writing as a method of answering questions about the meaning of the original automatic writing. At the end visual images were evoked by having the subject, while under hypnosis, gaze into a mirror which reflected a blank ceiling.

During the course of these observations a wholly unsuspected dual personality was uncovered. It is possible that the presence of such a well-organized dual personality may be an essential precondition for the successful use of such devices as automatic drawing or writing, mirror gazing, and the like, since they would seem to depend upon a rather high degree of hysterical dissociation. It is possible also that the unsuspected presence of just such dual personalities, closely knit and completely segregated from the rest of the personality, may account for certain analytic defeats.

Psychoanalytically the automatic writing is of particular interest because it makes use of the same condensing and obscuring devices as those which occur in humor and in the language of dreams. In less extensive observations this has been noted in the past by Erickson (1937b), and the same fact was recently reported with regard to automatic drawing by

Erickson and Kubie (1938). It would seem therefore that in selected cases automatic drawing and automatic writing may offer an accessory method of approach to the unconscious, a method, furthermore, which depends upon principles of interpretation that are thoroughly familiar from dream analysis. In special circumstances these devices may have advantages over more customary technical procedures. For instance, one of us (L.S.K.) has found that in certain types of dreams they can be used to demonstrate vividly and objectively the latent content of the dreams without resort to any verbal interpretation. (Observations not yet reported.)

Of further technical interest is the utilization of mirror-gazing while under hypnosis. In the interplay between the two main personalities, and by means of questions asked by the investigator and answered in automatic writing by the second personality, much work had already been done to elucidate the meaning of some fragments of the original automatic script. Furthermore, it had become increasingly clear that the content latent behind this script was charged with intense and unbearable terror; but by these procedures alone it had not been possible to transcribe this unintelligible writing into clear, understandable prose or to recover the original experiences which underlay the panic. The preliminary steps seemed rather to establish a situation in which the subject gradually came to feel safe under the guardianship of her protective dual personality and of the investigator. As the subject became sufficiently reassured, she was able to face the sources of her terror and finally could recover the lost memories while gazing into a mirror under hypnosis. It is especially worthy of note that the suggestion that this device be tried was given by the second personality.

The use of hypnotism merits further discussion. Hypnotism is under such a cloud that the debt which psychoanalysis owes to it is often forgotten. Freud's earlier writings are full of allusions to the various phenomena of hypnotism, some of which will be quoted in another connection below. As the years went on, however, all reference to the problems with which these phenomena confront us disappeared until the papers on *Group Psychology and the Analysis of the Ego* (Freud, 1921), the German edition of which appeared in 1921 and the English translation in 1922. Here it became evident that the derogatory attitude toward hypnotism, which its therapeutic failures and its commercial exploitation had engendered in every serious scientist, had turned Freud's thoughts too from its scientific importance, even as an object of analytic study. (See the chapter, "The Group and the Primal Horde," pp. 95–100.) Yet in spite of his antipathy to the use of hypnotism, on page 100 he says of hypnosis that it "is solidly founded upon a previous position which has survived in the unconscious from the early history of the human family." The implication here is that hypnotic phenomena are universal and must be taken into consideration in all efforts to understand the neuroses. If this is true, then the study of hypnotic methods is a duty for psychoanalysts, and they must return to that fountainhead of original and dramatic unconscious material from which Freud himself derived his first impetus.

It is interesting furthermore to see that Anna Freud in her book *The Ego and the Mechanisms of Defense* (1937) subscribes to the traditional derogatory judgments against the use of hypnotic methods to elicit unconscious material. There she says (pp. 111–13)

that under hypnosis the revelation of the unconscious is achieved by a "total elimination" of the ego, which therefore takes no part in the therapeutic procedure but in the end throws off the influence of the physician and again represses the unconscious material which has been brought to light. She contrasts with this the process of free association, under which the ego is induced to "keep silent" only for interrupted fragments of time, so that the observer's attention is constantly oscillating between the elicitation of material during the period of ego acquiescence and direct investigation of the activities of the ego itself when it becomes resistant.

It should be obvious that there is no a *priori* reason why hypnotic investigations of the unconscious cannot be carried on in just this way. Nor is there any necessary reason why analytically informed investigators or therapists who in these days are using hypnotism should forcibly thrust upon their patients the material which has been gained from the unconscious under hypnosis, merely because in a more naive period before anything was understood about the forces of resistance the traditional hypnotist proceeded in that ruthless fashion. The lessons learned through psychoanalysis can be applied in the use of this allied method, and there is no more reason why hypnotic therapy should consist of an explanation of the patient's symptoms to the patient without regard to the attitude of the patient than that this should be the process of analysis. On the contrary, it is possible in the hypnotic as in the waking state to secure information from the unconscious and then so to motivate the total personality that there will be an increasing interplay of conscious and unconscious aspects of the personality, so that the former gradually overcomes the resisting forces and acquires an understanding of the latter. Just as in analysis there can with practice be a full opportunity to delay, postpone, resist, and distort when necessary, and yet through this activity always bring the process nearer to a therapeutic goal.

In fact this process is well illustrated in the case under discussion, when, for instance, during the questioning of Brown Miss Damon suddenly interrupted, saying, "Every subitement catalepsy the consequences of catching the muskrat to the little idiot." This was a sudden and seemingly meaningless eruption of unconscious material into consciousness; yet in it a few important fragments of memory returned. By this "meaningless" verbalization Miss Damon participated on a conscious level but in a safe and partial fashion; thereby, however, she prepared herself for the more dangerous complete participation that occurred later. Thus it played a role identical with that of a dream which is only partially remembered and partially interpreted.

It is a clinical fact that the memories brought to light and the emotions discharged in this strange experience permanently relieved this young woman of a serious and rapidly increasing compulsive phobic state. The question may fairly be asked, however, whether the investigators are in a position to explain either the origin of the phobia or its resolution. Here perhaps it is best again to let the facts speak for themselves by reviewing the brief story as far as it is known.

For a short time a little girl of three believes she is lost, and while lost she gets into a state of intense terror. She is found again, or else finds her way home, and is greeted by a grandfather who scolds her, makes her feel guilty of leaving doors open, laughs at her,

humiliates her by calling her a little *niaise* (idiot), and finally tries to comfort her by telling her a story of an occasion in his own childhood when he was lost and a muskrat entered the house through an open door and got into a pantry, where it did a great deal of damage. At this the little girl is thrown into a state of increased terror, rage, anger, resentment and confusion. She mixes up her grandfather's story, and especially the tale of the muskrat, with her own experience. She feels as if it had happened to her *almost as though she were her grandfather*. She is angry, and out of spite and revenge she deliberately begins to leave doors open as he had done and as he had unjustly accused her of doing. Then she begins to fear that she will make a mistake, that she will leave doors open unwittingly and that something dreadful will come in. She begins compulsively to check up on the doors over and over again.

The identification of the child with her grandfather is presumably an example of that form of defense by identification with the aggressor that is described by Anna Freud in *The Ego and the Mechanisms of Defense* (1937).

Brown's statement was that when Miss Damon was "so scared" her grandfather should have explained fully all about her scare instead of "selfishly" telling her about his being scared too, because that meant that Damon's scare was so bad that it scared even grandfather, and besides "it added his scare to hers." Brown stated further that it was Damon who resented this and Damon who punished grandfather, although Brown confessed, "I helped a little, too. Damon thought of leaving the doors open and Damon did that, but I helped by getting Damon to get her brother to do it." Brown then explained the phobia as a direct consequence of this effort to punish the grandfather: Damon concluded that if she punished grandfather in this way, she would be hopelessly caught and unable to stop punishing him. Brown added, "It's just like she still believes that thing about a child crossing its eyes and not getting them uncrossed. That is, she believes it in a certain way, even though she knows it isn't true. That's what happened then."

Without attempting to settle the question of whether or not this is an adequate explanation of the phobia, one may feel justified in concluding that the first component of the motivating forces—namely, the revenge fantasy against the grandfather—was repressed and that the phobia remained obsessive until this original motive was recovered. From the point of view of analytical therapy it is particularly interesting to emphasize that the obsessional phobia was relieved merely by the recovery of these specific conditioning events and without any investigation or discharge of underlying patterns of instinctual cedipus relationships, castration anxiety, or the like.

Perhaps most surprising of all is the entirely unanticipated discovery of a dual personality in a young woman, who aside from the phobias described above had been living a relatively normal and well-adjusted life, and in whom the existence of such an alter ego had not even been suspected. Inevitably this raises the question of how frequent such unrecognized dual personalities may be, either as partial or as complete formations. If they exist, the complications which they must create in transference relationships in formal psychoanalytic therapy are of utmost significance and have never been

investigated. The mere possibility that they are more frequent than has been suspected demands the development of methods to test out their frequency and their significance.

One cannot say that the existence of such multiple personalities has not been suspected or mentioned in analytical writing; but its far-reaching significance seems to have been strangely overlooked, probably because of the disrepute into which all hypnotic phenomena have fallen because of their traditional association with commercialized hypnotism. Breuer and Freud (1936a) state, "that the splitting of consciousness, so striking in the familiar classical cases of double consciousness, exists rudimentarily in every hysteria, and that the tendency to dissociation, and with it the appearance of abnormal states of consciousness which we comprise as 'hypnoid,' are the basic phenomena of the neuroses." Further, "The existence of hypnoid states is the basis and determination of hysteria." Later they speak of the varying "facility" which people show toward "hypnoidal dissociation" as having an etiological relationship to the development of neuroses. On pages 174| 175 Breuer, in his discussion of the Theoretical Material, describes a mechanism for this "splitting" that emphasizes its universality. On page 101 of his paper on General Remarks on Hysterical Attacks, Freud (1924) notes the role of multiple identifications and the fantastic and dramatic playing out of various roles in a hysterical patient. Nor have other observers limited the phenomena to these hysterical structures. Alexander in *The Psychoanalysis of the Total Personality* (1930), page 55, says:

> Therefore, when I describe the superego as a person, and neurotic conflict as a struggle between different persons, I mean it, and regard the description as not just a figurative presentation.... Furthermore, in the study of the neuroses there is no lack of such visible manifestations of a divided personality. There are, for example, the true cases of dual personality—quite rare, to be sure. But the compulsion neurosis lacks few of the indubitable manifestations of a dual personality.

In view of these observations it is somewhat surprising that with all of the emphasis that has been laid on the varying roles of the analyst in the transference situation, so little has been said about the varying role of the patient who may present to the analyst not one personality but many.

This is not the place to discuss the mechanism by which such multiple personalities are established. Perhaps it can be said that no single case has been studied deeply enough to answer this question, despite the dramatic literary descriptions which exist in classical literature. Nor is there as yet sufficient evidence at hand to establish how many degrees of such multiple formations may exist. Another perplexing problem is presented by the relationship of the phenomenon to the process of repression. Clearly, in the production of multiple personality a process must occur in which certain psychological events are rendered unconscious. Is this the same process of repression as that with which we are familiar in the psychopathology of everyday life and in the neuroses? The topographical figure of speech which comes to mind is, that that which we ordinarily think of as "repression" is a repression downward, and that the psychological structure that results is a series of layers one upon another; whereas the "repression" which would result in a

multiple personality would be a vertical division of one personality into two more or less complete units, like the splitting of paramecium. Yet obviously, such a concept has purely diagrammatic value and may be misleading.

In fact one must ask whether one is justified in dismissing the possibility that all acts of repression involve the creation of a larval form of a secondary personality. In his only reference to the problem Freud, in his *Note on the Unconscious in Psychoanalysis* (1925), p. 25, refers briefly to the existence of alternating states of separate and independent systems of consciousness. After stressing the fact that they are *alternating* and not coexistent states of consciousness, Freud leaves the issue without discussing how this form of segregation of conscious material differs from that which occurs in ordinary repressions. Here again it would seem that we face a basic gap in psychoanalytical knowledge, a gap which exists at least partly because we have turned our backs so completely upon material available only through the experimental use of hypnosis. The states of conscious and unconscious mentation existing in cases of multiple personality *coexist* quite as truly as in simpler repressions.

In the case here under discussion, we are unable to explain the existence of the personality first known as Jane and later as Jane Brown. We are in a position to understand in some measure the function which this dual personality performed, but not how it came into being. The story makes it evident that under the impulse of terror and anger, the young woman had made a very deep and painful identification of herself with her grandfather. Somehow all of her later anxieties and compulsions stemmed from this momentous event. At some time she built up a protective companionate alter ego, Jane, who knew the things that she did not want to know, who was either unable or else forbidden to tell them to anyone but who exercised an almost continuously protective role toward the patient herself. This was evidenced on innumerable occasions during the course of the sessions described in this report, and is in striking contrast to the destructive or malicious alternative personality which has more frequently been described in the literature (Prince, 1908).

The "Sally" type of personality, described by Morton Prince, often seems to glory in a sense of power but by adroit maneuvering can be made to demonstrate this power in the interests of therapy by compelling the other personality to accept unconscious data which it is trying to reject. In the present case the disagreements between the two personalities—that is, the abuse, the epithets, the supercilious arrogance, the sulking, the apologies—appear to have been sham battles by means of which the one manipulated the other. The evidence for this is given in the following scrawled statement by Brown: "D need help; D not no [know] D need help. B must help D. E must help D. D not no so got to be made to take help. Got to give help when she not no so she take it. D not no right thing to do. D do wrong thing. B no right thing. B can't tell D; B got to make D do right thing the best way B no how." This explanation is typical of many others and shows that this apparent internal warfare was a byproduct of the clumsy efforts of Brown to guide Miss Damon toward an understanding of matters that Brown understood but could not communicate directly. Even the anger Brown showed against Miss Damon seemed to serve the same purpose of impressing on Damon the seriousness of the whole matter.

Similarly, the occasional impatient abuse of the investigator was like the anger of a child who impatiently tells an adult that it has explained everything when the whole matter remains incomprehensible to the adult.

The apparent "impishness" does not seem to be an expression of Brown's real attitude, which was one of deadly seriousness and concern, of worry and anxiety, which she seemed to mask from herself, from the investigator, and especially from Miss Damon in order to prevent Miss Damon from sensing her anxiety. It was particularly when Miss Damon became alarmed that Brown went off on some irrelevant tangent, inducing laughter on the part of the investigator and his assistants. That Brown herself was also afraid is shown in her statement, "E not hurt. E can do it. E not afraid. E won't be afraid. D afraid; B afraid so let E do it."

The ambiguities of the responses, and the insistent demand of Brown for an absolutely right question before she could answer, is a characteristic and at the same time a puzzling phenomenon. It was as though she could not tell her story outright but could only betray it, as we have said, like the schoolboy who dares not tell on the school bully, but can betray him indirectly if asked the correct question. To this end much of the seemingly irrelevant material turns out on close inspection to. have been highly relevant, because it betrayed cues which were evident to Brown but not to the investigator until the whole story was made clear. It was for this reason that the investigator seemed to Brown to be so intolerably stupid.

A detailed study of multiple personalities might shed much new light on the problem of anxiety: how anxiety is distributed between the various personalities, what different forms anxiety may take in each, how this correlates with special traits of each.

The material from this case justifies only a few comments at this time. In the first place it is clear that the subject herself suffered from two types of fear. There was the initial horror state which overcame her when the hypnotically induced catalepsy reproduced in her the terror originally experienced when she was lost and when her grandfather told her the story of the muskrat. In her catalepsy this old fear recurred as a state of paralyzing panic without phobic distortions or projections but with characteristic bodily immobility. Against this she originally defended herself by a partial dissociation and an attempted identification with her grandfather. However, this had served only to plunge her into deeper waters when the grandfather told the story of his own fears. The relationship of this type of experience to the formation of the second personality is something about which we are in a position only to speculate.

The second type of fear from which Miss Damon suffered occurred whenever disturbing unconscious material suddenly threatened to breakthrough the barriers into conscious expression. She dramatized this type of fear more freely than the other, with obvious vasomotor disturbances and with evidences of shame and embarrassment as well as of fear. Such anxiety is familiar of course from clinical analytical experience and from Freud's descriptions; but its demonstration in the interplay between these two personalities was particularly clear.

The protecting Brown, however, was also not immune to fear. She showed momentary anxiety about looking too closely at the visual images that were called up in the mirror. She was afraid she would see something too horrible to endure, and frequently she made use of euphemism, ambiguities, and circumlocutions of all sorts to escape dealing directly with a frightening topic. She seemed to know that the investigator could name the "awful thing" without experiencing a dread similar to her own. Thus she said, "E not hurt. E can do it. E not afraid. E won't be afraid. D afraid. B afraid. So let E do it." It is not easy to say how much of Brown's fear was for her own safety and how much for Miss Damon's.

A word of further explanation is necessary to clarify the peculiar and confusing way in which the subject first counted out the positions of the words in the sentences. After the sentences were fully deciphered, it was possible completely to explain the counts:

> Erickson: "The real sentences?"
> Brown: "Trance, will my muskrat enter, also go. Every subsequent catalepsy the consequences of catching the muskrat to the little idiot."

Word	*Position*	*Sentence*
Trance	**1**	**1**
Will	**2**	**1**
My	**3**	**1**

Word	*Position*	*Sentence*
Catalepsy	**10**	**1 and 2 together.**
Catalepsy	**11**	**1 and 2 together, if *muskrat* is counted as two words.**
Catalepsy	**12**	**1 and 2 together, if *also* and *muskrat* are each counted as two**
Every	**8**	**1 and 2 together.**
Every	**9**	**1 and 2 together, if *muskrat* is counted as two words.**
Every	**10**	**1 and 2 together, if *also* and *muskrat* are each counted as two**
Ever	**13**	**After the following sequence: "Trance, will, my, muskrat, musk, rat, enter, also, all, so, go, every, ever."**
Ever	**14**	**After the following sequence: "Trance, will, my, muskrat, musk, rat, enter, also, all, so, go, every, eve, ever."**

Catalepsy could have been given different positions, but the subject later explained that it had not occurred to her to split and reduplicate the words in this way until after she had reached the word ever, and then it was too late to go back to the word catalepsy.

This fragmentation of automatic words and sentences is strictly comparable to the fragmentation of the automatic drawings described in another paper of Erickson and Kubie (1938); instead of being counted as parts of a sentence, the words are counted purely as syllabic units with only a numerical relation to one another. The task of resolving this deliberately misleading system of counting was tremendously difficult.

[1]This is a frequent trick in automatic writing and is one reason why it is not sufficient just to read automatic writing, and why one must watch it as it is being written. Adequate objective records therefore could be made only by use of a motion picture. Brown's explanation of the reverse writing was, "D no [know] question. D read answer. D thinks she understands. E see writing. E no real answer. D don't. That way D not afraid."

[2]Here Brown specified the exact time at which full insight would be achieved. It is often found to be desirable to ask subjects to specify the hour at which they will understand something, urging them not to set this hour at either too immediate or too remote a time. This seems to give them a definite task and goal and to relieve them of the difficulty of making up their minds in the final moment of decision as to when to expect insight. Thus it gives them ample opportunity to prepare for that insight. Not infrequently analyses are brought to conclusion in a manner comparable to this when the analyst arbitrarily sets a date for the termination of the treatment.

[3]An explanation of the various times alluded to here is necessary. (1) Brown promised to tell everybody at 7:30. (2) Shortly thereafter Miss Damon mentioned that it was 7:12, while Brown wrote 7:21, at which Miss Damon remarked, "Look, she reversed it," and Brown immediately replied, "Damon thinks 7:07." This was promptly disputed by Damon. (3) Brown then remarked, "E won't [understand]. E will later." This was followed by the statement, "Damon will begin to remember at 7:23." (4) At 7:221/2 Damon remarked more or less casually, "Time is fast," but at 7:271/2 Damon developed a panic. (5) At 7:30 Brown wrote the significant material, of which Damon remained unaware until exactly 7:35. The explanation of these events is as follows: Miss Damon glanced at a watch which was face up on the desk and read the time as 7:12, Brown wrote these digits but in doing so reversed the last two digits, thereby directing attention to the minutes. Miss Damon remarked, "Look, she reversed it," at which Brown said, "Damon thinks 7:07," and then promptly declared that the investigator wouldn't understand then but would later on. Now it must be noted that 7:07 is exactly five minutes less than 7:12. Furthermore, the promise was made that at 7:23 Damon would begin to remember; but at almost that time the only thing that occurred was the casual remark that "time is fast." At 7:271/2, however, a panic ensued, apparently five minutes late. At 7:30, actually in accord with the promise "to tell all," the full material was written; but again Damon remained unaware of it until 7:35. When the investigator later asked Brown, "Why didn't you keep your 7:30 promise?" her remark was "Did–my watch." Checking Damon's watch, it was found to be exactly five minutes slower than that on the table, and as this was being noted, Brown's hand moved up to point to the 7:07 on the written page. From there it slid over to "E won't. E will later."

[4]Brown's persistency here is noteworthy. Twice Brown brought Damon back to the story by writing, "Petite niase thinks she is her grandfather," apparently in order to compel Damon to keep to this important issue.

The Clinical Discovery of a Dual Personality

Milton H. Erickson

Unpublished manuscript, circa 1940s.

The clinical phenomenon of a dual personality constitutes an inexplicable form of personality construction. It consists of the coexistence within the same person of two separate and distinct personalities. Although this phenomenon has been known for over 60 years, and despite its marked importance as an approach to the many problems of personality construction, it is still the same unsolved problem it was when first reported. Azam in 1876, Mitchell in 1888, Prince, Sidis and Goodhart, and Janet about the beginning of this century, and Kubie and myself only recently have recorded such cases in the literature. The interest and significance of these studies and the wealth of their contributions to psychological and psychiatric understandings are easily appreciated. Yet, despite the importance that has been readily accorded to these reports, especially to Morton Prince's famous study of the various coexistent personalities in Miss Beauchamp, there has been a persistent, serious oversight and neglect of the dual or multiple personality as a profitable field of inquiry regarding the nature and structure of the human personality. Also, there has been no active realization of the fact that the multiple personality offers an exceptional opportunity for a laboratory analysis of those elements entering into the formation of distinctive and separate personalities. Yet, the problem of personality—its development, organization, and structure—constitutes a question of central interest to both psychology and psychiatry.

Accordingly, in this preliminary report upon the clinical discovery of a dual personality, my purposes are several. Particularly do I wish to direct attention to the importance of as many as possible of the general considerations centering around this psychological phenomenon, and about which misunderstandings, false beliefs, and incorrect assumptions are most generally prevalent. Among these considerations are the significant questions concerning the actual incidence or frequency of multiple personalities, the possibilities for discovery, the clinical nature and character of multiple and secondary personalities, and especially the significant values of this clinical phenomenon as a research problem.

Finally, I wish to give an account of the various observations, clinical steps, and investigative procedures by which it became possible to discover in a young woman the existence of a second unknown and concealed personality. This discovery constituted a fact unsuspected by her ordinary personality, and she continued to remain unaware of it for approximately a year after its discovery. Then, only through being systematically and forcibly acquainted with the facts, did she realize the possibility of the truth.

Concerning the actual incidence or frequency of well-integrated, highly organized, distinctive multiple personalities coexistent within a single individual, no definitive

information is available in the literature. During the course of Prince's study of this problem, he expressed the belief that these personalities were not necessarily infrequent, but that probably it was the difficulty of discovery that made them apparently rare.

In my own experience with approximately 500 hypnotic subjects, which does not include the case to be reported today, I have found a total of four persons with well-developed, well-organized secondary personalities. In addition I have found three others with fairly well-integrated subpersonalities and a half-dozen more who showed separate but incomplete organization about certain aspects of the personality. In all these instances discovery was accidental, no systematic search was made, and so the actual frequency may be higher than indicated by my findings.

On the other hand, a large proportion of my hypnotic subjects constituted a highly selected group, chosen because of neurotic traits and personality disturbances. Hence the incidence found may be unduly high. At all events my findings do indicate that multiple personalities are not necessarily rare, even though no definitive conclusions can be offered concerning their actual frequency.

Serving to confirm my general experience in this connection is the trend of conceptual developments in personality study. Recently the tendency in psychology and psychiatry has been toward intensive studies of personality as a clinical problem meriting analysis rather than simple acceptance as an established fact. From these intensive studies, particularly those made by the psychoanalysts, has come a general and progressive realization that the human personality is characterized by infinite varieties and complexities of development and organization, and that it is not a simple limited unitary organization. It is, rather, to be regarded as having as complicated a structure, organization, and development as has the individual's experiential background. From this realization of the complexity of the structure of the personality there has developed the understanding of the possibility—and the actual probability—of separate and specific integrations within the total organization as a common characteristic. Particularly has this multiple concept of the personality been emphasized by Franz Alexander in his book *The Psychoanalysis of the Total Personality*, in which he declares emphatically that the human personality actually constitutes a collection of personalities. More recently in this regard Oberndorf has spoken of "that galaxy of personalities which constitute the individual." Finally, mention may be made that medical history is replete with instances of definite entities that were originally considered as rare and infrequent—if, indeed, actually existent, and not a manifestation of some other known entity. As we now know, these presumably unusual conditions needed only the adequate development of medical techniques to permit ready discovery and recognition, and such development probably is all that is lacking in relation to special forms of personality construction.

In relation to the question of the possibilities for discovering multiple personalities, one is impressed at once by certain attributes in common among the studies recorded in the literature. In all these cases the discovery was essentially an accident. Also, in all instances the discovery was total in character; that is, there was sudden immediate and full realization on the part of the investigator of the nature of his discovery.

Next, in each instance—and this is an item that has given rise to innumerable misapprehensions and false assumptions and beliefs—the discoverer was either employing hypnotic techniques at the time or was well experienced in the use of hypnosis. Hence, the case I am reporting today is of special interest since it was not, like my previous cases, an accidental discovery. Hypnosis was not employed, and my patient had never been hypnotized. However, I do feel that my experience with hypnosis made me more acutely aware of the striking contrasts and startling dissimilarities noted from time to time over a period of months in the general behavior of my patient. My belief is that the role of hypnosis in such discoveries is essentially indirect and coincidental. The hypnotic experience of learning to differentiate waking behavior from trance behavior in the same subject provides a general background of understanding by means of which one learns to recognize integration.

My interest in today's case was stimulated entirely by observing in a young woman various different sets and patterns of complete, well-integrated personality reactions and manifestations. Some of these patterns were familiar and easily recognized as hers; others were unfamiliar, seemed alien to her, and could not be fitted to her personality as ordinarily known. Hence, I would stress as an adequate measure of discovery for multiple personalities any procedure of systematic clinical observation that would permit the recognition of different sets and patterns of behavior integration and a determination of the interrelationships or lack of interrelationships between various organizations of behavior reactions.

The question of the clinical nature and character of multiple personalities is most controversial, much more so than the marked limitations of available information warrant. In this regard association with hypnosis has contributed to the development of both prejudices and mistaken beliefs and assumptions. In addition, as has been the case with hypnosis, there has been a marked confusion between the symptomatology of hysteria and the manifestations of multiple personalities. However, it is only fair to admit that much of the confusion between hysterical states and multiple personalities derives from the fact that, unfortunately, the literature does contain reports of hysterical states described as multiple personalities. Eventually such errors will be corrected.

Foremost among the various misunderstandings prevalent about multiple personalities is the belief that they are more or less unintentionally built up by the hypnotist and hence are artifacts. However, as is readily appreciated by anyone with adequate experience, hypnosis is not a miracle worker. It is possible to build up in the hypnotic subject pseudopersonalities, but these are extremely limited in character and extent of development, and they obviously are temporary, superimposed manifestations. In addition, such personality constructions are restricted by the nature and origin of their development to the hypnotic situation. In my own hypnotic work I have, as an experimental approach to personality problems, attempted over a period of years to build up new personalities in hypnotic subjects, only to realize the futility of such attempts. Furthermore, for a person adequately experienced in hypnosis there is no real likelihood of confusing the manifestations of the hypnotic trance with an actual secondary

personality. They are distinctly different despite the superficial resemblances that may cause persons limited in their knowledge of hypnosis to confuse the two.

Finally, one need only read with the utmost of critical attention such a study as Morton Prince's to realize the error in such beliefs. Accusations have frequently been made that his discovery was directly the result of hypnotic suggestion. Yet, every one of Prince's findings serves to emphasize the nonhypnotic character of the multiple personalities he discovered.

Another prevalent misapprehension is that multiple personalities represent essentially nothing more than a fugue state, an amnesiac state of hysterical origin, or a hysterical dissociation of a single complex (or even a constellation of complexes) into a limited, restricted, isolated, independent existence. However, careful, critical comparative studies of these conditions and of multiple personalities will disclose only apparent, not real similarities. Unfortunately, opportunity for such comparative study is as yet limited. Nevertheless, a careful analysis of the material actually available on these topics in the literature will enable the earnest student to reach a satisfactory realization that multiple personalities constitute something of a different character from special hysterical states.

Nor should there be a confusion of the condition of multiple personalities with those prolonged amnesiac states that result only in a loss of personal identity and a new organization of the individual's life. In such amnesic states the personality as such remains constant, and the general pattern of personality reactions persists. The only significant difference is the loss of conscious memory—only the memory—of the experiential past. However, it is possible for a dual personality to behave in a fashion wholly suggestive of only a simple major amnesic state. In this connection I have found that by cautious, tentative, and deliberate experimental measures it is possible to reverse the role of dominance. That is, by appropriate procedures it is possible to make the secondary personality actually the primary, dominant personality. When this is done, I have found that the secondary personality becomes dominant and loses its knowledge of the actual experiential background of the originally dominant personality, which in turn acquires all the true characteristics of the secondary personality. However, I have not yet dared to do much investigative work in this direction.

Another serious misapprehension is the common but mistaken belief that multiple personalities can occur only in highly neurotic persons and that the secondary personalities are necessarily destructive and vicious in character. My experience is contrary to this belief. Of the four instances I have discovered, two of the individuals were neurotic, one seriously so, and in both of these the secondary personalities were decidedly destructive in character. However, in both of these cases the undesirable behavior was directed exclusively against the ordinary personality and not, as in the fictional account of Dr. Jekyll and Mr. Hyde, directed against society.

The other two persons, well known by competent psychiatrists, are regarded as well integrated and well adjusted, and their secondary personalities are definitely of a helpful and protective character in all their relationships with the primary personality.

Today's case represents a third type of relationship between the two personalities. As originally discovered, the secondary personality wished the primary personality well, was willing to be of assistance to that personality, but was often either markedly indifferent to or highly impatient with, the primary personality in specific situations. On occasion the secondary personality would declare emphatically that the ordinary personality was "silly," "stubborn," and "lacking in good sense." Hence, no absolute rule of thumb is warranted in describing the interrelationships that exist between multiple personalities.

To proceed with the question of what actually constitutes the clinical nature of the dual or multiple personality is a most unsatisfactory task. One must make the simple, dogmatic, and not satisfactorily informative statement that the person with a dual personality actually possesses two separate, distinct, independent personalities. Each of these personalities derives from a single, total experiential background that serves each of the personalities in a markedly different fashion. The dominant, ordinary, or primary personality has the richer background of reality experience, and nearly all contacts with reality belong to it. The secondary personality, however, has the richer background of intellectual and emotional knowledge commonly held by passive, observant, nonparticipants. Thus, there is a dominant personality that has actively participated and shared in the major portion of all contacts with reality; out of this experience a personality complete with its various attributes is derived. The second personality, however, except for a limited number of reality contacts unknown to the other personality, has usually not shared actively to the same significant degree in reality contacts and has largely only observed reality in a passive fashion. For the secondary personality the experiential background is largely a matter of intellectual and emotional understandings acquired passively through the proxy constituted unwittingly by the primary personality. Out of this background of chiefly passive experience the secondary personality, also complete with its various attributes, is derived.

When direct comparison of one personality with the other is made, the question is not one of the completeness or the incompleteness of the two personalities, as is so commonly believed. Rather, it is entirely a question of the totally different uses and interrelationships established for the various items in the total experiential background. To appreciate these facts one needs prolonged and instructive contact with a dual personality.

Of particular interest in relation to the nature of the dual personality are certain primary characteristics. First of all, the ordinary personality is totally unaware of the secondary personality. Even when confronted with adequate proof, there is a marked tendency to reject such proof as pure invention or as having some other explanation. For example, take the case I am reporting today. When Ellen, the primary personality, was presented with one proof after another, she rejected them as fabrications or, when the truth could not be denied, as inexplicably acquired knowledge on my part. When Mary, the other personality, was asked about this, she replied with amusement, "Oh, Ellen is awfully upset about finding out about me. She thinks you're just lying." Then Mary added, apologetically, "I hope you're not offended by Ellen. She just can't believe the truth."

A second characteristic, apparent in the above quotation, is that the second personality tends to know all about the first personality, or, if such knowledge is lacking, has ready access to it. For example, I asked Mary the name of a new acquaintance of Ellen's. She replied, "I wasn't paying attention when they were introduced, but if you need the name, I can get it from Ellen." However, certain items of information of a minor type are not available to the second personality. For example, in reply to one question Mary answered, "I wasn't there when Ellen put that pencil away, and now I don't know how to find out from her. You'll have to ask her."

Yet, immediately afterward Ellen could give the desired information. Prompt questioning of Mary elicited the reply, "Oh, I listened in when she told you, so I know now. I didn't before she told you, and I couldn't find out because I didn't know where to look in her mind."

Another item concerns the matter of dominance by the primary personality, which has already been mentioned and which will be illustrated later.

In relation to the potentialities of the multiple personality as a research problem, I wish to stress the opportunity it provides for a laboratory approach to the task of identifying and analyzing the various elements that enter into the development of distinctive and markedly different personalities. This value becomes particularly apparent when it is realized that the person with dual or multiple personalities must necessarily have constructed them out of a single experiential background. Hence, any differences in the personalities constructed must reflect differing uses, differing interrelationships, and differing qualities of activeness or passiveness for the same items in this experiential background. Thus there is opened the possibility of studying within a single experiential setting diverse developments in these direct relationships.

Having made this survey of an exceedingly important problem in personality research, a problem that has remained essentially undeveloped since its recognition 60 years ago, we may now turn to a direct consideration of my patient.

Ellen is an attractive, capable, and intelligent 24-year-old woman who has held several secretarial positions, with promotions leading to her present position as secretary in a university office. Despite her general capability she consistently gave the impression of being extremely shy, timid, fearful, withdrawn, self-conscious, and easily embarrassed. She had no friends, avoided all possible social contacts, and seemed to be incapable either of making or of receiving social advances. She was repeatedly described as cold, haughty, sullen, superior, and disagreeable.

In her work situation she was displeasingly meek and unreasonably insecure despite her excellent ability, and she never dared to show any emotion. Her entire work performance could be completely disrupted for as long as 20 minutes by any startle situation such as the dropping of a book or the slamming of a door. In her necessary contacts with

students, she was insecure, uncertain, self-conscious, and fearful, and she seemed able to function only by rigid, precise attention to her duties.

In her general behavior she was forgetful and absentminded, exceedingly clumsy and jerky in her movements; she walked either with a long, awkward stride or a timid, hesitant step, and always seemed to be on the alert to avoid social contacts or to be most uncertain and confused about her exact whereabouts both in the university halls or on the street.

Arrangements were made to have her observed without her knowledge by capable psychiatrists, whose opinions can be summarized by the words, "insecure, unhappy, and extremely neurotic and unstable emotionally." The consensus was that she was seriously in need of psychotherapy.

Observation over a period of months served to confirm all of these neurotic symptoms and to add many others of a similar character. During that period of time, however, many observations were made of a totally different and inexplicable character. These all related to peculiar, usually momentary manifestations entirely at variance with, and alien to, her known behavior; they were always replaced immediately by her customary shrinking and uncertain behavior. These variations may best be listed in brief descriptive accounts. Of particular import was the fact that these moments, however brief, served to effect a serious disruption of her work, and each time after their occurrence she was observed to go through what seemed to be a process of mental reorientation in order to resume her usual activities. Following are a dozen of these manifestations:

1. Brief periods of reverie and self-absorption during which she remained unresponsive to all stimuli despite the alert and highly interested look on her face.

2. Marked change from her hesitant or awkward gait to a casual, easy, graceful walk.

3. Failure to recognize individuals entering her office, and responding to them with a coldly critical gaze or a totally indifferent stare of curious appraisal.

4. The extreme and awkward care with which she would laboriously arrange the objects on her desk, and then, a moment later, she would disarrange them with one easy, graceful movement, and not discover this fact for some time.

5. Marked instances of disorientation; in particular, complete bewilderment at finding herself in an adjacent office or at the other end of the university hall with no understanding of how or why she happened to get there.

6. A direct approach to a fellow worker, staring in a curious, intent fashion, and then turning away, later to deny emphatically that she had seen that person on the previous occasion.

7. Frequent failure not only to recognize acquaintances but also to acknowledge their direct greetings, later denying emphatically that she had even encountered them.

8. The extreme care with which she would prepare to do something and but a moment later, with a facial expression of curious amusement, nullify that preparation. Thus, she would carefully put a letter in her purse to take home, but before leaving the office, she would remove the letter and put it in some place of concealment, only to search worriedly the next day, while expressing aloud to herself the certainty that she really must have put that letter in her purse.

9. The extreme ease with which she became lost either in the university buildings or in the city, necessitating constant effort on her part to keep in touch with her whereabouts.

10. The frequency with which she remained totally unaware of events occurring in the office, such as the entrance of students and the conversation of others, and the sincerity with which she would disclaim the actuality of these occurrences.

11. The discovery on her part as well as mine that her shorthand notebook frequently contained writings, scribblings, and drawings that she insistently denied doing, yet I knew them to be hers since I had often seen her doing them in a state of reverie.

12. Finally, as she became better acquainted with me, the appearance on the desk assigned to me in that university office of curious cryptic notes and drawings similar to those in her notebook, which both she and her superior disowned most disinterestedly.

As these observations were made repeatedly, I became interested in their interrelationships and also in their bearing upon the woman's general pattern of behavior. Soon I became convinced that there was some unusual form of dissociation involved. With the advent of the cryptic writings and drawings, an opportunity to investigate developed. Finding on my table a note written in a juvenile script containing a comment about a red hat, I concealed it. Several days later, apropos of nothing, I addressed the general inquiry to nobody in particular, "Was it a black hat?" and then, without awaiting any answer, absorbed myself in my work. After an interval of a few days I found on my desk another note that said, "No, red," in a similar juvenile script. In this manner I began a correspondence. Thus, upon finding a drawing or a note upon my desk, I would make some remark pertinent to it, but apparently silly, irrelevant, and meaningless. Within a few days I would find, concealed in my papers or on my desk, a reply bearing upon the previous note or drawing and my apparently meaningless comment.

When shown these notes and drawings, Ellen evinced only a polite interest. However, I soon began to discover that if when I found a note on my table, Ellen happened to be looking my way, there would appear momentarily on her face that peculiar alert, interested, and amused expression seen previously in different situations. I discovered further that Ellen was not aware that I had just picked up that note. After verifying these observations repeatedly and under varying conditions, the question arose as to what role Ellen played in this total situation despite her apparently complete unawareness of it.

This question led rapidly to the discovery that her unusual behavior constituted a separate, complete, and consistent general pattern never in evidence at the same time as Ellen's usual behavior. In other words, there were two separate and distinct patterns of general behavior that did not overlap but, rather, alternated in appearance.

Then one day I found on my desk a note that bore the name Mary Ann Peters. I concealed it immediately. Several days later, on my next visit to the university, I remarked casually to Ellen upon the frequency of double meanings in apparently simple remarks. I suggested that she listen carefully to what I was about to say, since it would have a double meaning, and I urged her strongly to be sure to understand that second meaning. I then remarked that one may describe someone as having the "*map* of Dublin—M.A.P.—on his face." Ellen listened intently but in obvious bewilderment, incapable of realizing that in spelling the word map I had actually given three initial letters. At the same time her hand was observed to pick up a pencil and to write, "Yes, Mary understand," in the script made familiar by the notes left on my table. This name "Mary" was later found to derive from the heroine of a novel read by Ellen in her childhood.

This was the first definitive evidence that there was a secondary personality, and upon the strength of it, arrangements were made with Dr. Lawrence S. Kubie to develop further investigative procedures. The details of our findings, however, belong to another paper and not to this preliminary report, which is intended only to introduce and focus attention upon a most important psychiatric topic. Suffice it to say that later we were able to establish full contact with the hitherto unknown personality, Mary, a well-poised, self-confident, extremely capable woman, free from Ellen's neuroticisms and markedly different in every way, even giving the impression of being several years older than Ellen.

Now, to summarize, I have stressed the importance of this entire problem of dual or multiple personalities, a problem that has confronted psychiatry for more than 60 years and is still unfortunately in the descriptive phase. I have briefly mentioned significant considerations bearing upon this type of phenomenon and have given a brief account of clinical observations that led to the discovery of a dual personality. My hope is that this account, even though a preliminary report to a more extensive study, will serve to dispel some of the mystery surrounding the entire problem and that it will also arouse sufficient interest to stir others to investigate and to study.

Findings on the Nature of the Personality Structures in Two Different Dual Personalities By Means of Projective and Psychometric Tests

Milton H. Erickson and David Rapaport

Unpublished manuscript written with David Rapaport, circa 1940s.

Last year a report was given before this association of the clinical discovery of a dual personality in a young woman; that is, there existed in that young woman two independent personality structures. One of these personalities was found to be primary and dominant, while the other was found to be secondary and essentially passive, but capable of alternating with the primary personality at a certain level of personality functioning. In presenting this material particular emphasis was placed upon the fact that the discovery had been based essentially upon the relatively simple clinical procedure of observing various dissimilar and conflicting responses, reactions, and patterns of behavior in the young woman. It was found that she manifested at different times one or the other of two sets of reactions, which not only alternated with each other but which were often unrelated, opposed, and even alien to each other in their manifestations. Once these two distinct and separate sets of behavior responses were recognized, the further steps leading to the clinical recognition of a dual personality and the identification of two different personalities, each with its own individual patterns of behavior, were relatively direct procedures.

While such a clinical study is of interest and value, there is an imperative need to confirm, to disprove, or to demonstrate some better interpretation of its findings by investigative procedures more objective and controlled than is clinical observation. The complexity of the phenomenon of dual personality, and the fact that the many cases reported in the literature are all essentially clinical studies, makes the need for independent, controlled test-studies even more obvious.

Accordingly, in today's presentation we have two purposes. The first of these relates to the need for a more systematic and critically controlled study of the phenomenon of dual personality. The second purpose is that of developing more adequately the clinical findings presented last year. To these ends we now offer a report of the investigative findings on dual personality obtained under the controlled conditions of the testing situation and by means of standardized psychometric and projective test procedures. These tests were chosen because they compel responses to be essentially in terms of personality reactions, attitudes, and capacities; hence, they preclude significant predeterminations of detailed patterns of response, such as is possible in personality inventories and similar tests. Independently of this investigation, however, one form of personality inventory was used on several occasions over a period of 18 months, not only

to disclose possible differences between primary and secondary personalities, but also to determine the constancy of the responses made.

The selected tests, administered by Dr. Rapaport, were given to the dual personality upon whom I reported last year and to another dual personality previously reported in the literature by me.[1] The use of two people increased the extent of the study and secured comparative and confirmatory findings.

TESTS AND THE TEST SITUATION

The tests employed in this study may be listed and described briefly as follows:

(1) Rorschach Test. This is a well-known test in which 10 ink-blot pictures are shown to the subject. In response to the question "What might this be?" semidirected associations are obtained from the subject for each of the pictures. The formal characteristics of these responses can then be interpreted in the light of test experience and psychological theory. The test gives information about the relation of cognitive and emotional processes and permits a description of the personality and a diagnostic classification.

(2) Szondi Test. This is a nonverbal, projective personality test in which the subject selects from six series of eight photographs each the picture most liked and most disliked. Each series shows a homosexual, an epileptic, a hysterical, a catatonic, a paranoiac, a depressive, a manic and a sadistic murderer. The choices thus made permit an interpretation of outstanding character trends of the subject and frequently an approach to the diagnostic category to which the subject belongs.

(3) Thematic Apperception Test. This test consists of a series of pictures presenting various scenes. The subject is asked to tell what each scene represents, how it came about, and what the outcome will be. This test gives insight into the content of the subject's fantasies and emotional attitudes.

(4) Babcock Deterioration Test. This test contains items similar to those of the Wells Memory Test and the Merrill-Terman Test. Simultaneously with the test a vocabulary test is given. By a computation based on the assumption that vocabulary deteriorates less than other achievements, a measure of mental efficiency is obtained.

(5) Bellevue Intelligence Test. This intelligence test was standardized on adults and consists of a 10 item-groups: comprehension, information, digit-span, arithmetic, similarities, picture arrangement, picture completion, block design, object assembly, and digit-symbol. The intelligence quotient is expressed in terms of percentiles, and the relation of the individual scores of the item groups is clinically meaningful.

(6) Bernreuter Personality Inventory. This self-administered test contains 125 questions and is variously scored to measure neurotic tendencies, self-sufficiency, introversion-extroversion, dominance-submission, self-confidence, and sociability.

The conditions under which the tests were administered deserve mention. Neither of the two dual personalities was acquainted with Dr. Rapaport, nor did they know that a study of them was planned. Instead, they were introduced to Dr. Rapaport and immediately and arbitrarily inducted into the test situation. This surprise method excluded premeditated test response. I felt that the natural objection and resentment of the subjects toward such an arbitrary procedure would aid in eliciting unguarded, and hence all the more informative, personality reactions and attitudes.

The actual administration of the tests lasted over a period of several days and required a total of more than 24 hours of intensive work in the test situation. Every effort was made to keep the administration of each test under adequately controlled conditions and to secure informative comparisons and contrasts within individual test situations. The tests were administered in the case of Ellen and Mary to the primary personality first and in that of B and A to the secondary personality first.

THE SUBJECTS

The subjects of this investigation are two women in their early twenties, both of whom are successfully employed and regarded by competent observers as decidedly capable and efficient. The one reported upon last year has the primary personality of Ellen and the secondary of Mary. The primary personality of the other is best known as B and her secondary asA.[2]

Ellen and Mary is looked upon by her friends as somewhat difficult, neurotic, and unstable in social adjustments, while B and A is regarded by her friends as decidedly well adjusted and socially able. In both instances, however, the secondary personalities are unknown except to a few selected persons.

TEST FINDINGS

No attempt will be made to present test findings in full detail because of their extent, complexity, and often all too technical character. Instead they will be reserved for publication in the complete report: only a general summary of them is offered here. Before proceeding, however, I wish to interject two cautionary statements so as not to mislead you. First of all, time limitations have compelled us, for brevity and clarity of presentation, to sacrifice cautious, limited, and qualified statements in favor of general, comprehensive, and hence more dogmatic statements. Next, while Dr. Rapaport and I are essentially in agreement in this present interpretation of our data, we both realize that further study and analysis might necessitate revision and further elaboration of our conclusions. For this reason, despite our confidence in our present judgments, such further study is planned.

With these reservations the following general statements may be made:

First, although there were definite test similarities between the primary and secondary personalities of each of the two women, the degree and character of those similarities in the case of Ellen and Mary were not inconsistent with a distinct separateness or, in other words, with the individuality of those primary and secondary personalities. In the case of B and A this distinct separateness was less obvious, and only in view of the unusual consistency of test findings were the results here surprising. In summary, the tests of Ellen and Mary appeared to be comparable to those of two different persons with some similar character traits; those of B and A were comparable to those of a person in two different phases of life.

Second, there was a consistency throughout the tests of each personality within the single tests as well as from one test to the other.

Third, the differences in the test findings between the primary and secondary personalities were greater and the similarities less in the projective personality tests; in the intelligence tests the similarities prevailed and the differences were relatively insignificant.

Fourth, the analyses of the various test findings, which were made by Dr. Rapaport independently of the clinical facts and observations, are in accord with the clinical history of, and my own findings on, each of the various personalities. In brief, investigative findings by means of standardized test procedures, interpreted in accord with established principles, warranted the same general diagnostic and descriptive judgments as did prolonged clinical study.

The test findings concerning the personalities of Ellen and Mary and of B and A may be summarized as follows:

Both Ellen and Mary are neurotic and of a compulsive type. However, while Ellen appears to present a picture of an acute neurosis with features of compulsive doubting and feelings of insufficiency colored by the impulsiveness of an inhibited person, Mary presents the picture of a solution of a severe problem by the formation of a passive, retiring, unconcerned, self-sufficient character. While Ellen thinks in vague generalities and displays rather weak judgment, Mary has, in spite of her interest in extravagances, a ready grasp of the obvious and keen powers of judgment. Ellen shows a great amount of free-floating anxiety and is an intensive daydreamer, with some weak emotional adaptation to her surroundings. Mary is self-sufficient, displaying neither adaptation nor anxieties.

Ellen's I.Q. is 126 and her percentile score is 98, placing her in the superior intelligence group; Mary's I.Q. is 113 and her percentile score is 82, putting her into the bright-normal intelligence group. The scatter in the tests is strikingly similar, however, where intellectual maturity is of importance. For example, in conceptual problems Ellen is

decidedly superior to Mary, but where emotional stability is crucial for the performance, as in concentration and attention, Mary is the superior. Similarly, in general mental efficiency Ellen is superior, but in immediate memory Mary is the better.

B and A are essentially introversive. While the tests of A appear to indicate a rather well-balanced personality, B's test results are such as would be predicted if A were to lose her balance and suffer a neurotic break. The findings are somewhat similar to those that might be found in a neurosis of mixed obsessive and hysteriform symptoms.

In personality makeup, however, B and A are quite similar. They are both rich in fantasies; both are very able and have manifold interests; both reveal a strong striving to adapt themselves to their environment, and in this striving both reveal considerable intellectualization of their adaptations—in other words, quite a bit of unfree, cautious adaptation. Both are interested in fellow human beings to an unusually strong degree. There are, naturally, differences in the degree and even in the quality of these similarities. A's psychomotility is less vivid and more constructive than B's, whose fantasy has frequently a fabulatory touch. Both have manifold interests, although much more so for A; B's diversity of interests has a touch of flightiness. The striving toward adaptation is strong in both, but B is impulsive in spite of this, while A is pliant to an unusual degree. And both have an unusual interest in people, though B's interest is loaded with quite a bit of insecurity and even fear.

In spite of her difficulties B has more sense of detail than A, who has a rather strong tendency to generalize. In spite of this B, for all her sense for detail, reveals less common sense than does A in her generalizations. Correspondingly, the judgment and logic of B is uneven and undependable, while that of A is rather stable. In spite of these discrepancies the intelligence makeup of the two girls is still very similar, and compared with the average they are both very inclined to make generalizations making use of their unusually good natural endowment.

B's I. Q. is 139 and her percentile score is 99. The I. Q. of A is 136 and her percentile score is 99, so that both are in the very superior intelligence group. The tests are very similar in score distribution and verbalization, in only one item requiring concentration does B fall much below A, even though A took the test first. The efficiency indexes of the two personalities are strikingly parallel, but with those of A on a lower level.

CONCLUSIONS

1. The testing of the two dual personalities appears to corroborate the fact that we deal here with a clinically unusual phenomenon. The two persons in question each appear to have organized their past experiences into two different patterns and to react alternatingly, now on the basis of one and now on the basis of the other pattern. These patterns differ more significantly for the one than for the other person. The reactions on the basis of these patterns are significantly different in the emotional sphere and much less so if the reaction in question is of a cognitive nature.

2. The test findings are in accord with the clinical histories. They appear to contradict the general assumption that the phenomenon of dual personality is a hysterical manifestation, since both these personalities were found to be rather of a compulsive-obsessional type. The findings appear rather to give weight to Oberndorf's assertion that co-conscious mentation is an obsessional disassociation phenomenon.

3. Although no explanatory account as to the genesis and nature of dual personality is offered here, it is hoped that the description of these phenomena of personality organization will contribute to the theory of personality organization in general.

RORSCHACH TEST

Comparative report of the tests of B and A

Test given to A Sept. 17, 8:35 P.M.; to B Sept. 18, 11:40 A.M.)

I. *Reaction time*.
There was no consistent relation between the reaction times of B and A. At times that of one, and at others that of the other, appeared to be the longer. In the third card, for instance, A took the test as first, had a reaction time of 40 seconds, and gave a rather weak response; B took the test as second, had a reaction time of 10 seconds, and gave a more elaborate and better response and an additional other response. No evidence can be thus derived from the reaction times that would speak against the phenomenon of double personality.

II. *Type of personalities*.
(*a*) A appears to be a rather healthy person, while B appears to be quite neurotic. The main indicators of this neurosis appear to be the impulsive color responses, the extremely low animal percentage, and the low Form plus percentage. The neurosis of B is a mixed one in which one would expect to find symptoms belonging to hysteriform as well as to psychastenic syndromes. The former should be prevalent, and as the movement responses are numerous, one would expect rather ideational and characterological than conversion symptoms.

(*b*) As to the personality makeup, however, B and A are quite similar. They both are rich in fantasies, are very able, and have manifold interests; both reveal a strong striving to adapt themselves to their environment, and in this striving both reveal considerable intellectualization of their adaptations—in other words, quite a bit of unfree, cautious adaptation. Both are interested in fellow humans to an unusually great degree. There are, naturally, differences in degree and even in quality in these similar features. A's psychomotility is less vivid and more constructive than B's, whose fantasy has frequently a fabulatory touch. It is true that both have manifold interests, but A much less than B, in whose diversity of interests there is a touch of flightiness. It is true that the striving toward adaptation is strong in both, but B is impulsive in spite of this, while A is pliant to an unusual degree. It is true that both have an unusual interest in fellow humans, but the interest of B is loaded with quite a bit of insecurity and even fear of humans. B's protocol

has quite a few anxiety indications, while A's has nearly none. However, both show an equal number of space responses, which in B's protocol ought to be interpreted as outwardly directed oppositional tendencies as well as doubts, while in A's protocol they ought to be interpreted as self-willedness and perhaps some doubt.

3. *Type of intelligence*. In spite of her difficulties, B has more sense for the obvious than A, who has a rather strong tendency to generalize. In spite of this B reveals with all her sense for the detail less common sense than does A in her generalizations. Correspondingly, the judgment and logic of B is uneven and undependable, while that of A is rather stable. In spite of these discrepancies the intelligence makeup of the two women is still very similar, and compared with the average they are both very inclined to make generalizations, making use of their unusually good natural endowment.

SZONDI TEST

Comparative report of the tests of B and A

(Test given Sept. 17, 8:15 P.M. to A; Sept. 18, 11:20 A.M. to B)

I. *Attitude toward the test*.
Both women were very cooperative and apparently liked to take the test. Some uneasiness and anxiousness was, however, observed in the behavior of B.

II. *Personality of B and A*.
The manic column, which usually corresponds to the oral tendencies of the subjects, is the only one that is equal in B and A. Both women appeared to have a rather significant oral dependent tendency, although a part of this is channeled and controlled. A appears to be childish, energetic, somewhat aggressive, but not neurotic. B is full of ambivalences and of extremely strong anxieties, giving a decidedly neurotic picture, resembling neurastenic-psychastenic neuroses. B has a mood coloring that might be called depressive and a fantasy life that is extremely vivid and most probably full of the anxieties indicated above and of the ambivalence conflict as to her aggressions. A has a much more stable mood life and a vivid but balanced and most probably not morbid fantasy life.

BELLEVUE TEST

Comparative report of tests given to B and A

(Test given to A Sept. 17, 9:30 A.M.; to B Sept. 18, 4:30 P.M.)

1. B's verbal score was two points lower than that of A (73, 75). B's performance score was higher than that of A (80 and 74). The relation of the I.Q.s is similar:

	I.Q.			***Percentile Score***			***Intee. group***
	V	***P***	***Total***	***V***	***P***	***Total***	***VP Total***
A	**133**	**134**	**136**	**99**	**99**	**99**	**very superior**
B	**131**	**142**	**139**	**99**	**99**	**99**	**very superior**

It is hard to understand how the verbal average of A can be higher, even if slightly, than that of B. The scatter gives to this an answer inasmuch as the digits backward of B is significantly below her own level and also much lower than that of A. This should correspond with a general difficulty of concentration. Except for this one significant score, there are no significant differences either in verbalization or in scores in these two tests.

BABCOCK DETERIORATION TEST

Comparative Report of Tests Given to B and A

(Test given to B Sept. 19, 1940, 3:40 P.M., to A Sept. 19, 1940, 5:30 P.M.)

ITEMS:

	A	**B**
Immediate memory for a story	**20**	**18**
Symbol digit test	**16.5**	**16.5**
Immediate memory for digits forward	**19**	**19**
Immediate memory for digits backward	**18**	**12**
Speed of writing	**16.5**	**9**
Speed of tracing	**12.5**	**14**
Delayed memory for a story	**21**	**17**
Learning of paired associates	**19.5**	**20.5**
Memory span for sentences	**19**	**20.5**
Total	***162***	***146.5***
Vocabulary age	**20**	**20**
Total test score average	**18**	**16.3**
Learning score average	**19.2**	**18**
Motor score average	**15.2**	**13.2**
Repetition score average	**18.7**	**17.2**
Deviations from Babcock's norms		
For the total average	**+0.6**	**-1.1**
For learning	**+2.7**	**+1.5**
Motor	**-1.4**	**-3.4**
Repetition	**+2.4**	**+0.9**

(*a*) The mental efficiency of B appears to be good with an especially good learning efficiency. Peculiarly, however, her motor efficiency is rather weak, and this is a sign she has in common with A, whose motor efficiency appears to be extremely poor. It is noteworthy that in the comparison of M and L we found similar interrelations. The general mental efficiency of A appears to be poor, which is most likely due to her extremely poor motor efficiency, while her learning efficiency is very good. In general one might say that the efficiency indicators of B and A run perfectly parallel, except that A's is on a quite lower level than that of B's. On this point there is a deviation from the findings of M and L,[3] where only the motor and immediate memory scores were parallel, while the learning scores were significantly deviating from each other.

(*b*) The five reaction times of the symbol digit test for B and A are as follows:

B	**11.5**	**1.5**	**11.5**	**16**	**15.5**
A	**13**	**14**	**12**	**17**	**16**

The parallelism of the scores' sequences, which might be interpreted as work or fatigue patterns of the women, is thus extremely similar.

(*c*) The handwriting of the two women does not appear to be different for the observer unschooled in graphology. It is peculiar also that A has a very long writing time while her speed of tracing is better than that of B. However, this could be easily explained by considering the fact that A hasn't had much experience in writing; in tracing, where experience counts less than security, she can do better.

RORSCHACH TEST

Comparative Report of the Tests of L and M

(Test of L given Sept. 16, 1940, 10 A.M.; test of M given Sept. 17, 1940, 9:30 A.M.)

I. *Attitude to the Test*.
Neither of the women liked the test. Both seemed to be puzzled by it. However, M gave more clear-cut expression of her dislike than did L.

L's *reaction times* have been fairly long (30.4 sec. average), ranging from 13 to 65 seconds. M's reaction times, however, have been extremely long (98.5 sec. average), ranging from 25 to 240 seconds. For the first one might suggest that M had a hard time finding other responses than did L, and even L took her time in order to weigh carefully what she should say and what to leave for M. It is true that they have only one response in common, and even the spaces chosen for the other responses are different. But closer investigation reveals quite a few facts that are not consistent with such an explanation: (*1*) both girls give a constricted protocol indicative of inhibited personalities, M more so than L. In such cases an elongation of the reaction time is a common fact. The measure of constriction in L and M compares favorably with the reaction time in their protocols. (*2*) As we will see below, the scoring shows a rather systematic difference in the spaces chosen by L and M, which could have been hard to produce by any conscious plan. (*3*) The answer occurring in both of the protocols is the most frequent Rorschach response. Its appearance in both protocols pleads for the genuineness of the differences.

II. *Personality of L and M*.
(*1*) Both women are neurotic, L significantly more so than M. Their neurosis is, however, rather of a compulsive type with psychasthenic features. In L the psychasthenic and compulsive doubt-features prevail. The doubts are directed against herself, taking the form of feelings of insufficiency and inhibitedness in spite of her impulsive ideas. M is rather passive (more than L) and evasive, interested in extravagancies, unusual things.

(*2*) L favors vague generalities and is lacking a sense of the obvious. M avoids generalizations and has a rather lucky grasp for the obvious, in spite of her interest in the unusual. Paradoxically, L, who lives (according to information) steadily exposed to community, shares the way of thinking of the community to a much lesser degree than M does. The same appears to be true for the keenness of logical judgment. L is here again decidedly weaker than M.

(*3*) M and L are both interested in fellow humans, but simultaneously both are shy and somewhat afraid of them. M is the one who is more interested and more withholding than the other.

(*4*) Both women are intelligent, but in the meantime quite stereotyped in their interests. M is the less stereotyped and more intelligent.

(*5*) L shows a great amount of free-floating anxiety, is a very strong daydreamer, but displays some, although very weak, affective adaptation. M is rather closed within herself, displaying neither adaptation nor anxieties.

(*6*) The two movement responses of L (as movement responses do in general) probably reveal some contents significant of this woman: (*a*) ". . . impression of pair of very large shoes walking in duck-fashion ... actually the whole thing might be a gorilla." (*b*) ". . . I can vaguely outline a couple of fat people ... or animals ... they are apes ... their faces turned back over their shoulders, holding onto a cliff." Two features of these responses should be especially remarkable: (a) in both the response starts with human beings which turn immediately into animals; (*b*) the character of these movements—namely, "walking in duck-fashion" and "holding onto a cliff"—should describe L herself.

SZONDI TEST

Comparative Report of the Tests of L and M

(Test of L given Sept. 16, 1940, 9:30 A.M.; test of M given Sept. 17, 1940, 9.A.M.)

I. *Attitude toward the test*.
Both women seemed to be somewhat reticent toward the test. Both commented that hardly any of the pictures appealed to them. While L commented frequently on this and on individual pictures, M was rather silent, and every choice took her a long time. When asked about her silence, she said: "I speak only if I have something to say.... This does not inspire conversation."

II. *Personality of L and M*.
(*1*) The number and distribution of choices in the catatonic column, which usually designate the narcissism and degree of withdrawal of the subject, represent the only area that is identical in M and L. It is the experience, however, that when a subject is retested

with this test, the catatonic column is the one most apt to remain unchanged. Thus, the tests relate to each other as if they were representing two sides of the same personality; these two tests have the same thing in common as the Rorschach tests, which were both constricted, including few responses, long reaction times, and, with few exceptions, only form-responses. The Szondi tests are also those of inhibited persons. In most of other respects, however, the two subjects give a quite different record.

(*2*) L appears to be severely neurotic, very impulsive, with strong anxieties, infantile in her sexuality in a manner that probably makes her ready to assert her womanhood by being ready for "passing affairs." To what actual behavior such a readiness in an inhibited person might lead is hard to foretell. M is practically within the range of the normal, although inhibited, and carrying a definite number of bottled-up anxieties.

(*3*) L is civilized and controls her aggressions, while M is aggressive but has something that could be called culture.

(*4*) L is an anal character (probably expulsive), with a very strong oral-dependent tendency. In M oral and anal tendencies appear to be rather channelized.

(*5*) L's empty epileptic column and M's two "most liked" epileptic choices refer probably to another interrelation of the two personalities, which is at present not clear to me. However, as similar interrelations occur in B and A, it might be that certain "epileptoid" trends have to do with the occurrence of such phenomena as that of L and M, B and A.

THEMATIC APPERCEPTION TEST

Comparative Report of the Tests of L and M

(Test of M given Sept. 17, 1940, 3:15 P.M.; test of L given Sept. 18, 1940, 8:45 A.M.)

I. *Attitude toward the test*.
On the surface both girls showed a rather agreeable reaction to the test. In fact, however, both attempted, and not without success, to disregard the test instructions.

II. *Formal characteristics of the fantasies*.
(*1*) Both subjects stated that they had once taken the test.

(*2*) M's fantasies can hardly be called such. Rather, they are descriptions, embellished mostly with some very matter-of-fact connecting story. Such an attitude would be consistent with her Rorschach test and is frequently found in inhibited but matter-of-fact normals, being concise and abrupt.

(*3*) L's fantasies could be called fantasies with some right. She gives stories, and these stories frequently even disregard the picture. These stories, however, very frequently are taken from tales or some history material and have a sarcastic, scoffing narrative—as if

she would demonstrate with her sarcasm, “You see, one can tell stories without committing oneself.”

(*4*) Peculiarly, however, in two fantasies (12th and 13th) M takes over the sarcastic, or the fantastic, trend of L’s narrative. This occurrence is striking and cannot be disregarded. Its explanation, however, is beyond the scope of the test material.

III. *Contents of fantasies*.
(*A*) *M’s fantasies*.

(*1*) Concerning sex: they are dancing, she is uninterested ... will dance with someone else; a man is defending his sister against his mother; young woman is going to marry someone; the mother did not want her to marry; her husband died, she is crying ... does not want her to leave, she will go, they quarreled. A rather disinterested, neutral, somewhat scoffing attitude.

(2) Concerning parents: they appear very rarely in the fantasies. A disapproving, stern mother who is beating the father, scolding the daughter, and disapproving of the daughter’s plan of marriage.

(*3*) Aggression: a mean old man buried all his friends either actually or in imagination ... his departure will doubtless cause much rejoicing; woman strangles another woman, halfway, because the other was reading her mail; a man murdered, while drunk, his wife, he will go to prison. Self-directed: a prick with a needle results in poisoning and death; lack of money results in suicide.

(*B*) L’s fantasies.

(*1*) Dependency: Disappointed little girl weeping into her father’s ear—he consoles her; princess, sacrificed to a dragon, is saved by a noble prince; asks for a new dress from mother to go to her first ball.

(*2*) Concerning sex: man torn between duty and desire, between homely wife and beautiful mistress; the outcome is a mess; mother scolds the daughter, asks why she was out last night with Parsifal and not with Mike; she will marry P and always wish she would have married M; a maid comments: my goodness, the way they are carrying on there they ought to be ashamed of themselves ... at his age too—oh, well—there is no fool like an old fool; man slept with a girl, wishes he hadn’t, feels rejected, commits suicide, she wakes up and says: “Now, what did you do that for? Wasn’t it silly” —and she will find herself someone else. These fantasies are quite consistent with her psychosexual immaturity as characterized by the Szondi test.

(*3*) Parents: Father appears to be a consoling figure; the mother figures, however, are in steady quarrel with her.

(*4*) Toward herself: she describes herself as ineffectual, in a nightmare-like fear of remaining alone in the world, as disappointed and reaching out for help, as the princess who will be saved by the prince of dreams, as an orphan who will be cared for by the aunt. Concerning money: she is richly married and gives in depression time 10 dollars to his brother to get rid of him; she quarrels with her mother to get a new dress; a man is being hanged for having murdered a man for 2 dollars, he did it for hunger.

IV. *Comparative summary*:
While M is rather indifferent toward sex, L is rather full of strange erotic fantasies indicating her psychosexual immaturity. Neither of them has much interest in parents, but both agree in rejecting the mother figure. Aggressions play a significant role in both, but in L's fantasies they have a rather anal coloring. In one fantasy of M's similar motivation of suicide appears to be present. While M remains in these fantasies noncommittal concerning her attitude to herself, L describes herself as an ineffectual person in need of help, dependence, despaired. While M appears here again to be rather realistic, L is rather fantastic in her fantasies, but the fantasies are frequently borrowed from historical or literature sources.

BELLEVUE ADULT INTELLIGENCE SCALE

Comparison of tests.

(L, given Sept. 16, 1940, 1;35 P.M.; M, given Sept. 17, 1940, 11. A.M

I. *The numerical results*

Scores	*L*	*M*
Intelligence Quotient	**126**	**113**
Percentile score:	**98%**	**82%**
Verbal I.Q.:	**129**	**115**
Percentile score	**99%**	**85%**
Performance I.Q,	**119**	**109**
Percentile score:	**91%**	**73%**

These numerical results indicate that L has a higher I.Q. than M. L's total I.Q. is "superior," her verbal I.Q. "very superior," and her performance I.Q. on the borderline of "bright normal" and "superior." M's total I.Q. is "bright normal," and so is her verbal I.Q.; her performance I.Q., however, is only "high average."

It is obvious that the distribution of scores of L and M are strikingly parallel. There appears to be no qualitative difference between the two distributions. L and M are both somewhat weaker in performance items. Two possible conclusions could explain this fact. One would maintain that the formal intelligence structure of the two personalities does not differ much, because M achieved gradually but not completely the knowledge of L. The other explanation would maintain that the intelligence test shows that there are not

two intellects present, that the same intellect was measured under different conditions and with a different degree of cooperation on the side of the subject.

II. *Attitude toward the test*:
(*1*) Concerning the information items, M frequently declared (in 18 cases) that she did not know the answer but she could ask L. This was refused, and thus in the scattergram the information item was excluded. The verbal part of the I.Q. thus was computed taking 5/a of the sum of the other four item scores.

(*2*) In the comprehension and similarity items M assumed frequently a very naive attitude that was strikingly different from her other responses, and it was not quite obvious why she was able to give an informed and mature response to some questions, while others were answered in a perfectly childish way. While the similarities of orange and banana, coat and dress, dog and lion, eye and ear, etc., are answered on a high level—properly, just like L answered them—the wagon and bicycle similarity is explained by L "both vehicles," and is explained by M, "both have wheels," or the egg and seed similarity, by L, "they are the embryonic state, one of a chicken, the other of a plant," and by M, "plant a seed—a plant grows; have an egg—a bird grows." While L would mail the letter she finds sealed, stamped, and addressed, M would pick it up and put it down where people would not step on it. But, in a strikingly reversed way, L thinks that people should pay taxes because "each of us cannot run the country by himself, so by paying taxes those appointed can run it," while according to M, payment of taxes "supports the government." These and similar responses constitute a barely understandable set of interrelations. It is hard to understand, for instance, why M knows about the government, while she does not know anything about the nature of letters.

III. *Scatter*.
(*a*) Verbal item average for both girls is slightly better than performance item average.

(*b*) Among the verbal items the lowest scores for both girls are the comprehension and arithmetic score. The highest score in both is similarity—this in spite of the significantly lower scores of M.

(*c*) Among the performance items the highest score for both girls is the digit-symbol score. Peculiarly, however, while L's lowest score is the picture completion (10), M's picture completion score is fairly high (12); and her lowest item is the object assembly, which was the second lowest for L.

This scatter distribution shows extremely strong similarity in the intellectual makeup of the two women, except for the better concentration of M, shown in the picture completion. In spite of these similarities, however, the whole performance behavior and activity was strikingly different for the two women. These differences do not imply only formal behavior; they imply rather different attitudes to the test items and different approaches to them, which are very tangibly put down in a test record.

BABCOCK DETERIORATION TEST

Comparison of tests.

(L, given Sept. 16, 3:30 P.M.; M, given September 17, 1940, 4:10 P.M

ITEMS:	M	L
Immediate memory for a story	**14**	**19**
Symbol digit test	**16**	**16**
Immediate memory for digits forward	**14**	**18**
Immediate memory for digits backward	**19**	**19**
Speed of writing	**9.5**	**16**
Speed of tracing	**13**	**11**
Delayed memory for a story	**13**	**21**
Learning of paired associates	**8.5**	**13.5**
Memory span for sentences	**23**	**23**
Total	**130**	**165.5**
Vocabulary age	**15**	**18**
Total test score average	**14.4**	**17.4**
Learning score average	**12.9**	**17.4**
Motor learning average	**12.8**	**14.3**
Repetition score average	**18.6**	**20**
***Deviations from Babcock's norms*:**		
For the total average	**-0.6**	**+1.4**
For learning	**-2.6**	**+1.4**
Motor	**-2.2**	**-1.7**
Repetition	**+4.9**	**+4.4**

(*a*) The difference in scores would indicate that M's general mental efficiency is rather weak, her learning abilities extremely poor, and the motor efficiency of both women extremely poor. The learning score of M appears to be, however, quite contradictory to her whole performance in the different tests.

(*b*) The handwriting of the two women does not appear to me to be significantly different. M's handwriting of the sentence in 19.3 seconds seems to be a slow calligraphic writing, extremely similar to that of L.

(*c*) The symbol digit test has five rows of symbols, and they were measured as to performance time separately. While L's speed improves in the course of the work, M's speed drops.

(*d*) The paired associate learning is very weak in both cases.

(*e*) The speed of tracing of M is better than that of L.

A Clinical Note on a Word-Association Test

Milton H. Erickson

Reprinted with permission from *The Journal of Nervous and Mental Disease*,
Nov., 1936, Vol. 84, No. 5.

The usefulness of the word-association test in detecting the presence of concealed or repressed memories is well recognized. Usually, however, the results obtained are indicative only of possible avenues for exploration, and it is customary to resort to other techniques to obtain more information. In the following account an instance is reported wherein the word-association test served not only to indicate the presence of a repressed or concealed memory, but also, upon repeated administrations of the test, to elicit, in one-word summaries, the entire sequence of events in the unhappy memory. The situation leading to this finding was as follows:

Experimental work was being done on the constancy of responses to the words of an association test in which lapse of time and hypnosis were employed as variants. The procedure was essentially to give the subject a carefully selected list of words in the normal waking state and then the next day to repeat the test with the subject in a deep hynotic trance. Following this, at intervals of one to three days, the test was repeated in either the waking or the hypnotic state until it had been given seven times. One subject employed was a 25-year-old, single, white female. At the time of the first administration of the test, it was noted that the subject showed a very long reaction time to the stimulus word *stomach* and had shifted her position uneasily. It was thought immediately that this behavior indicated possibly a repressed complex, but before the test could be continued, the subject spontaneously explained that at the previous meal she had overeaten and still felt her stomach to be uncomfortably distended. No additional significance was attached to this matter, although it was noted that on subsequent administrations of the test she still showed a long reaction time and tended to shift her position uneasily. This continuance of her original behavior was considered to be possibly nothing more than a conditioning occasioned by the original setting, especially since the subject gave only casual explanations for her replies when questioned later and always listened to the word *stomach* with an amused smile. Unfortunately, no record was made of her rationalizations at the time, since no apparently unusual explanations were given.

Several months after the completion of the test, but before the data had been analyzed, this subject made a confidant of the author, explaining that several years previously she had had a love affair which had resulted in a pregnancy. As she related this story, she declared that her first intimation of this pregnancy had been “the enlargement of my abdomen” since her menstrual cycle was most irregular. This “worried me just terribly,” and upon seeking medical aid she had been advised that she “was going to have a baby.” This “made me awfully afraid,” and she had decided to meet the situation “by having an

operation done. I was awfully sick afterward—I thought I was going to die. When I finally got well, I just forgot about it all, but during the last couple of weeks it's come back to me and I felt like talking about it to you." She could give no explanation of why she had revived that memory, nor was there any thought at the time that there could he any possible relationship between this story and her responses on the word-association test. Further, the subject had never had an opportunity to read her responses on the tests.

Subsequently, in analyzing the data obtained from the experimental procedure, the sequence of responses to the word *stomach* and the states in which they were obtained were found to be as follows:

Response Word	*Mental State*	*Reaction Time in Seconds*	*Day*
(1) Big	**Hypnotic**	**6**	**Mon.**
(2) Worried	**Waking**	**5**	**Tues.**
(3) Baby	**Hypnotic**	**4**	**Fri.**
(4) Afraid	**Waking**	**6**	**Sat.**
(5) Operation	**Waking**	**6**	**Tues.**
(6) Sick	**Hypnotic**	**4**	**Wed.**
(7) Forgotten	**Waking**	**3**	**Sat.**

The paralleling of the response words and the actual story is at once obvious. Consideration of the response words alone requires no imagination to construct the entire story. Almost identical terms were used in both instances and in the same sequence, despite the lapse of time intervening between the experimental and the personal situations and the absence of any conscious realization that there existed any relationship between the two situations. This verbal rigidity is suggestive of the emotional intensity of the problem and the need of adhering to a definite method of approach to it.

More remarkable, however, is the peculiar persistence manifested in the disclosure of the complex material during the experimental situation. The induction of a deep hypnotic trance was apparently without any effect upon her unconscious emotional problem. Neither did the intervention of nonexperimental days seem to modify the emotional needs aroused by the fortunate coincidence which occurred during the first test. One may conjecture that the initial setting of a gastric indiscretion resulting in abdominal distress and distension constituted a most favorable background for the revival of the originally repressed material. The nature of that setting permitted easy rationalization, thereby obviating any need for defense or disguise mechanisms. Thus, a train of associations was stimulated into action and was conditioned to a certain limited method of expression. In consequence, it manifested itself progressively at each properly offered opportunity. Evidently, to judge from the course of development of the personal situation, the strength of the emotions involved exercised a compelling force upon the subject, causing her to seek relief from her problem by confiding it to someone. She had done this in the experimental situation, but in such a fashion that only partial emotional satisfaction had been obtained. This relief had sufficed for a time, but finally, because of its inadequacy, the problem became acute, causing her to recall it consciously and to seek a more complete catharsis by confiding it again in a direct fashion to the same person.

Study of Hypnotically Induced Complexes By Means of the Luria Technique

Paul E. Huston, David Shakow,
and Milton H. Erickson[1]

Reprinted with permission from *The Journal of General Psychology*, 1934, Vol. 11, pp. 65-97.

INTRODUCTION

Recently Luria (Lebedinski & Luria, 1929; Luria, 1929, 1930, 1932) has experimented with a technique which may be applied to the investigation of affective conflicts. This method[2] involves the association of higher central nervous system processes with a voluntary movement so that conflicts in the former are disclosed in the latter. Experimentally the central processes are activated by the verbal stimuli of an association test, the subject being instructed to make a slight pressure with his preferred hand on a tambour simultaneously with every verbal response. If the verbal stimuli do not arouse affective conflicts, the voluntary pressures are regular in character, but if a conflict is aroused, the pressure curves become irregular. Luria explains this effect as follows: Having trained a subject to associate a motor response of the preferred hand with every verbal response, thereby establishing a close functional relationship between them, [3] any word occurring to the subject which he does not give as a response will appear in the voluntary movement as a partial reaction. It is assumed here that the inhibition of the verbal response is associated with affect, i.e., the subject does not respond with the first word since some complex would be revealed. Also the pressure curve may lose its smooth regular character or, to follow the Luria terminology more closely, the normal, voluntary movement is discoordinated or disorganized because stimuli which elicit responses possessing affect may also arouse larger amounts of excitation than stimuli eliciting nonaffective responses. This excitation tends to discharge itself immediately via the voluntary motor pathway. Luria has referred to this tendency as the "law of the catalytic action of the stimulus." This law appears to be a corollary of another, the "law of the decreased action of the functional barrier." The functional barrier is a cortical property. It regulates by inhibition the motor activities of the organism, giving them an integrated character. Affective excitation weakens the functional barrier, and hence the motor activities become disorganized. A third law is that of the "mobilization of inadequate masses of excitation." This seems to involve "neurodynamical perseveration." The excitation which accompanies the affect is not always discharged completely via the verbal response, hence some movements will persist in the preferred hand after the voluntary response. Under conditions of large amounts of excitation a further spread to other motor systems may occur—for example, disturbing respiration and/or causing involuntary movements of the non-preferred hand. [4]

It is not our purpose to review the numerous experiments reported by Luria upon which these so-called laws are based. We were interested primarily in the possibilities of the Luria technique for obtaining information about the affective conflicts of a subject and for its possible application to psychotic patients. For this purpose we repeated, as part of an exploratory procedure, one of his important experiments, that of the attempted induction of a conflict in a subject by means of hypnosis. Such a procedure affords the opportunity of examining a subject before, during, and after the establishment of a conflict.

To produce a conflict in a subject Luria fabricated a story of a reproachable act committed by the subject—an act which would be contrary to the subject's usual personality trends. A number of critical words were taken from this story and placed in a list of control words which were not specific to the story. The total list was presented in the setting of a free discrete association procedure. The subject was required to press with his preferred hand on a tambour with each verbal response. He was then hypnotized, and the story recounted to him. After this he was awakened and the combined word-association and motor-response method was repeated. Under hypnosis the conflict was removed. This was followed by a waking control session. If the theory and technique are valid, the critical words should show discoordinated voluntary pressure curves as compared with those of the control words. This assumes, of course, that the suggested story was accepted by the subject, that a conflict was produced in him, and that it had been removed successfully. In addition to the voluntary pressure curves Luria recorded verbal reaction times and in some cases involuntary movements from the nonpreferred hand and respiration. All were recorded on an ordinary kymograph.

APPARATUS, TECHNIQUE, AND POPULATION

This was the experiment[5] which we repeated with some modifications. Luria's list usually contained 20 to 30 words with six to nine "critical" words. We used 100 words, including 10 taken from the fictitious story, to avoid, if possible, perseveration effects and to give more control material. Furthermore, the "critical" words were separated by seven to ten control words, whereas Luria often placed two or three "critical" words together. In addition, hypnotic control experiments were introduced, and in some cases the control and the "complex" sessions were repeated to study the effects of hypnosis and of repetition per se. By way of definition, the term complex is used as referring to the story of a reproachable act committed by the subject intended to produce an affective disturbance or conflict in him.

Four male and eight female subjects between the ages of 20 to 30 years were used. This group consisted of four medical interns, two graduate students in psychology, two nurses, two occupational therapists, and two college graduates doing special work about the hospital. All were well-trained hypnotic subjects and fairly well known to us. None of them had any knowledge of the Luria theory or technique. We shall present in detail the complex, the experimental procedure, and the results on one subject. The results obtained on the other subjects will then be summarized.

DETAILED REPORT ON ONE SUBJECT

The complex for the sample subject, a male aged 24, was narrated as an account of his personal experience, and an attempt was made to establish it as a falsification of memory. The story in summary form was as follows: One night, while visiting some friends, he met a girl to whom he was much attracted. During the conversation, attention was called to her new brown silk dress, and she explained that, although not able to afford it, she had bought the dress hoping to make a good appearance when applying for employment. He gave her a cigarette and lighted one also. While smoking, he noticed the smell of burning cloth occasioned by contact of his cigarette with the girl's dress. Unobtrusively he withdrew his hand, noting with relief that the girl had not yet noticed the accident and that she held her own cigarette above the burned hole. The girl soon became aware of the damage. She attributed it, however, to a spark from her own cigarette. He tried to take the blame by assuming the responsibility of having given her the cigarette, but the girl refused his apparent generosity. The next day, by which time he had summoned up enough courage to tell her the truth in order to save his self-respect, he found that she had left the city.

From this account ten words: *silk, dress, brown, cigarette, burned, hole, blame, damage, smell, self-respect,* were selected as "critical" words and placed as Nos. 7, 16, 28, 40, 49, 60, 68, 77, 88, and 98 in the list of words[6] (see Table 1).

In the experimental room the subject reclined on a chaise lounge and rested his fingertips on deep, large tambours, one on each side, the forearms being supported by the wide arms of the chaise lounge.[7] He was instructed to respond to the verbal stimuli of the association test with the first word which came to him and simultaneously with his response to make a downward pressure on the tambour with his preferred hand. Voluntary responses of the preferred hand and such involuntary movements of the nonpreferred hand as might occur, as well as thoracic respiration and verbal reaction time, were recorded on a special long-paper kymograph. The experimenter, seated out of the subject's view, gave the verbal stimuli, wrote down the verbal responses, and marked the verbal reaction time with a telegraph key. A practice series of 20 words, none of which appeared in the experimental list, was first administered in order to establish the association of verbal response with simultaneous voluntary movement of the preferred hand. The list of 100 words was then given in a *waking control session*. After this the subject was hypnotized and the procedure repeated. This was the *hypnotic control session*. At the next experimental period—usually the following day—the subject was hypnotized first, the complex story told to him, and the experiment performed during hypnosis. This constituted a *hypnotic complex session*. The subject was then awakened from the trance, and a *waking complex session* was held. After this the subject was rehypnotized and an attempt made to remove the conflict by giving him insight into the situation and permitting him to understand the falsity of the story. At a third period additional *hypnotic* and *waking control sessions* were held.

In this particular case two hypnotic controls instead of one were obtained after the complex was removed.[8,9] Also the complex was not removed in this subject for 24 hours. That night he slept poorly, awakened with a headache which persisted until the removal

of the complex in the afternoon, had no appetite, was resentful and antagonistic toward the hypnotist, and somewhat uncooperative toward additional hypnosis. He was unable to assign any reason for these manifestations. Throughout the day he gave away his cigarettes and apparently could not enjoy smoking. He rationalized his behavior by the statement that he "guessed" he was giving up the habit. We offer this as evidence that the attempt to induce the conflict produced a profound reaction in the subject.

The results have been analyzed within each session and from session to session. Various aspects of change in the verbal, voluntary, involuntary, and respiratory responses, in reaction time and certain other aspects of behavior such as bodily movement, laughing, sighing, etc., were considered for different word classes. The word classes were the following:

1. *Complex* words the 10 words taken from the story told to the subject.

2. *Complex-Associated—First Type*. These were words which the subject himself apparently connected in some way with the story, as indicated by the verbal responses. For example, in the subject under discussion, the stimulus word *Smooth* (No. 18) elicited the response "rough" in the control sessions and in the waking complex session, but in the hypnotic complex session the response was "silk." To qualify for classification as a Complex-Associated—First Type word the response had to appear to all three of the authors as definitely related to the complex situation, to be one of the words actually used in the complex story, and not to have appeared in any control session prior to the induction of the complex. This criterion for selecting Complex-Associated—First Type words we consider as being conservative and as likely to result in the omission of some items since the same response in control and complex sessions may have a different meaning for the subject. This point will be discussed later.

3. *Natural Complex* words. These were chosen on the basis of our knowledge of the person: and from what he reported when the list was reviewed with him after the conclusion of the experiment. In this particular person they were words which presumably would usually arouse some affect outside of the experimental situation. The stimulus word *fall* (No. 90) was such a one. The subject two years previously had been in an airplane accident in which he had broken an ankle.

4. Reference to Table 1 shows that the same word (No. 90) elicited a response in the first control session which might be connected with such a natural complex, but after the complex induction the responses changed to "light" and "spark," which fact led us to believe that this stimulus word also became related to the complex. Because there were a number of such words which changed in class from one session to another, an additional class was formed, called *Natural Complex + Complex-Associated* words.

5. A *Complex-Associated—Second Type* classification was made on the basis of disturbed nonverbal responses which might be related to the complex story in an

indirect way. We made the assumption here that the technique used did reveal the presence of affect and attempted to see if we could establish some association with the complex story. Sometimes the subject could explain why he responded with the particular word. In either case the stimulus was put into the second type of *Complex-Associated* words. Such information was obtained from the subject after the experiment was finished and the procedure had been explained to him. This was done by examining with him each of the verbal responses.[10] Obviously there re many more possible sources of error in this classification than in the others, and the results therefore must be scrutinized with great care.

6. All the remaining words were called *Neutral*. Our knowledge of each subject's life was not adequate, and the Natural Complex class probably suffers mostly on the side of omission. It is also likely that among the Neutral words are some which should have been classed Natural Complex and Complex-Associated.[11]

Each of these word classes was first analyzed for the number of "disturbances" in the verbal and nonverbal material from session to session. By a "disturbance" in the verbal response is meant any significant word from the complex story which first appears in a complex session, e.g., to the *C* word *brown* (No. 28) the subject's responses for the first control sessions are "eyes" and "color," whereas in the complex sessions the responses are "burn" and "silk"; after the removal of the complex the responses are "white," "color," and "white." Here the responses "burn" and "silk" are rated as verbal disturbances. Because of the criteria set, it is likely that some verbal disturbances may have been omitted, e.g., the response "clothes" to *dress* (No. 16) in Session IV. Since "clothes" appeared in the second control, we did not count the same response in this session as a verbal disturbance. It may have been specific to the complex here and have had an entirely different significance for the subject. In the voluntary, involuntary, and respiratory responses any fairly definite deviation from the normal was counted as a disturbance, after agreement by two of the authors working independently and then combining judgments. If there was disagreement as to the presence of disturbances, the nonverbal response was considered as not disturbed. In the voluntary responses irregularities in the baseline after the stimulus word was given, or in the pressure response, or after the stylus had returned to the baseline but before the next stimulus word was given, were recorded as voluntary disturbances. Figure 1 gives examples of these. Involuntary changes in the nonpreferred hand consisted of either an increase in tremor amplitude or shifts in the baseline. Respiratory changes were those which involved sudden inspirations or expirations or increased depth or rate of breathing. The respiration curve was complicated by the chest movements which accompanied the verbal response, hence these had to be considered when rating respiratory disturbances. A verbal reaction time was considered as disturbed only if it was extremely long.[12,13]

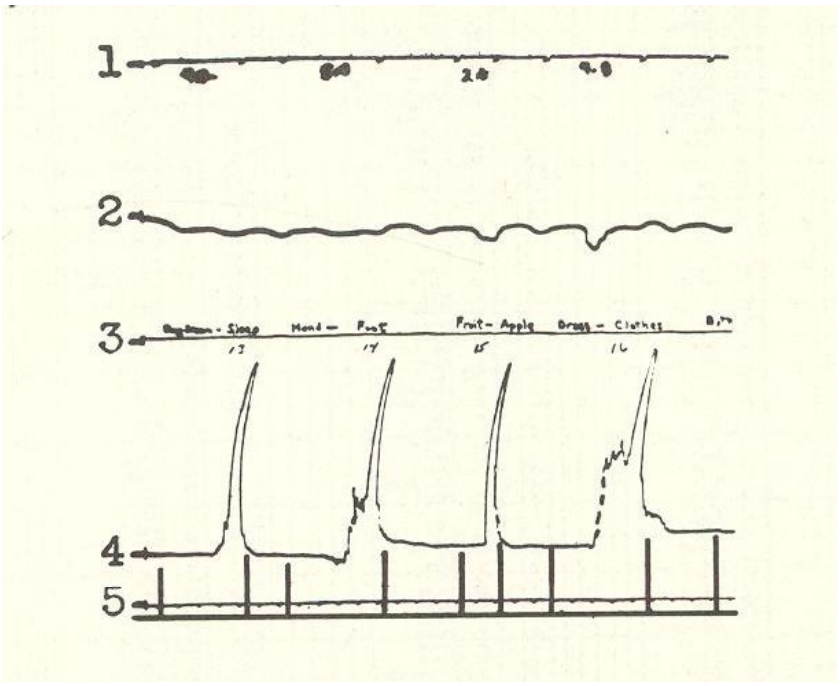

Figure I. This figure is from the waking complex Session IV of the sample subject (No.1). (1) Verbal reaction time. (2) Respiration. (3) Left-hand, involuntary. (4) Right-hand, voluntary. (5) Time in seconds. The voluntary pressures on words Nos. 14 and 16 are disturbed. The respiration line does not show characteristic breathing since the pneumograph was not drawn as tightly about the chest as was the usual practice. The loose adjustment was made in this subject because such large inspirations generally accompanied his respiratory disturbances that the stylus of the recording tambour moved off the kymograph.

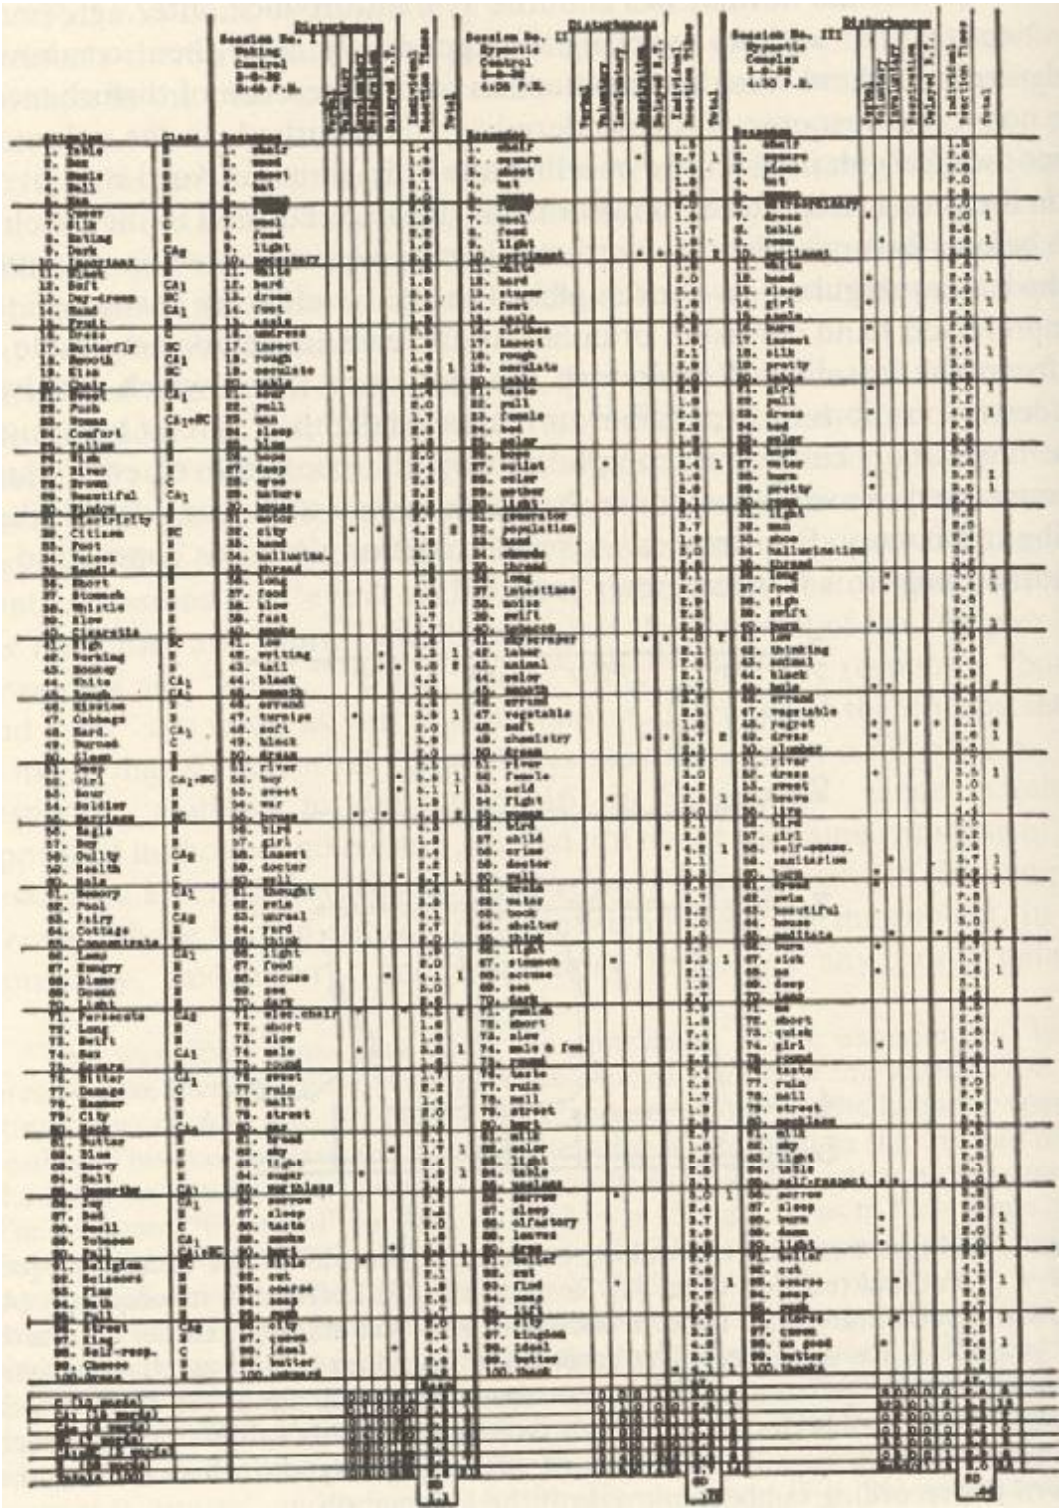

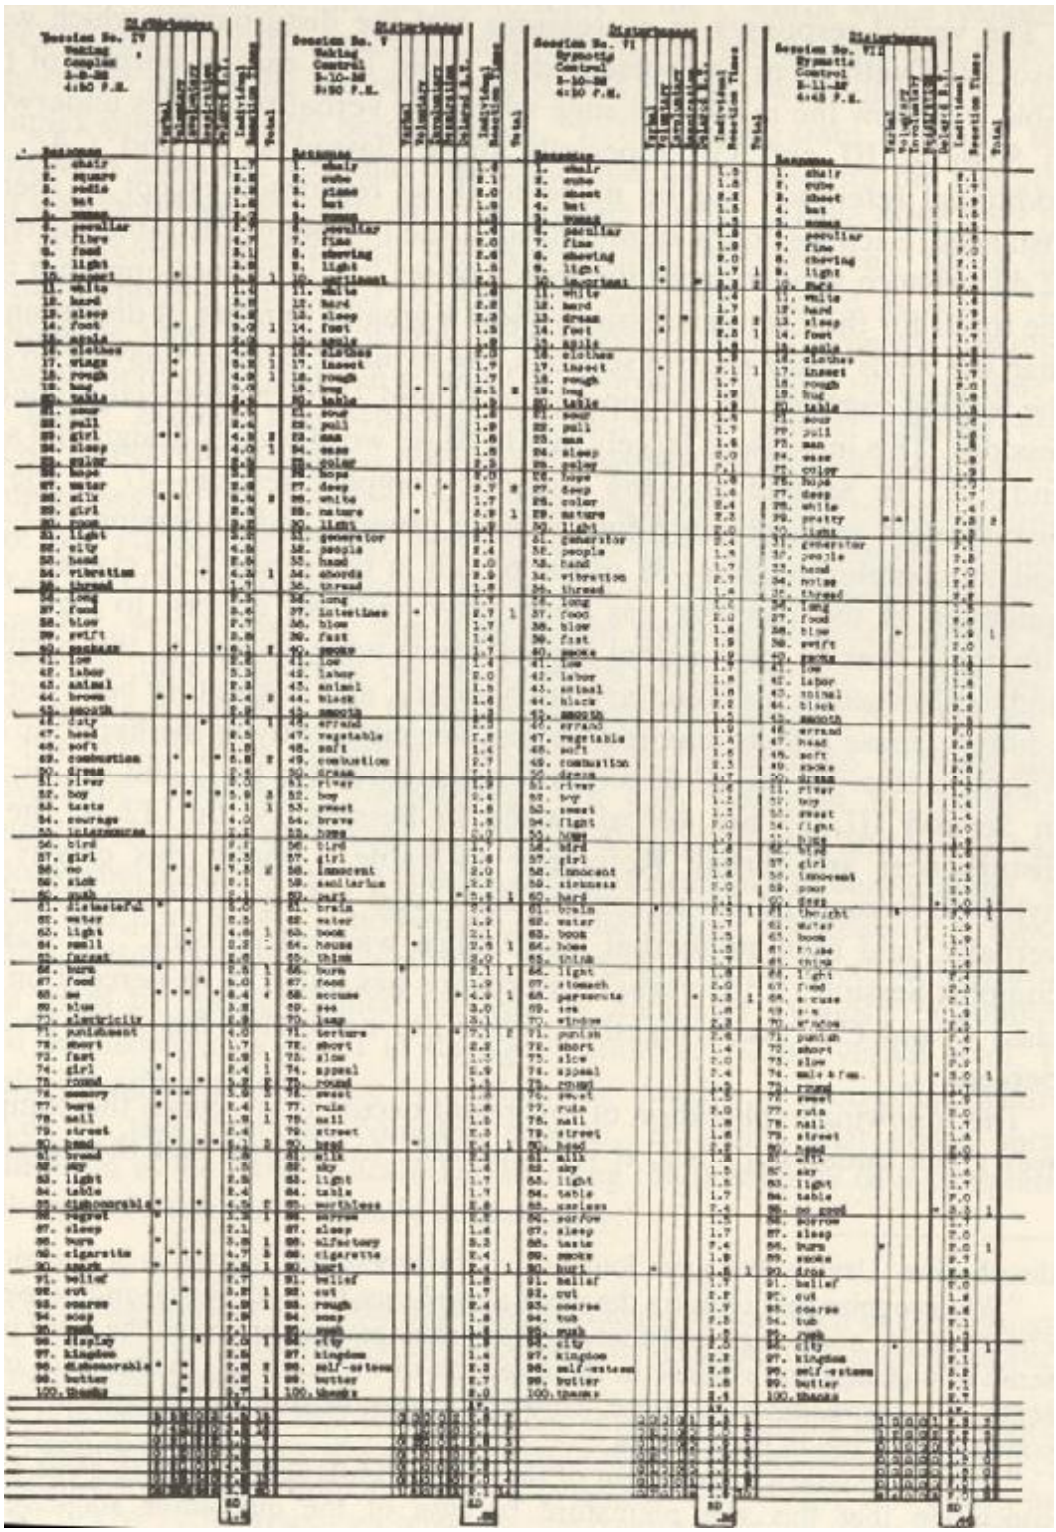

The verbal responses in all sessions and the disturbances which were associated with them are presented in Table 1. A careful perusal of this table will show the marked change which the verbal responses underwent in Sessions III and IV, especially those classed as *C* and CA_1,. No additional reference will be made to these responses except in special instances. Each session is summarized at the bottom of the table for types of disturbance appearing on the word classes. [14] It is at once apparent that the totals for the complex sessions show a greater number of disturbances than the totals of the control sessions, the hypnotic complex having 38 and the waking complex 60, as opposed to 14 and 21 of the respective control sessions. This increase is largely due to those word classes designated as *C* and CA_1. In Session III—the hypnotic complex session—27 of the 38 disturbances are accounted for by these groups, and in Session IV—the waking complex session—31 of the 60 fall in the *C* and CA_1, classes. The induction of the complex has apparently had two effects: to "set" the subject so that he gave verbal replies which were related to the complex and to disorganize his voluntary, involuntary, and respiratory behavior. In addition, these effects manifest themselves differently in the hypnotic and waking states. Of the 27 disturbances accounted for by *C* and CA_1, words in Session III, 21 are verbal, while in Session IV but 12 of the 31 disturbances are verbal. Reference to Table 2 shows this clearly. In hypnotic Session III 84 percent of the *C* and CA_1, words were disturbed verbally, and their nonverbal disturbance was 5.3 percent.[15] In waking complex Session IV the verbal disturbance has fallen to 48 percent on the class *C* and CA_1, taken together, while the nonverbal has risen to 21.4 percent.

The following explanation of this result occurs to us. Since the complex was given under hypnosis, it is reasonable to assume that the resulting mental set would cause the subject to reply to the *C* words with a response which is related to the complex story. That this set was of considerable importance is seen by the other words (CA_1) which were drawn into the complex situation, there being 15 such. [16] In the waking state, however, the subject, as nearly as we could determine, had an amnesia for the complex and was therefore probably in lesser contact with it. At the same time he was in greater rapport with the experimental environment, hence the verbal responses related to the complex were not elicited as easily. To explain the small number of nonverbal responses in the hypnotic complex session, there being four on *C* and CA_1 words (excluding reaction time), we might assume that whatever excitation the conflict created was discharged verbally in giving the related response. In the following waking complex Session IV, however, the verbal responses related to the complex were not elicited as readily and the excitation created by the conflict spread into the motor response, giving rise to greater disturbances. Both *C* and CA_1 words illustrate this point. In the hypnotic complex Session III there were nine responses on the *C* words related to the complex and none on the nonverbal. But in the waking complex Session IV there were but two which were disturbed verbally alone, three both verbally and nonverbally, and three nonverbally. On CA_1 words in the hypnotic complex Session III the results are: verbal alone, 9; verbal and nonverbal, 3; nonverbal alone, 0; in the waking complex Session IV: verbal alone, 4; verbal and nonverbal, 3; nonverbal, 3. The further implication of these results is that, while the combined association-motor method of Luria does seem to reveal conflicts

induced by means of hypnosis, a conflict need not necessarily result in disorganization at the nonverbal level. It would be difficult otherwise to explain the paucity of nonverbal disturbances in the hypnotic complex session. It seems that some such assumption as we have indicated concerning the possibility of a complete discharge of excitation verbally is necessary. [17]

TABLE 2
Percentage Verbal and NonVerbal Disturbances for Word Classes (C & CA, Combined) and for All Others (CA, + NC, NC, CA,, N)

Session I
Waking Control

	Verbal		*Nonverbal*	
	D	**%**	**D**	**%**
C & CA₁	**0**	**0.0**	**3**	**4.0**

C & CA1	**2**	**8.0**	**2**	**2.7**
All Others	**0**	**0.0**	**2**	**0.9**

D =Number disturbed

Possible total verbal disturbance	**C & CA_1**	**25**
Possible total verbal disturbance	**All others**	**75**
Possible total nonverbal disturbance	**C & CA_1**	**75**
Possible total nonverbal disturbance (Reaction time excluded)	**All others**	**225**

But how shall we account for the other disturbances which have appeared in these two sessions? Indeed, what is the meaning of the disturbances which occur in the control sessions? In Session III there were three verbal disturbances on the word Class *CA_1+ NC* which have not been discussed thus far. It is clear that the verbal disturbance is due to the *CA_1* and not to the *NC*, since our criterion of classifying them *CA_1*, was based on relationship to the complex story. No nonverbal disturbances appear in this class. [18] Two voluntary disturbances appear on the class designated as *CA_2* on Nos. 9 and 96. These are probably related to the complex as already indicated by the way in which they were selected. The remaining 6 disturbances are on 5-words. [19] These are numbers 36, 37,59, 65, and 93. No. 37 ("Stomach-food"), with a voluntary disturbance, and No. 59 ("Health-sanitarium"), also with a voluntary disturbance, may both be considered as indicative of some natural complex material, since the subject reported he was taking a tonic for stomach trouble at the time of the experiment. This re-receives some confirmation from No. 67 ("Hungry-sick"). On the other hand, it is possible that this group of words implies that the subject felt miserable—a "sick to the stomach" feeling-because of his behavior in the complex story. Such an interpretation finds support in the somewhat greater unpleasant affective tone of the session as compared with the first two control sessions. [20] Nos. 37 and 59 may also involve an element of perseveration from 36 and 58, respectively. The disturbances on No. 65 ("Concentrate-meditate") —voluntary and reaction time—may have arisen because of the subject's preoccupation with the complex story. On No. 93 ("Fine-coarse"), disturbed in the voluntary aspect, the response which appeared in a previous control session may have taken on a figurative meaning for the subject, referring to his behavior in the complex situation as "coarse." We are unable to account for the voluntary disturbance on No. 36 ("Short-long") satisfactorily.

We have attempted to account for all the disturbances in the other sessions according to the principles set forth above. However, since we do not feel these explanations are pertinent to our present purpose, we shall give but a few additional examples.

The waking complex Session IV has 15 disturbances on 14 N words: Nos. 10, 24, 34, 46, 53, 64, 67, 73, 75, 92, 93, 99, and 100. No. 53 ("Sour-taste") —this is the only time in which "taste" appears as a response to this stimulus words. This fact in combination with the appearance of an involuntary disturbance suggests that the subject was referring to the unpleasantness of the complex in a figurative sense. There may also be an element of perseveration from No. 52 involved, which also showed considerable disturbance. No. 73 ("Swift-fast") —the response "fast," which is a different type of response from that of the control sessions, being a synonym as opposed to an antonym, appears with a voluntary disturbance. We may interpret this as probably referring to the necessity of speed in notifying the girl of the truth, a point touched on in the complex story. [21]

Having considered the complex sessions we shall take up the control sessions, beginning with Session I. In this first waking control session there are 21 disturbances on 17 words. It is especially interesting to note that there are six disturbed *NC* words out of a possible seven—a fact which would seem to indicate that *NC* material may be turned up, at least the first time the test is given. These *NC* disturbances are on Nos. 19, 32, 52, 55, 90, and 91.

The possible explanation that may be given to the other disturbances is that they are the results of natural complexes, permanent or transitory, of which we were not aware (enhanced or unenhanced by a "shock" effect), chance disturbances due to "shock," somewhat unusual, stimulus words for the subject, or perseveration. No. 68 ("Blame-accuse") with a respiratory disturbance, and No. 71 ("Persecute-electric chair") with voluntary and reaction time disturbances are probably disturbed because the stimulus words are somewhat unusual and often carry an unpleasant tone.

In Session II, hypnotic control, we should expect the "shock" effect of Session I to be reduced, but since hypnosis may reach a deeper personality level, the possibility of more natural complex material being aroused should be considered. The total disturbance in Session II has fallen to 14 and appears on words 2, 10, 27, 41, 49, 54, 58, 67, 86, 93, and 100. Word No. 41, with disturbances of respiration and reaction time, is *NC*, and No. 67 ("Hungry-stomach") with a voluntary disturbance, may also have been connected with a natural complex, as has been already indicated. As for No. 49 ("Burned-chemistry") — respiration and reaction time disturbed—we have a post experimental report of severe acid burns received by the subject at one time, which may account for the present disturbance. No. 54 ("Soldier-fight"), having a voluntary disturbance, may be connected with the natural complex involving *fall* and *high*, since the subject's airplane accident, already mentioned, took place while he was in the Army Air Corps.

In Session V, the first waking control after the complex session, we find 14 disturbances which fall on Nos. 19, 27, 29, 37, 60, 64, 66, 68, 71, 80, and 90. Any analysis must now consider the possibility of verbal and nonverbal affective residuals and nonaffective

verbal residuals from the complex sessions. No. 19 ("Kiss-hug"), disturbed in the voluntary and respiratory aspects, is *NC*, and it is probable that the *NC* part of No. 90 is responsible for the voluntary disturbance on it since the verbal response is "hurt." The verbal disturbance on No. 66 ("Lamp-burn") is probably due to a verbal affective or nonaffective residual.

The disturbances fall to 10 in the hypnotic control Session VI—on Nos. 9, 10, 13, 14, 17, 61, 68, and 90. Nos. 13, 17, and 90 are *NC* words.

Session VII shows 9 disturbances on Nos. 29, 38, 60, 61, 74, 85, 88, and 96. The nonverbal disturbance of a voluntary nature combined, with the verbal responses on No. 29 ("Beautiful-pretty") suggests an affective residual. The verbal disturbance on No. 88 ("Smell-burn") suggests either an affective or nonaffective residual.

The attempt to account for disturbances not related to the induced or natural complexes has, in the very nature of the case, to be quite speculative. We included examples of these interpretations because it seemed to us to point out the problem which future experimentation must face in order to make the technique a really satisfactory one.

Reference to Table 1 shows the mean reaction times and S.D.'s for all sessions and the means for the word classes. Examination of the means and S.D.s of all the sessions, despite questions which might be raised about the legitimacy of this measure of variation in this case, shows several interesting points. While the means of the first two controls are practically identical, the S.D. of Session I is somewhat larger than that of Session II, which may be an expression of what we have referred to as the "shock" effect. The word classes which contribute largely to this larger S. D. in Session I are CA_1 + *NC, NC,* CA_2, and *C*, in order of their departure from the total mean from great to small. Since in the first control sessions the CA_1 + *NC* and *NC* groups are really all *NC*, it seems clear that there is a tendency for NC words in this session to be delayed. The longer-than-mean time on the CA_2 class may be caused by some natural complex material. Word No. 71 ("Persecute-electric chair") and its response suggests this inference. Since the *C* words, in general, were a bit unusual, this might lengthen their time. The class means have come together considerably in Session II—the *NC*, however, still being the longest. The mean of Session III is slightly greater, but the S.D. has continued to fall, the most surprising fact being the short reaction time of the *C* words, nine of which were disturbed verbally. This seems to support the verbal discharge hypothesis presented earlier and is in line with Luria's "law of the catalytic action of the stimulus." In the waking complex Session IV the mean has continued to rise, being greatest of any session, and the scatter has increased. The increases are on CA_2, *C*, and CA_1, words, which is to be expected if there has been any tendency to inhibit verbal responses. After the removal of the complex the means and S.D.'s decline to new low levels, probably due to a practice effect (Wells, 1927). In none of the sessions may the differences between means be regarded as significant statistically. Rather it is their general agreement with what might be expected which is striking.

Another point which might be mentioned is that there was a tendency for responses which were more highly specific to the complex to appear on the 10 Complex words and for those which were less specific to appear on Complex-Associated words. This tendency was not paralleled in the magnitude of the voluntary disturbances.

SUMMARY OF RESULTS ON ALL SUBJECTS

Twelve subjects went through the same general procedure. There is evidence that nine accepted the story told to them as an account of something they had done. We base this on their general behavior during and between experiments, an example of which we have given in discussing the sample case.

Table 3 summarizes the results on all cases. Since there is a considerable amount of overlap, the plus (+) signs should be regarded only as indicative of predominant trends. In the waking state nonverbal behavior was disturbed in Subjects 1, 3, 4, 5, and 6c; in the hypnotic state in Subjects 2, 3, 4, 5, 6*a*, and 6*b*. The results on Subjects 7, 8, and 9 are largely negative so far as disorganization of the nonverbal aspects are concerned. Of the nine subjects who accepted the complex (Table 3), six gave definite evidence that some aspect of the Luria technique revealed the presence of a conflict. One of this group (No. 2) presented disturbances which were almost all of a voluntary character in hypnosis, with almost none in the waking complex sessions, so that it would have been difficult on the basis of the latter alone to know whether the subject had a conflict. However, after reinforcement of the suggestion, a few verbal and nonverbal disturbances appeared in the next waking complex session. This implies that this type of conflict may be entirely at the hypnotic level but if sufficiently strong may result in disturbances in the succeeding waking session. Two subjects (Nos. 3 and 4) showed voluntary disturbances in both states. One subject (No. 5) had greater involuntary responses than voluntary in hypnosis and waking, and the subject (No. 1) whom we discussed in detail showed his greatest nonverbal disturbance as voluntary in the waking state. Another subject went through the experiment three times: in the first two (Nos. 6*a* and 6*b*) the disturbances appeared in hypnosis as voluntary, the third time (No. 6*c*) voluntary disturbances were found in both states. [22] It is difficult to generalize about these six cases because such marked individual differences are found among them. However, one of the consistent findings is that the preponderance of verbal disturbances occurs in hypnosis and the relative importance of the nonverbal increases in the waking state. Another is that the *C* words, as would be expected, tend to evoke verbal responses which are more specifically related to the complex than any others.

TABLE 3
Results on All Subjects

Subject		Complex Accepted	How revealed as disturbances					
			Verbal only		Both verbal and nonverbal		Nonverbal only	
No.	Sex		H	W	H	W	H	W
1	M	Yes	+			+		
2	F	Yes			+			
3	F	Yes			+			+
4	F	Yes			+	+		
5	F	Yes			+	+		
6a	F	Yes			+			
6b		Yes			+			
6c		Yes			+	+		
7	M	Yes	+					
8	F	Yes	+	+				
9	F	Yes	+	+				
10	M	No						
11	M	No						
12	F	No						

H =Hypnotic Complex Session
W =Waking Complex Session

Of the other three subjects who accepted the complex, in two the evidence that there was any connection between the complex and the nonverbal disturbances was of a dubious character. Each case presented some peculiarities of its own which are worth mentioning. One subject (No. 7) who had eight sessions—two complex sessions, one hypnotic and one waking, being added—had the largest group of words associated with the complex of any of our subjects. In the first hypnotic complex session there were 24 CA_1 words and 16 $CA_1 + NC$ words. Yet only three CA_1, and two $CA_1 + NC$ words were disturbed in the voluntary responses. One of each class had a voluntary disturbance without a verbal disturbance. Likewise there were eight verbally disturbed C words, but only one had a voluntary disturbance. In the succeeding waking complex session there was one verbal disturbance on Class *C* and one on $CA_1 + NC$. The *C* class had two voluntary disturbances, and the CA_1 class had five. In neither session was there an increase of nonverbal disturbance on the other word classes. In such a case it is important to examine the disturbances in the other classes and attempt to discover if these can be related to the complex, paying especial attention to those which were undisturbed in the control sessions. It was found that a few of these could be connected, but the result was not very convincing. The results on the other two complex sessions were essentially the same except that the total disturbance declined somewhat. Another fact about this case was the large increase in nonverbal disturbances in the first hypnotic control session, as against the waking control, the numbers being 18 and 5, respectively. This suggests that there may be a "shock" effect which appears in hypnosis in some cases. This interpretation is supported by the fact that there were but two disturbances in the last hypnotic control and an increase in unusual responses in the first hypnotic control session over the previous waking control—the values being 10 and 2.

Another subject (No. 8) gave somewhat different results. Although there was a considerable amount of nonverbal disturbance in each session, there was little apparent relation to the complex. Verbal disturbances were few. In the hypnotic complex session there were found but five—two on *C* and three on CA_1 words. This was true, likewise, of the posthypnotic complex session. The verbal responses were, however, sufficiently specific to the complex story to show its effect. The interesting point about this case is that from an examination of the total disturbances for each session there appears to be a "shock" effect in both the waking and hypnotic states, greater in the former, and which has a differential rate of decline upon repetition, being faster in hypnosis than in the waking condition.

In another subject (No. 9) there were a considerable number of verbal disturbances in both the hypnotic and waking complex sessions but few nonverbal disturbances which could be related to the complex situation in either the hypnotic or waking states. This individual had 12 sessions, six complex and 6 noncomplex, divided equally between the hypnotic and waking states. Four control sessions preceded the induction of the complex, and two were conducted after its removal. The control tests showed an interesting phenomenon—with repetition of the experiment there was a decline of disturbances. This was true of both the waking and hypnotic conditions and is better evidence for the existence of a "shock" effect than the decline in the case of those subjects in which but two controls were performed before the complex was suggested. There is also the possibility that this decline in disturbance is evidence of an "abreactive" effect. Failure to take this factor into consideration, whatever its cause, may lead to questionable conclusions. Luria, we believe, has not taken sufficient account of it in his studies of students before and after school examinations, criminals before and after confession of a crime, etc., (1930, esp., pp. 43-128), and for that reason the differences may not be as marked as he indicates. Along with repetition went a slight reduction in reaction-time means and a shrinkage of scatter about these means. (This same general effect was noted in three other cases in which control repetitions were obtained.) Because of our failure to obtain many nonverbal disturbances we allowed this subject to keep the complex overnight and repeated the hypnotic and waking sessions the following day. The result was a slight decline in total nonverbal and verbal disturbances. The next day we tried to reinforce the complex by repeating the suggestion to the subject. This resulted in a slight increase in both types of disturbances, bringing them back to about their original level. (In another subject reinforcement was tried with much more positive results—i.e., a great increase in disturbances, the effect being especially marked in hypnosis on nonverbal disturbances.)

It seems certain, then, that with repetition one has a reduction in disturbances during the complex sessions. An abreactive factor, a forgetting factor, or a decrease in "shock" effect, must all be considered as possible causes for this decline.

The levels-of-discharge hypothesis which we have suggested in this paper is consistent with results obtained on all the subjects who accepted the complex. Stated broadly, the hypothesis implies that if affective excitation created by a conflict is not discharged

completely at one level, it ought to appear at another. In terms of the present experiment, if the affect was not totally released in giving a verbal response related to the complex, there ought to be a nonverbal (voluntary, involuntary, or respiratory) disturbance. This may occur with or without a lengthened reaction time. The reaction time would be increased on those items in which there was some inhibition (conscious or unconscious) of the verbal response. The time would not be lengthened if a response related in some way to the conflict was either adequate or inadequate to discharge the affective excitation.

It should be noted that Subjects No. 2, 3, 4, 5, 6*a*, and 6*b* give motor evidences of a conflict in hypnotic states, a point which we discussed in connection with Subject No. 1 when we analyzed in detail the results obtained from him. The motor disturbances were much more marked in these cases than in Subject No. 1. Subjects No. 1, 3, 4, 5, and 6*c* gave similar evidence in the waking states. In the hypnotic states Subjects No. 1, 7, 8, and 9 did not give motor disturbances, and in the waking condition Subjects No. 2, 6*a*, 66, and 7 did not show many nonverbal disturbances. It may be argued, as indicated previously, that the failure to give motor disturbances in the hypnotic or waking states in these subjects shows the absence of conflict.

The levels-of-discharge hypothesis we have advanced, on the basis of our experiments, is an extension of the Luria theory as we have stated it. Motor disturbances occur, according to Luria, when there is an inhibition of the verbal response or when there are large amounts of conflict-excitation present. Our hypothesis assumes that motor disturbances will appear when there is inhibition of the verbal responses. However, motor disturbances may or may not be found when the conflict arouses large amounts of excitation. If the verbal response is adequate to discharge this excitation, there will be no motor disturbances, but if the verbal response is inadequate, then motor disturbances will appear. We have attempted to account for the failure to obtain motor effects when the subject had a conflict in this way.

Of the remaining three subjects, two definitely refused to accept the complex (Nos. 10 and 11). Both were given the same complex, which was of a serious nature. As medical interns they were supposed (in the story suggested to them) to have been anxious to acquire proficiency in the technique of the cisterna puncture, practicing on patients who had just died. Through a mistake in the location of the bed in a poorly illuminated ward, they performed the puncture on a comatose patient instead of a dead one, and due to faulty technique the vertebral artery was pierced by the needle. An internal hemorrhage resulted and death ensued. Each had gone from the ward without making a report of the accident. After we had finished the experiments, we questioned the subjects and discovered that they had not believed that they were involved in the complex situation. One said that the behavior of the person in the story was so different from his own that he could not imagine himself as committing the action, although he tried hard to believe it. The other subject reported that after the suggestion of the story he had had a mental picture of himself performing a cisterna puncture, but that this was entirely dissociated from the complex. The whole situation had seemed very real to him, but he had known that he had not gone on the ward in the evening to perform the operation. Both of these

cases, however, showed an increase in disturbances in the complex sessions. These disturbances fell almost entirely on words classed as *N* and in one case to a slight extent on *NC*. In one case the increases appeared largely as respiratory disturbances; in the other they were scattered among all the nonverbal aspects. Luria has spoken of an increase in respiratory disturbance as indicative of "trauma," by which he means those cases in which the person has reacted to a "shocking" experience. He contrasts these with those in which the individual has taken a part in some act which, if contrary to the personality trends of the person, leads to a conflict. The implication of the results in these two subjects is that to produce a conflict the complex act must be one possible for the subject to imagine his doing.

The third case (no. 12) in which negative results were obtained, from the standpoint of accepting the complex, involved the failure to mail a roommate's letter of application for a graduate school fellowship until after the final date for application had passed, while the subject mailed one of her own and obtained the same fellowship. This subject explained after the experiment that the account as stated had not been entirely logical and that she felt it was artificial. She had elaborated it with numerous details to make it more credible. In the posthypnotic complex state she was aware of a desire to let her mind dwell upon events that might have happened in the trance state; by so doing she thought she might rid herself of something unpleasant. Yet she felt vaguely that she ought not do this since it might disturb the hypnotic situation. Complex removal was accomplished in her in the waking state by suggesting that she recall the story, and this she was able to do. It is our impression in this case that the acceptance of the story was more intellectual than emotional. There was a slight increase in disturbances in complex sessions, appearing in the hypnotic state on *N* and *NC* words almost entirely, In the waking complex session there was a small increase over the hypnotic complex session Caused by disturbances appearing on *C* and CA_1, words. This makes it appear that some conflict has been set up. The most striking thing about this subject, however, was the large number of unusual verbal responses. By unusual responses we mean those which are individual to the subject as compared to those expected from a group of persons living in a similar environment. In the case of the words which we took from the Kent-Rosanoff list we designated as unusual those responses which had a very low or zero frequency, unless the subject's occupation and habitat made the response seem appropriate. (In the subject whose case we presented in detail [Table 1] the response "sigh" to the stimulus whistle No. 38 was considered as unusual. This was true also of the response "me" to the stimulus *persecute* No. 71.) The values ran as follows: Session I, waking control—7; Session II, hypnotic control—11; Session III, hypnotic complex—18; Session IV, hypnotic control—9. The majority of these fell on the word classes *NC* and 1V. An examination of the individual responses which appeared in Sessions III and IV which had not occurred in Sessions I and II showed that some could be accounted for as *NC*, some as related to the complex, and some as influenced by both. This analysis was made in the same way as in the attempt to account for all the disturbances in the sample case. Although the numbers dealt with are small, they suggest that the increase in unusual responses may be augmented directly by the complex, or indirectly through the sensitization of *NC*.[23,24]

CONCLUSIONS

The outstanding difficulty of the technique is the more or less speculative method which must be resorted to for the explanation of nonverbal disturbances not clearly related to the complex. For more exact experimental investigations one certainly should know more about the personalities of the subjects than we did. It is likely also that the list of neutral words would vary from subject to subject. An attempt should be made to secure subject constancy rather than constant conditions for all subjects. This would make it possible to attack a number of problems on a more objective basis, some of which are here presented.

1. Must a subject be aware of a conflict to obtain voluntary disturbances? Our data offer arguments for, but mainly against, this possibility. We believe that Luria's point both ways also. However, he seems to hold for the necessity of awareness to obtain voluntary disturbances.[25] The problems dealing with repression and suppression of conflicts and Luria's concept of "functional barrier" are involved here.

2. To what limits can the technique be carried to reveal the "natural complexes" of a subject? Our data suggest that what we believed were natural complexes are disclosed especially during the first experimental sessions.[26] In any attempt to study natural complexes the complications introduced by what we have termed the "shock" effect must be considered. Both problems are probably related to personality types. Luria has suggested in another connection that there are what he calls "reactive-stable" and "reactive-labile" personalities. It is probable that natural complexes will disclose themselves more easily and shock effect be greater in the latter type.

3. Can one get information about the interrelationship of conflicts? Our material suggests that in some subjects the artificially induced complex may cause at least temporary disappearance of the natural conflicts, and in other subjects enhancement of the natural complexes. Also in this connection we found that the *NC* words carried fewer nonverbal disturbances after the removal of the complex than before its induction. Does the removal of one complex have a general "abreactive" effect upon the subject, or is the apparent "abreaction" due to mere repetition?

4. Can one study by this method the kinds of objects and situations to which complexes attach themselves? Witness our CA_1, CA_2, and $CA_1 + uc$ word classes. This problem is closely related to that of symbolization.

5. Are there different levels of affective discharge? If so, under what conditions does one level rather than another carry the discharge? What relationship obtains among the various discharge levels? Is there a hierarchy? Can one level become a surrogate for another? Our results indicate that the more discharge at a verbal level, the less at a nonverbal level, and vice versa. It must be remembered,

however, that these differences were quite marked between the hypnotic and waking states and may be partially due to hypnosis.

6. Can a distinction be made from the pressure curves alone between affective conflicts and those which are at a more intellectual level—e.g., the attempted solution of difficult intellectual problems? Or is affect at the basis of both types? Luria has made some beginnings in this direction (1932, p. 205-239).

7. Can a complex be induced by direct-or by indirect-waking suggestion? An example of the latter might be that in which a person is made the subject of some unpleasant rumor by a group of persons.

8. What correlation would there be between sympathetic variables such as heart rate, blood pressure, galvanic skin reflex, etc. and those studied here? In this connection it would be well to know more about gross movements of the subject which may or may not be associated with affect.

9. What are the possibilities of this method in the study of conflicts as revealed during the course of the psychoanalytic interview? It would seem that data of theoretical value could be gained from such an investigation.

10. What is the effect of fatigue and toxic states in making conflict material more available? Luria has suggested that the regulating ability of the "functional barrier" is lowered during fatigue (1932, p. 384).

11. Under what conditions do perseverative effects appear? Do they tend to appear at one level more than another? There is some indication from our data that perseveration tends to appear at a level lower than that of the level of the preceding disturbance; for instance, if the disturbance is verbal, then the perseverative disturbance tends to be voluntary, involuntary, or respiratory.

12. What is the effect of hypnosis on the individuality of verbal responses? (This is a question not connected directly with the Luria technique but was suggested by our experiments.) There seemed definite indications that hypnosis increased the individuality of the responses, as was seen from a comparison of the means of the frequency ratings by Kent-Rosanoff standards on *N* words. [27] However, we are not certain that this is caused by hypnosis, since in those subjects in whom we had a repeated waking control there was also a considerable fall in frequency. Yet there were three subjects in whom the frequency-decline from waking to hypnotic states was so marked that we feel we may be dealing with personality types in this respect. In setting up an experiment of this kind it would be necessary to take the "shock" effect on individuality of response into account.

13. What is the effect of a complex on the individuality of verbal responses? This might be studied from the point of view of Kent-Rosanoff frequencies or some autogenous standards such as a frequency table built up on a number of

repetitions of the stimulus word series for each subject. There is some indication in our material that a complex individualizes the responses on N words in the waking state and makes the responses less individual in the hypnotic states.

SUMMARY

In an attempt to test the validity of the Luria method of detecting affective conflicts, one of his experiments was repeated. A complex was induced hypnotically. Verbal, voluntary, involuntary, and respiratory responses were studied. Four male and eight female subjects were used. The results obtained and the interpretations suggested are the following:

1. There was evidence that nine subjects accepted the story told them as something they had done and that it produced a profound reaction in them.

2. In six of these nine subjects some nonverbal (motor) aspect of the Luria technique revealed the presence of the conflict in either the hypnotic or waking states. These subjects in the hypnotic states tended, in general, to give verbal responses definitely related to the conflict with relatively few nonverbal disturbances. In the waking state the relative importance of the nonverbal disturbances increased over the verbal. The hypothesis is suggested that there may be "levels of discharge" so that if excitation created by the conflict is not discharged verbally, there is a spread to voluntary and involuntary motor levels. An implication of this hypothesis is that the motor aspects of the Luria technique sometimes may not reveal the presence of the conflict.

3. In the three other cases, those of subjects who accepted the story suggested to them, the evidence that the Luria technique revealed the existence of a conflict was lacking or was of a dubious character. These three cases are discussed with special reference to the effect of the artificial conflict upon their verbal responses.

4. The results from the three subjects who refused to accept the complex suggest that the reproachable act must be of such a nature that the subject can plausibly conceive of his participation.

5. Data collected from repeated sessions on the same subject indicate that there is a "shock" effect which appears chiefly in the first session as a large number of motor disturbances and declines upon repetition. This "shock" effect must be evaluated properly before valid conclusions in this type of experiment can be drawn.

6. Repeated experimental sessions on the same individual while he had the conflict showed a gradual decline in motor disturbances from day to day, pointing to an "abreactive" factor or a forgetting factor.

7. Certain other theoretical implications of the experiment are discussed, and a list of problems which may be approached by the Luria technique are included.

[1]The division of labor in this study was as follows: the problem was set and the data analyzed by the first two authors (psychologists); the hypnotic work and organization of the complexes was done by the third author (a psychiatrist); and the experimental work was performed by the first author.

[2]In general we shall adhere to Luria's terminology in this paper.

[3]Luria argues that previous work on affection and emotion has yielded disappointing results because there was no intimate relationship between the affect and such physiological expressions as blood pressure, heart rate, respiration, etc. According to Luria the expressiveness of any motor system will depend upon its degree of inclusion in the psychological structure where the conflict is located, hence the preferred hand is selected to make the voluntary pressures because of the close relationship between the speech centers and the neural control of the preferred hand.

[4]This exposition is our attempt to state the Luria theory succinctly. Other attempts may be found in recent reviews of Luria's latest publication (1930): Brown, J. F., *Psychol. Bull*, 1933, 30, 376-381; Kubie, L. S., *Psychoanal. Quar*. 1933, 2, 330-336; Oakland, F. A., *J. Gen. Psychol*. 1933, 9, 485-487; Taylor, W. S., *J. Abn. & Soc. Psychol*., 1934 (to be published).

[5]The work was done during the years 1930 to 1932.

[6]The 90 other words consisted of 66 from the Kent-Rosanoff Association Test (1), which give high frequencies of "most common" responses and which might be considered as neutral in character, i.e., generally without emotional tone; five we believed significant for schizophrenic patients—words 10, 31, 46, 65, and 85; five significant for psychotics in general—words 6, 13, 34, 58, and 71; and five words which are often of affective value for normal individuals—words 19, 37, 55, 74, and 91. (Words 37 and 91 appear also in the Kent-Rosanoff list.) The remaining eleven words are "double-barreled," that is, they may easily be taken in more than one sense. These were Nos. 2, 4, 22, 43, 62, 63, 80, 90, 93, 95, and 100. (Words 25, 75, and 82 among the Kent-Rosanoff group may also be considered as "double-barreled.") Since our ultimate purpose was the application of the procedure to psychotic patients, we introduced the affective and "double-barreled" words, planning to use the responses from the normal subjects as control material.

[7]Our tambour system, while not quite like that of Luria, is not different in its essential requirements.

[8]All the hypnotic work was done by the psychiatrist. Hypnotic rapport with the subject for experimental procedures was transferred to the experimenter, the same instructions being used on all subjects. The psychiatrist kept all subjects under observation for at least a month to note any possible residual effects of the experiment. (None were observed.) Close supervision was particularly maintained in those cases in which the subject was allowed to keep the complex overnight. All trances were of a profound somnabulistic type, characterized by dissociation and, with one exception which will be discussed later, apparently by total amnesia for trance events. Administration of the complex was achieved by two sets of instructions identical for all subjects. These were planned to prepare them to "recall" the complex as an actual memory and to strengthen their acceptance of this "memory" and their emotional reaction to it. Removal of the complex was accomplished by the hypnotist's reviewing the preliminary instructions, the story, and the final instructions, indicating the falsity of the whole account and allowing the subject to verify in his own mind the unreality of the entire complex story. This was—had to be—done in both the trance and waking states.

[9]Each session took about 15 minutes. The stimulus words were given as rapidly as the experimenter could write down the verbal responses, except when a disturbance appeared. In the latter case the disturbance was allowed to subside before the next stimulus was given.

[10]This was done some time after the conclusion of the experiments. In the present case there were six "Complex-Associated" words of the second type. The stimulus word *dark* (No. 9) elicited the response "room" in the hypnotic complex session. This was so classified because the subject informed us that he had placed the complex situation in a poorly lighted room to make the action more plausible. The response "beautiful" to *Fairy* (No. 63) was thought by us to have come about through "girl"—i.e., Fairy ⇒ girl⇒beautiful. (The attractiveness of the girl had been emphasized in the complex story.) *Guilty* (No. 58) yielded two unusual reactions in the complex sessions, "self-conscious," and "no." These, responses might be related to the emphasis on the loss of self-respect in the complex. *Persecute* (No. 71) as stimulus, with the unusual response "me," may fall into the same context. The subject reported that the response "necklace" to *neck* (No. 80) resulted from his visualizing the girl in the story as wearing a necklace. The responses "stores" and "display" to the stimulus *street* (No. 96) may have been connected with window displays of new dresses, since the fact that the girl was wearing a new dress was stressed in the story.

[11]Hereafter we shall refer to the word classes by the following symbols:
C—Complex
CA_1—Complex-Associated—First Type
CA_1—Complex-Associated—Second Type
NC—Natural Complex
CA_1 + *NC*—Complex-Associated—First Type + Natural Complex
N—Neutral

[12]An attempt was made to determine which reaction times might be considered disturbed. This was first done by distributing the reaction times of every session of each subject and computing the S.D. However, because of the illegitimacy of such computations on a heterogeneous population and because of the skewed distributions which we obtained in many cases—1.5 times the S.D., which we set as our criterion, fell outside the limits of the distribution—this attempt was given up. We finally took those reaction times which seemed to stand apart from the rest of the distribution. Usually this gave four or five disturbed reaction times in a session.

[13]We recognize that in using the word *disturbance* for both verbal and nonverbal effects we are not being consistent. In the former case we, are using the word in the sense of a *change* in response in the direction of the complex, in the latter in the sense of a *disorganized* response. However, since the term is convenient, we are continuing its use in both senses.

[14]A refined statistical treatment of the data was attempted, but we came to the conclusion that this was premature because of the qualitative stage of the technique and the exploratory nature of the experiment.

[15]These percentage figures are arrived at by dividing the actual number of disturbances by the possible number of disturbances. Since there are 25 *C* and CA_1 words, the possible verbal disturbance is 25. However, since each word may be disturbed nonverbally in the voluntary, involuntary, and respiratory aspects, there are 75 possible nonverbal disturbances. The total possible nonverbal disturbance on all other words together is 225. Reaction time is excluded since the standard we used was relative to the whole distribution of reaction times, so that only a few long times for each session could be marked as disturbed.

[16]The actual number probably depends upon many factors such as the strength of the complex, the nature of the complex itself, its relation to the stimulus words, and personality traits.

[17]It is possible to urge that the subject had little or no conflict in the hypnotic state because the complex was given to him in this condition. Thus, by virtue of having heard the story, without assuming personal responsibility for the act, he was set to give verbal responses related to the complex with no affect necessarily associated with them. It should be noted, however, that an attempt was made, in the hypnotic instructions which were used when the complex story was told to the subject, to associate affect with the story. It was repeatedly emphasized to the subject that he had committed an act which made him feel miserable. The subjects in general were restless after the induction of the complex and gave one the impression that something distressed them. It is interesting also to examine the verbal reaction times of the *C* and CA_1 words in Session III. The mean of the *C* words is 2.6 seconds, being shorter than the mean of the

100 words, which was 3.0 seconds. None of these words carried any nonverbal disturbances. A reaction time mean on the *C* words which is close to the total mean of the whole stimulus word list is consistent with both the levels-of-discharge hypothesis and the "nonaffective set" view. That is, there is no reason in either case why any delay should take place. The reaction process simply runs its normal course, discharging more affective excitation in the former case than in the latter. The CA_1 words have a mean of 3.2 seconds. Of the 15 words in this class, 12 have verbal disturbances. It is interesting to note that three of these 12 have nonverbal disturbances, words No. 45, 48, and 85, and each one has a long reaction time, the values being 4.4, 5.1, and 5.0 seconds, respectively. This result would seem to imply that there was inhibition of the verbal response which was reflected in the nonverbal aspects as disturbances. The motor responses give some evidence of conflict in the hypnotic state. Unfortunately there are only a few instances in this subject, so that the question cannot be answered decisively. In some other cases the issue is clearer, however, and we shall return to this topic later.

[18]We have kept the class separate, however, since there are some nonverbal disturbances in other sessions which may be due to *NC*.

[19]There are numerous disturbances which are not accounted for on the basis of a relationship to the induced complex or to natural complexes. One might attempt to explain these disturbances by the following methods. Often it is impossible to make a satisfactory decision. Some of these methods apply to all sessions and some only to particular sessions. Those which apply to *all* sessions are the following: (*1*) Perseveration effects (disturbances appearing on words following affective stimulus words), which may be both verbal and nonverbal or either one separately. If the perseveration is verbal and the subject gives a response which is related to the complex, then it would be classed CA_1 but if it is unrelated, we would be unable to tell whether or not it is a case of perseveration. There is the possibility, however, that perseveration may make the verbal response unusual. The clearest example of perseveration in a nonverbal disturbance would be that which follows a verbal or nonverbal disturbance and which appears on an *N* word. (*2*) Cases of unusual stimulus words to which the subject has difficulty in giving a response, or cases where the subject inhibits the first response which occurs to him but which is not connected with a conflict. Here one would expect longer reaction times. (*3*) Transitory "natural-complexes"—those which have arisen just prior to a particular experimental session and which were not present at the next session. (*4*) Chance disturbances due to movements of the subject because of physical discomfort of some kind. One may raise the question here of the relationship of such movements to affective stimulus words. Our data on this point are not sufficient since a semiopaque curtain separated the subject and the experimenter through which only gross movements of the former could be detected. The subject was unable to see the experimenter because the latter's corner of the room was darkened. (*5*) Natural complex situations unknown to us.

The explanations which apply to *particular* sessions are the following: (*1*) Responses which are related to the complex, but which we did not detect. These could be *C*, CA_1 or CA_2;*C* and CA_1, in those cases in which the response was the same as that of the first control sessions but in which the subject ascribed new meaning to the stimulus word, relating it to the complex; CA_2, in which we were unable to establish the associative links. This should apply especially to complex sessions and to some extent to control sessions after the removal of the complex (see 5 below). (*2*) Natural Complex situations, the thresholds of which have been lowered by the artificial complex so that words not marked *NC* become disturbed nonverbally. This should apply primarily to complex sessions. (*3*) Disturbances which are reactions to hypnosis itself and not the complex as such. These might be due to two different factors. The words which were used by the hypnotist in putting the subject into the trance, e.g., "Sleep," might become disturbed if the subject had developed any antagonism toward the hypnotist because the unpleasant complexes were suggested in hypnosis. The other factor is the possibility of ambivalence toward hypnotism. One would expect such disturbances to appear largely in the waking complex sessions and perhaps in later waking control sessions, since in the waking state rapport is probably not as good as in the hypnotic state. (*4*) Disturbances due to "shock"—those arising from the subject's apprehension in a new situation in which he does not know entirely what is expected of him. This is mainly relevant for the first session. One speculates in this connection whether or not apprehensiveness in a new situation sensitizes the" natural complexes" of the individual. (*5*) In the control sessions after the complex removal one has the possibility that there are residuals of the complex. Also, if there has been an enhancement of the subject's natural conflicts, disturbances on *NC* words might be found here. In attempting to account for disturbances falling on N

words we shall point out which of the above explanations seem the most likely to us insofar as we have any basis for our conclusions.

[20]An analysis of the verbal responses of the complex sessions indicates that there has been such a shift toward unpleasantness from the first control session; cf., e.g., in Session III, Nos. 38, 48, 61, and 98.

[21] Another interesting point with regard to Session IV is that the subject showed one of the general behavioral characteristics which we were observing. On No. 89 ("Tobacco-cigarette"), a CA_1 word, the subject sighed deeply.

[22]In this subject the instructions were altered the third time the experiment was performed. Instead of permitting her to have a posthypnotic amnesia for the complex story, which was the usual technique, we told her while hypnotized that she would be aware of the complex posthypnotically but would not dare to think about it, although it would cause her to worry greatly. The increase in voluntary disturbances would seem to imply, if the instructions were followed, that the subject must be aware of the complex to minifest such disturbances. Luria has also commented on this point (1932, pp. 149-161), maintaining that if the complex is removed from consciousness, it is also insulated from the motor area since the two have been combined functionally by the technique. On the other hand, in the other five successful cases posthypnotic amnesias were present, and all of them (one after reinforcement) showed a rise of nonverbal disturbances in the waking complex sessions. When these sessions were completed, the subjects often manifested surprise about some of their verbal responses which related to the complex. Luria has also noted this (1932, p. 136). Whether the surprise of the subjects was genuine or was in the nature of rationalizations based upon some knowledge of the complex we are unable to state definitely. Our impressions is that the surprise was real. Luria, however, argues that each critical stimulus word makes the complex conscious, at least partially, and hence disrupts the motor responses. His evidence in this connection is based on continuous free association experiments in which the subject eventually got around to giving responses related to the complex. These were accompanied by motor disturbances. Our material indicates that both conscious and unconscious conflicts may be revealed by the technique. This question is probably connected with the strength of the conflict and the intimacy of the relation between it and the motor response.

[23]The general result on all cases was that four subjects showed some increase in the number of individual responses in the first hypnotic control session as compared with the first waking control session. Three of these four showed increases in the first hypnotic complex session and three showed increases in a waking complex session over the hypnotic complex session.

[24]Besides the aspects already discussed, additional analyses were made of the following: stereotypy, echolalia, individuality of response by autogeneous norms, and disturbances of the ascending and descending limbs of the voluntary responses. However, we are not reporting on these aspects in this paper.

[25]The ambiguity of the term "awareness of a conflict" must be pointed out. We find it difficult to determine what Luria means in his discussion of this point (1932, pp. 149–161). There seem to be three possibilities: awareness of the presence of affect, awareness of the situation connected with affect, awareness of why the situation arouses affect. In our series the subject (6*a*, 6*b*, 6*c*) in whom "awareness" was necessary seems to favor the last possibility.

[26]Olson and Jones (1931) have found that religious, political, and social attitudes may be studied by the Luria method.

[27]The mean of the first waking as compared with the first hypnotic was 34.33 higher and had a Fisher's '*t*' of 4.030, a value yielding a probability of less than 0.01. This means that the difference was significant.

A Study of an Experimental Neurosis Hypnotically Induced in a Case of Ejaculatio Praecox

Milton H. Erickson

Reprinted with permission from *The British Journal of Medical Psychology*, Part I. 1935, Vol. XV.

The experimental investigation of the clinical problems of personality disorders presents an interesting but difficult task. Most studies on such problems have been done by psychoanalysts acting chiefly in the role of therapists. For this reason purely experimental work has been neglected because of the necessity of abiding by prescribed rules and definite concepts. However, students in this clinical field, foremost among whom are the psychoanalysts themselves, are becoming increasingly aware of the need for a systematic technique which will lend itself to laboratory proof as contrasted with the present empirical proof of subjective and clinical experience. As an approach to the experimental study of personality disturbances, a case of ejaculatio praecox was selected and subjected to a laboratory procedure intended to yield some information regarding the psychological mechanism termed *abreaction*.

The technique of experimentation was suggested by the well-established clinical fact, both in medicine and in psychoanalytic therapy, that recovery from one illness (or conflict) frequently results in the establishment of a new physiological equilibrium (or "redistribution of libido"), thereby permitting the favorable resolution of a second concurrent and perhaps totally unrelated illness (or conflict). Of similar influence was the well-known fact that an intercurrent disease may exercise a favorable effect upon the original illness—for example, malaria in paresis. Consideration of these ideas suggested their adaptation to the case in hand at a psychic rather than the usual somatic level. It was determined to give the patient a second illness, which was to be a neurosis so formulated that it might symbolize or parallel the original difficulty, and might be expected to arouse similar or possibly identical affects. The assumption was made that such similarity or identity of affects would establish some dynamic relationship between the two neuroses, possibly through identification, or perhaps through an "absorption" of the one conflict upon the other; and that when the patient, by virtue of the experimental situation, was forced to relive, abreact, and resolve the conflict of the induced neurosis, there might occur a transference or generalization of the abreactive process to the original difficulty. Or perhaps the abreaction and resolution of the induced conflict might establish a new attitude or organization of the personality. At all events the immediate experimental purpose was to establish a dynamic interrelationship of the two neuroses and to induce a readjustment of the personality.

The subject of this experiment was a single white male, 25 years old, who possessed a degree of doctor of philosophy in psychology. In addition he possessed a fair knowledge of clinical psychology and was well acquainted with the author's hypnotic techniques and

methods, since he had been acting as a hypnotic subject for the author and had been used extensively in experimental work for a period of a year before he disclosed his complaint. Finally, because his difficulty had become progressively worse, he decided to seek psychiatric assistance, and to this end he complained to the author of ejaculatio praecox and requested aid in overcoming this symptom. His story was essentially as follows: Three years previously he had decided to engage in sexual intercourse and had made many attempts, but always with a strong sense of guilt which he rationalized as a feeling that he was desecrating womanhood. From the first he had suffered from ejaculatio praecox, but on a few occasions he had succeeded in securing a second erection permitting penetration, but this was always followed by a precipitate orgasm and flaccidity. As these failures had been repeated, he had become increasingly concerned and worried, and his problem had become progressively more acute. Originally the overt act of beginning intercourse had resulted in an ejaculation, but at the time he sought aid, kissing or embracing and sometimes merely casual contact with an attractive girl would cause an erection and precipitate an orgasm with a complete loss of potency. Even when he did succeed in securing a second erection, he had not been able to utilize it either because of another precocious ejaculation or because of a precipitate orgasm upon penetration. He had resorted unsuccessfully to such measures as "prophylactic" masturbation to reduce his sexual tension and to the selection of girls without erotic appeal for him. His emotional reaction to these experiences was one of acute shame, bitterness, self-disgust, and inferiority.

At the conclusion of his story the young man was informed that the author would do no more than to take his case under advisement, and no therapy would be attempted until after a period of consideration; also, he was urged to seek assistance from another psychiatrist. Then, changing the subject matter of discussion, the patient's cooperation was requested for a special hypnotic experiment *which he knew had already been under consideration for some time* and which was to be developed in the course of the next few months. Although not fully content about the postponement of therapy, he continued his cooperation in regard to present and projected hypnotic work. Later, during the elaboration of the plans for the special hypnotic work, the idea of this experiment was conceived and promptly elaborated for investigation. No intimation of this fact was given to the patient. Instead, he was allowed to continue in his belief that therapy was indefinitely postponed and that the author was wholly absorbed in the previously projected hypnotic work, concerning which the patient had not been given any information. The rationale for this deception was the assumption that any therapeutic results of the hypnotic procedures utilized could be attributed then to the therapy itself rather than to the patient's hopes and expectations. A second gain, an important consideration in hypnotic therapy, was the possibility of hypnotizing the patient deeply for the experiment without making his success as a subject contingent in any way upon his neurosis.

During the course of the experimental work in which the patient had cooperated, he had been trained to accept "artificial complexes." These complexes were fabricated stories of an emotional nature told to the subject while in a profound hypnotic trance as accounts of actual past personal experiences which should constitute definite memories for him.[1]

Utilizing this background of the patient's, a special complex was fabricated for him which, when properly implanted in his mind, would tend theoretically to produce a second neurosis of the type discussed above. This fabricated story, which follows shortly in its exact wording at the time of administration, together with all hypnotic instructions as recorded in full by the attending secretary, is purely a fancy of the author's based upon an actual wish of the patient's to secure a certain academic fellowship.

However, to orient the reader more easily, it may be advisable to indicate as a preliminary measure the symbolism contained in the complex story. The heterosexual situation and its implications are apparent at once. Less clear are the symbolic equating of cigarette with penis and ashtray with vagina, but consideration of the heterosexual drives involved and the emotional forces at play in that particular setting—the man's attraction to the girl, his desire to give her something and thereby to gain satisfaction for himself, the girl's display of herself by means of her artwork, and the parallelism of the catastrophe of this contact with those of past heterosexual contacts—gives rise to a fair plausibility of such identifications.

As soon as the patient had been placed in a profound somnambulistic hypnotic trance of the type characterized by an apparently complete dissociation from all environmental stimuli and by an apparently total amnesia posthypnotically for all trance events and suggestions, he was given the following instructions:

> Now as you continue to sleep I'm going to recall to your mind an event which occurred not long ago. As I recount this event to you, you will recall fully and completely everything that happened. You have had good reason to forget this occurrence, but as I recall it, you will remember each and every detail fully. Now bear this in mind, that while I repeat what I know of this event, you will recall fully and completely everything just as it happened, and more than that, you will reexperience the various conflicting emotions which you had at the time and you will feel exactly as you did while this occurrence was taking place.
>
> Now the particular event of which I am going to tell you is this: Some time ago you met a man prominent in academic circles who manifested an interest in you and who was in a position to aid you in securing a certain research fellowship in which you were much interested. He made an appointment with you to see him at his home, and on that day you called at the designated hour. When you knocked at the door, you were met not by this gentleman but by his wife, who greeted you cordially and was very friendly, making you feel that her husband had given a good account of you to her. She explained apologetically that her husband had been called away for a few moments but that he would return shortly and had asked that you be made comfortable in the library. You accompanied her to this room, where she introduced you to a charming girl who was obviously rather shy and reserved and who, she explained, was their only daughter. The mother then requested your permission to go about her work, explaining that the daughter would be happy to entertain you while you waited. You assured the mother that you would be very comfortable, and even now you can recall the glow of pleasure

you experienced at the thought of having the daughter as a hostess. As the mother left the room, you set about conversing with the girl, and despite her shyness and bashfulness you soon found that she was as attractive conversationally as she was pleasing to the eye. You soon learned that she was much interested in painting, had attended art school, and was really profoundly interested in art. She timidly showed you some vases she had painted. Finally she showed you a delicate little glass dish which she had painted in a very artistic manner, explaining that she had decorated it as an ashtray for her father, to be used more as an ornament than as an actual ashtray. You admired it very greatly. This mention of using the dish as an ashtray made you desirous of smoking. Because of her youth you hesitated to give her a cigarette. Also, you did not know how her father might feel about such things, and yet you wanted to observe the courtesies of smoking. As you debated this problem, you became increasingly impatient. The girl did not offer you a cigarette and thus solve your problem, and you kept wishing that you might offer her a cigarette. Finally in desperation you asked her permission to smoke, which she granted very readily, and you took a cigarette but did not offer her one. As you smoked, you looked about for an ashtray, and the girl, noticing your glance, urged you to use the ashtray she had designed for her father. Hesitantly you did so and began talking on various topics. As you talked, you became aware of a rapidly mounting impatience for her father's return. Shortly you became so impatient that you could not enjoy smoking any longer, and so great was your impatience and distress that instead of carefully putting out your cigarette and then dropping it in the ashtray, you simply dropped the lighted cigarette into the ashtray and continued to converse with the girl. The girl apparently took no notice of the act, but after a few minutes you suddenly heard a loud crack, and you immediately realized that the cigarette you had dropped into the ashtray had continued burning and had heated the glass unevenly with the result that it had cracked in pieces. You felt very badly about this, but the girl very kindly and generously insisted that it was a matter of small moment, that she had not yet given the ashtray to her father, that he would not know anything about it, and that he would not be disappointed. Nevertheless, you felt exceedingly guilty about your carelessness in breaking the ashtray, and you wondered how her father would feel about it if he ever learned of it. Your concern was plainly evident, and when he mother came into the room you tried to explain, but she graciously reassured you and told you that it really did not matter. However, you felt most uncomfortable about it, and it seemed to you that the girl felt badly too. Shortly after this a telephone call was received from the father, stating that he was called away for the rest of the day and asking your permission to see you on a later day. You left the house very gladly, feeling most wretched about the whole situation and realizing at the time that there was really nothing you could do about it.

Now, after you are awakened, this whole situation will be on your mind. You will not consciously know what it is, but nevertheless it will be on your mind, it will worry you and govern your actions and your speech, although you will not be aware that it is doing so.

> I have just told you of a recent experience of yours, and as I recounted it to you, you recalled it in detail, realizing the whole time that I gave you a fairly accurate account of the situation, that I gave the essential story. After you awaken, the whole situation will be on your mind, but you will not be conscious of what it is, you will not even be aware of what it might be, but it will worry you and it will govern your speech and your actions. Do you understand? And you do feel badly about this thing.

The patient was promptly awakened from the trance state, and within a few moments he seemed completely awake. He appeared to have a total amnesia, not only for the trance events and suggestions, but also for the fact of having been hypnotized, the usual finding after deep hypnosis. He showed particular bewilderment in orienting himself, since darkness had fallen during the time that he had been asleep. He was engaged immediately in a casual conversation by two colleagues of the author who were present, while the secretary made full notes of all conversation together with a description of the patient's behavior and manner. It is not possible to present this material in its entirety because of its length and because of the necessity of preserving the patient's identity. The significant parts, however, have been abstracted for presentation here.

Three general types of phenomena occurred during the posthypnotic period. The first of these was the domination of every train of thought in the patient by his implanted, now subconscious, complex. Although he conversed fluently on a variety of topics, each one was soon noted to be related to the complex, but in a manner apparent only to an observer who knew the whole situation. Care was taken not to suggest topics related to the complex, and the patient himself made no reference to the content of the complex story itself, nor did any of his utterances suggest any conscious awareness of it. Neither was he given any suggestions which would serve to influence the trend of his behavior. Indeed, the colleague of the author who bore the burden of conducting the procedure was kept uninformed of the author's purposes as a means of ensuring undirected responses from the patient. When the patient was asked about a certain friend of his, he told of that friend's small children breaking bric-a-brac. As the conversation continued, he told of the travels abroad of another friend who had visited art galleries and museums containing ancient painted vases; he spoke of the author's library and the advisability of insurance for personal property; and he laughingly told of an instance of careless smoking by a friend which had nearly resulted in a serious fire. Any topic of conversation introduced by the others present was soon developed by the patient in such fashion that a bearing upon the content of the complex became apparent to the observers. Furthermore, each conversational topic rapidly appeared to become unpleasant to the patient, and he would change the subject repeatedly, only to return compulsively to some remark which could be related easily to the complex.

Secondly, there occurred disturbances in the form of his stream of speech. Irrelevancies, stammering, blocking, loss of train of thought, repetitions, persistence of certain ideas, undue urgency, and sudden strong emphases were all noted frequently. Thus, upon awakening, he began smoking and talking until he suddenly observed a painted earthen ashtray at his elbow, whereupon he twisted uncomfortably in his seat, stammered, lost his

train of thought, but gradually recovered his poise as the author's colleague assumed the burden of the conversation. Later, while talking about traveling abroad, he interjected remarks about the irreparable loss to art occasioned by the breaking of ancient vases and then continued the main topic of conversation without apparent realization of his digression. Again, in mentioning the author's library, he became unduly solicitous and urgent about insurance. In none of these instances did the patient seem to sense anything unusual in his behavior, despite their frequent occurrence. Observation at the time and consideration of the record later indicated that these behavior disturbances of the patient arose not in response to external stimuli but rather from his own intrapsychic state.

The third type of phenomena noted during this period was phobialike, obsessive behavior in regard to ashtrays, as judged by his previous known behavior. When casually handed a substantial, though ornamental ashtray, he received it in a gingerly, fearful manner and appeared to be afraid to use it. Instead, after many hesitant, abortive, and apparently compulsive attempts to flick ashes into is, he put them into the cuff of his trousers in an embarrassed manner. Now and then he would succeed in dusting them into the tray, whereupon he would crush them repeatedly and uneasily with his fingertips, as if to reassure himself about sparks. He held his cigarette butt until it burned his fingers, glanced at the floor and lifted his foot as if to dispose of it in that fashion, attempted to extinguish it in the cuff of his trousers but seemed too embarrassed to do so, made repeated abortive attempts to extinguish it in the ashtray in front of him by tapping the cigarette gently against the tray, and finally searched the room casually until he found a metal dish, wherein he extinguished the butt methodically, over-carefully, examining and reexamining it as if to be sure that it was not still burning. Whenever anyone dropped a used match into a tray, he seemed compelled to retrieve it immediately and to cool it between his finger and thumb before replacing it carefully on top of the ashes. While conversing he examined and reexamined his ashtray in a detached manner, moved it unnecessarily away from the edge of the table and finally put a soft mat under it. Despite all this difficulty in smoking he accepted unconcernedly a cigarette whenever proffered or helped himself to his own supply, only to repeat his phobialike behavior as he smoked.

Having noted this much of the patient's behavior—of which the above is only a brief summary—it was felt that he had "accepted" the complex and had possibly developed in consequence an artificially induced neurosis. He was then questioned directly and urged to give an account of what had occurred since he entered the office. Despite insistent questioning he was able to state only that he had spent the time smoking and conversing with the author's colleagues. No information was obtained suggesting that he had any conscious realization of the fact that he had been hypnotized or subjected to an unusual procedure. Accordingly, he was rehypnotized, and in this trance he was instructed to recall completely upon awakening the entire experimental situation and to discuss freely his reactions, speech, behavior and conduct. It was assumed that by means of this procedure a "removal" of the complex could be effected, since the patient could thus relive it at a conscious level and thereby might gain an insight into his reactions. As he awakened, a casual conversation was initiated which he soon interrupted to ask if he had told the author of a recent unhappy experience of his. He proceeded to relate the story of the complex as the recollection of an actual event, doing so with appropriate emotional

responses, even identifying the father as a man who actually could have played such a role. As he concluded he started, looked bewildered, showed intense amazement, then smiled with relief and understanding, and declared, “Why, that was just a suggestion you gave me—in a hypnotic trance, too!”

After this realization he began to discuss fully the various details of his conversation and conduct, progressing in chronological sequence, each item serving to awaken its successor as a fresh memory. Meanwhile, the secretary made full notes of his discussion and manner and of the questions and remarks addressed to him. He explained that, as the complex was narrated to him, he had displaced, elaborated and falsified true memories, weaving them into the fabricated account, thereby giving the complex story the reality of an actual event. This transformation of the fabrication into a reality for him had been achieved readily upon his identification of the father with a gentleman whom he knew slightly and whom he had wished might play such a role. It was aided further by a strong resentment which he had developed immediately toward the author for having pried into his affairs and having learned about the unhappy incident. Upon awakening, he had felt at ease and comfortable but impelled to talk. As he talked, however, he had become aware of a constantly growing sense of discomfort, augmented by each topic of conversation and by his own remarks and those of others despite the casual, appropriate nature of such comments. He had been astonished to discover his fear of an ashtray, and he had tried to conceal this terror and to overcome it by sheer force of will. At the same time the tray had fascinated and distracted him repeatedly. Although he had tried, he had not been able to reach any understanding of his reactions. He had become even more distressed when he found that the same feeling of terror had attached itself to other ashtrays and even to used matches. “I was just terribly afraid,” he declared, “afraid of anything with heat in it.”

When asked to describe his emotional reactions in their sequences, the patient stated that, when the complex had been given to him in the trance state, he had reacted to it “just as any normal person would to such a situation. It was a miserable thing to have happen.” Upon awakening from the trance, he had not experienced any particular emotions, but as he had begun to talk, he had developed the same sort of emotional state as he recalled having experienced in the hypnotic trance during the administration of the complex. However, as he continued to talk and had experienced blockings of speech and periods of stammering, and had become aware of his intense fear of ashtrays, his emotional discomfort had increased markedly, and he had become “wretched,” “miserable,” “depressed,” “unhappy,” “anxious,” and “fearful.” He described these changes naively by saying that the familiar and pleasant surroundings in which he had found himself had made his emotional distress seem “silly,” “foolish,” “inadequate,” and “reasonless,” and that this feeling had impelled him to “reach into past experiences” and to seize upon “embarrassed affects” taken from “past embarrassing experiences” and to “add” these new and stronger emotions to those already existing. This had given him a sense of having improved the situation immeasurably in some indefinable way, but it had made him “feel terrible, awful then.” (It had been noted during the latter part of the time in which the patient had the complex that he had become labored and strained in behavior,

speaking with effort, sighing deeply, and perspiring profusely—an observation which had led immediately to rehypnotizing him and "removing" the complex.)

The patient was questioned about the "past embarrassing affect" which he had "added" to the original affects. However, without any apparent effort to evade the question, he launched into an academic discussion concerning the possibility of transference of learning as applied to emotional responses, which did not appear to yield any pertinent information. Neither did he seem to grasp the significance of the question.

Accordingly, he was asked how he felt about the whole situation as he recalled it. He replied, "Well, I'm glad to know that it was just a lot of suggestion and that it didn't really happen." He added that his hesitant, fearful manner of trying to use the ashtray must have appeared ridiculous, saying, "Let me show you how I did it." He proceeded to imitate his previous conduct in great detail, suddenly interrupting himself to say, "Now, I'll show you how I do it now." Lighting another cigarette, he tossed the match into the tray as he talked, and finally extinguished his cigarette by crushing the tip against the bottom of the tray and shoving it back and forth through the ashes, remarking with a smile, "Now, I can feel satisfied about it."

Following this the patient was thanked for his services and dismissed with the understanding that the experiment had been concluded.

Three days later the patient returned to the author's office in a jubilant frame of mind, declaring excitedly, "I can do it." When asked to explain what he meant, he stated that on the previous evening he had been in the company of a girl who had responded warmly to his advances. As usual, upon kissing her he had experienced an ejaculation, but instead of reacting with his customary sense of shame and depression, his erotic desire had increased, there had been no loss of his erection, and he had been able to consummate the sexual act, prolonging his pleasure greatly and repeating the act during the night. He was permitted to tell about this experience in detail, after which he began to question the author as to the origin and validity of his "cure." Noncommittal replies were made and he was reminded that in the past he had succeeded after a preliminary ejaculation. He protested that no comparison could be drawn between past successes and that of the previous evening, which had given him his first sense of genuine sexual satisfaction. Also, his whole psychic attitude and reaction had been entirely new, since he had not experienced any of his customary feelings of fear, shame, and inferiority, but on the contrary he had felt confident, secure, and free. Nevertheless, the author's disbelieving manner caused him to leave the office in a discouraged, doubtful frame of mind.

Several days later he returned, again jubilant, declaring "You're wrong, doctor, I am cured." His story very briefly was that, after leaving the office, he had been much depressed by the author's doubts, and for two days he had continued in a wretched frame of mind. Finally, in order to know the truth, he had secured a girl and had spent the night with her in his apartment. He had begun his love-making cautiously, and as his partner responded, he had become increasingly ardent. Since no untoward event had occurred, he had lost all doubts and had proceeded to the overt sexual act. During the act a neurotic

fear had developed that he might be unable to have an ejaculation, but this fear had been promptly dispelled by an orgasm. After a rest he had repeated his performance satisfactorily. The next night he had obtained another girl and had confirmed his "cure." (Subsequent investigation into the truth of the patient's story confirmed his report.)

At the close of this account the patient was asked what explanation of the change in him he could offer. He declared that he had no explanation, that apparently he had spontaneously resolved his conflicts, and that he was satisfied to let things remain as they were. The author suggested that he sit quietly and think hard, letting his mind wander at will, and as he did so, to recall all the various emotions he had so often experienced in conjunction with his precocious ejaculations. After a few moments he flushed, moved uneasily, then soon, in a low, monotonous tone of voice said, "I see it now—I put my cigarette in the ashtray and it broke—spoiled everything—I felt terrible—just the same way—I see it now—I was afraid to use the ashtray—I'd try to—I'd pat the ashes to be sure there were no sparks—I'd use my trousers." An expression of amusement and understanding appeared on his face. "But I showed you I could do it. Remember? First, I showed you how I acted when I was afraid, and then I showed you when I wasn't afraid. Remember how I put it out by rubbing it around?" He paused, his reminiscent manner disappeared, and in a puzzled tone of voice he said, "Say, that was that complex you suggested to me—say, that explains a hell of a lot to me—I see through a lot of things now—now I know what I meant when I said I could be satisfied." As an amused afterthought he added, "No wonder my feelings were so awful."

An attempt was made to secure an elaboration of these utterances and to elicit an explanation of his apparent identification of the emotions of his neurosis with those aroused by the fabricated story, but he became so ill at ease and appeared to develop such repressive mechanisms against further conscious insight that it was considered unwise to press questions. The only information obtained was the inadequate statement that "the emotions were just the same" for his ejaculatio praecox and the situation of the suggested conflict.

Several months later the patient was asked to read and check the accuracy of this account of his problem. When he reached the paragraph containing his "explanation," he put the page aside, saying, "Do you know, doctor, I can't remember what my explanation was. Let me think." Within a few moments he repeated in total the scene described above, uttering almost exactly the same words. As he concluded, he picked up the page, read it eagerly, exclaiming repeatedly, "That's it, that's it." Again he seemed unwilling or unable to elaborate further, protesting that he had explained the whole matter previously on the basis of the similarity of emotions.

More than a year has elapsed since this experimental procedure. During the first few months the patient indulged freely in sex relations whenever the opportunity offered, with no recurrence of his symptom. Then, after a period of abstinence, he again developed precocious ejaculation, but without the previous emotional concomitants and without loss of his erection, and in each instance he was able to consummate the sexual act satisfactorily. During the last few months he has discovered that a mere recollection of

the experimental procedure will suffice to inhibit a precocious ejaculation, and he is able to function normally. He does not feel handicapped in any way and is well satisfied with his sexual life, and he has not developed any other neurotic symptoms.

DISCUSSION

Careful examination of the above report discloses a wealth of complex psychodynamic manifestations which appear to have been elicited as stimulus-response reactions. From these a number of inferences may be drawn which invite discussion.

Concerning the ultimate soundness of the therapeutic result, there may be legitimate doubt, since the origin of the neurosis and its purposes and function for the personality are not known. However, the fact that the patient can function normally now and can obtain personal satisfactions hitherto impossible, indicates definite and significant changes in his personality reactions of clinical validity. Further, the results suggest that the psychoanalytic theory of pregenital fixation in ejaculatio praecox, developed by Abraham (1927), may not be applicable to every case, since in this instance it is difficult to comprehend how the experimental measures utilized could have bridged such a gap in libido development.

Another question concerns the possibility that the previous hypnotic experimentation, by developing suggestibility, capacity for dissociation, and responsiveness to direct or implied suggestions, might have influenced his neurosis by giving him special insights or new methods of expression. During that time, however, no improvement from his neurosis occurred. For the same reason the hypothesis may be excluded that the author's role as combined hypnotist and promised therapist was unconsciously formulated by the patient as one of an authority-surrogate and permissive agent upon whom he could place the responsibility for successful coitus. Further, it may be contended that the mere induction of a strongly emotional state in the hypnotic trance might have constituted a sufficiently vital experience to occasion a reorganization of the psychic economy with a consequent alteration of the neurotic structure. This is negated by the fact that in the previous work he had been subjected to procedures similar to the one used in this investigation which were equally strongly tinged emotionally, though in a different regard. None of these experiences appeared to have had any role other than that of teaching him how to accept suggestions and how to mobilize his affective responses.

An important consideration is the patient's demonstration of the phenomenon of interpolating into a communication one's own feelings, ideas, and experiences. Given a factually baseless communication, he incorporated it into his mental life, reacted appropriately to it emotionally, and apparently transformed it into a vital part of his psychic life. But in doing so, he interpolated into it other and past experiences, ideas and affects of other origin, formulating the admixture into a new emotional constellation of greater inclusiveness and significance, to which he reacted in a new fashion, as judged by his subsequent behavior and explanations. The means by which he achieved this elaboration appears to have been his unconscious response to the equating of the various emotions which were centered around a single object and which were aroused

simultaneously by the intentionally devised relationships, connotations and symbolizations contained in the story of the complex. His vague desire to possess the girl and at the same time to please her, and his desire to smoke and at the same time to give her something which would eventuate in his own satisfaction were integral parts of his general emotional state in relation to the girl. Similarly, his admiration for the ashtray constituted part of his admiration for her, and the expression of a part of his emotional reactions served as a vicarious expression of the other part. This composite nature of his affective reactions formed an emotional background against which one object could be substituted for another to evoke one or another aspect of a common emotion. Accordingly, the cigarette could acquire thereby the cathexis of the penis and the ashtray that of the vagina with a symbolic representation of the one by the other. That such symbolic values did obtain is indicated by the concluding part of the experiment in which the patient appeared to develop some form of conscious insight. His fragmentary remarks signify an intermingling of ideas and affects, an equation of the emotions from one source with those of another, and an identification emotionally of the suggested conflict with that of his neurosis. It is indicated further by the record of his speech and behavior during the time that he had the complex, and by his posthypnotic discussion, all of which suggests strongly that deep affects not appropriate to the story of the complex were stimulated. Particularly interesting are his naive descriptions of deep emotions, and the physiological concomitants of strong feeling states which he manifested in the first trance state of this experiment—namely, profuse perspiration, deep sighing, and strained behavior.

In this same regard arises the question of whether or not deep affects are amorphous in character and are dependent upon stimulation for definition and for direction into channels of expression. The patient's extreme emotional response to the content of the artificial complex suggests, figuratively speaking, the attachment of an amorphous mass of affect to the relatively simple ideas it contained with a consequent disruption of the personality reactions.

A final question for discussion is the rationale of the patient's explanation of his recovery in terms of the suggested complex. A plausible inference seems to be that, having verbalized the emotions of his neurosis in terms of the trance events during the experimental situation, he had been conditioned to that method of response. Hence, when asked to recall those same emotions and to explain his recovery, he did so in accordance with the established pattern. But as he did so, a new psychic factor—specifically, the mental perspective derived from his successful experiences—gave his utterances a new significance for him, enabling him to declare, "Why, that was the complex—that explains a lot of things to me—now, I know what I meant when I said I could be satisfied!"

SUGGESTED PROBLEMS FOR FURTHER INVESTIGATION

The author is well aware that, however valid the results are in this one instance, no general conclusions concerning the neurosis of ejaculatio praecox or its therapy can be drawn from a single case subjected to a new experimental approach. Nor has this account been offered as a possible solution to such a problem. Rather, the purpose of this report is

to direct attention to the practicability of the use of hypnotism as a possibly fertile technique for the laboratory study of the dynamics of human behavior.
Any therapeutic aspects of such study are of secondary value until a better understanding of the processes involved is achieved.

Although used profitably in experimental academic work, there has been a tendency to overlook the feasibility of hypnosis as an investigatory agent in the study of psychodynamic problems. This investigation indicates that hypnotic measures can be used in a significantly productive fashion to elicit dynamic responses and to manipulate psychological processes. Although no absolute conclusions can be drawn from the findings above, certain inferences and hypotheses, previously discussed are warranted concerning the mental mechanisms involved, the dynamic relationships developed, and the methods for determining or influencing behavior and affective responses. These, in turn, suggest a number of definite experimental problems which invite analytical study and of which a few most relevant to this investigation will be presented.

The first of these problems is the practicability of evolving a technique for the development of experimental neuroses in a human subject for laboratory study. The present investigation is not entirely satisfactory experimentally because of some degree of sophistication in the subject. Despite this fact and the crudity of the technique employed, the results obtained suggest significant clinical and experimental possibilities. The study needs to be repeated, however, on a naive subject with a simpler personality problem such as a specific mild phobia, and in connection with a thorough investigation into the genesis of the symptom for the purpose of elucidating the experimental results. By means of this procedure a more comprehensive appreciation of the interrelationships of conflicts and the influence of one complex upon another might conceivably be reached.

A second problem is the possibility of studying the concept of abreaction. An improved technique similar to that used above, but controlled by continuous observation of the subject and by the centering of his behavior around activities less heavily endowed with affective values and social implications, might offer a good approach to an experimental investigation of the nature, mechanisms, and methods of induction of abreactive processes. A counterpart of experimentally induced abreaction may be found in the "living-out" of fantasies in the psychoanalytic procedure, the clinical results of which also suggest the feasibility of studying abreaction in a laboratory setting.

Another investigatory aspect would be that of devising a technique whereby the subject could be induced to select from a communication the material requisite to form a complex. The present experiment indicates that such a selection was made in this study, since the fabricated story symbolized also an Oedipus complex and a sister-incest situation to which the patient apparently did not react. Such a technique might serve materially to disclose natural complexes and to reveal personality trends and types. Huston et al, referred to above, found suggestive evidence that the hypnotic induction of complexes served to reveal natural complexes. Malamud and Linder (1931) have also

made an approach to this problem from another angle by showing pictures to patients and then obtaining reports of their subsequent dreams.

The patient's emotional behavior during the experiment gives rise to the conjecture that affective responses may be "conditioned" somewhat like the conditioning of neuromuscular responses. This might conceivably be accomplished by arousing deep affects upon which, as a direct sequence, a second emotional situation could be created. An illustration of this is to be found above in the establishment of an affectively significant heterosexual situation out of which arose a special emotional state. From such experimentation, by noting sequences, direction, methods of expression, and purposes served, information regarding the genesis, attachment, and interrelationships of emotional reactions might possibly be obtained.

An approach to some of the problems of symbolization is also suggested by this report. The role of similarity of affects in producing symbolic values may be inferred from the patient's account of his recovery. Experimentation designed to attach similar affective tones to dissimilar objects or concepts might conceivably yield information regarding the development of symbolic equivalents. To illustrate, the present experiment might be repeated by arousing the affects of the Oedipus complex, followed by a second emotional situation centered around a fabricated role of authority exercised by the subject. Verbalization of the one situation in terms of the other would possibly indicate the establishment of symbolic values. Or, if the patient's symbolization resulted from the connotations and the relationships of the ideas communicated to him, experimental procedures based on temporal contiguity and association of ideas might give pertinent results.

Another problem is concerned with the question of the development of insight, the factors controlling its growth, its influence upon mental structures, and its function in the psychic economy. The patient studied apparently acquired insights, some complete, others partial, presumably as a result both of the sequences and the nature of his behavior. The same technique, but with continuous observation of the subject and an adequate objective record of his behavior before, during, and after the experiment, might serve to give an appreciation of any progressive manifestations of insight. Or, the omission of certain parts of the procedure, the changing of sequences in the experimental behavior, or the introduction of new measures might determine the relative importance of the various experimental steps. For example, what would have been the ultimate result in this case had the patient failed to demonstrate, "how I do it now," or had he been informed of the experimental procedure by the author instead of recalling it himself?

SUMMARY

A patient seeking a therapy for a neurosis of ejaculatio praecox was subjected to an experimental procedure wherein an attempt was made to induce in him a second neurosis by means of a hypnotically implanted complex. This complex had been formulated to symbolize or to parallel his actual neurosis. In consequence of this procedure there appeared to result an identification of the induced conflict with his original neurosis and a

fusing of their affective reactions. After the patient had been forced to relive, abreact, and gain insight into the suggested conflict, it was discovered that he had made a clinical recovery from his original neurosis and that he was still able to function normally a year later. A discussion is given in which possible psychological processes and mechanisms underlying the experimental results are elaborated, the ultimate soundness of the therapeutic results is questioned, and emphasis is placed upon the practicability of hypnosis as an experimental procedure in the analysis of personality disturbances. There follows a list of certain specific problems suggested by this study.

---

[1]A detailed report of such an experimental procedure may be found in Huston, P. E., Shakow, D., and Erickson, M. H. A study of hypnotically induced complexes by means of the Luria technique. *Journal of General Psychology*, 1934, 11, 15-97.

The Method Employed to Formulate a Complex Story for the Induction of an Experimental Neurosis in a Hypnotic Subject

Milton H. Erickson

Reprinted with permission from *The Journal of General Psychology*, 1944, Vol. 31, 67-84.

In 1935 a report was published on the induction by hypnosis of an experimental neurosis in a patient suffering from ejaculatio praecox (Erickson, 1935). The procedure employed was that of fabricating a story which would parallel and symbolize the patient's actual neurosis in terms of an ordinary, credible, but unpleasant instance of social behavior. This story was then told to him while he was deeply hypnotized in such fashion that he would believe it to be a true account of an actual past experience of his which he had repressed completely. The patient's profound psychological and neurophysiological reactions and responses to this procedure and the experimental neurosis he developed were reported in the original article. However, for reasons pertinent at the time, no explanation was given of the process by which this artificial complex was fabricated or of the logic that was employed in attempting to make that story uniquely significant to the patient. Instead, the original worksheets, outlines, and rough drafts as well as the final copy were filed away for possible future use. Recently, discussions with Margaret Mead, Gregory Bateson, Lewis B. Hill, and others on hypnotic techniques of suggestion and methods of interpersonal communications have suggested the possible value of presenting in detail the explanation of how that complex was fabricated. Also, such an analysis seems warranted by the continued experience of the superiority of this general type of technical procedure in inducing extensive changes in the behavior of hypnotized subjects, as contrasted to the less satisfactory results secured from spontaneous, unplanned, hap-hazard suggestions, or when the same degree of detailed care is not exercised in building up hypnotic suggestions and hypnotic situations. In considering how to devise or formulate a suitable complex applicable to the subject, the task seemed to be essentially a problem of, "It is not only what you say, but how you say it." Under the proposed experimental conditions "what" was to be said had to be a seemingly innocuous and credible but fictitious story of a past forgotten social error by the subject. The content of such a story was relatively simple to determine and required little imagination, since the patient had been a hypnotic subject of mine for over a year and I knew him intimately, I was well acquainted with his family, and I also had professional knowledge of his neurosis. Hence the content of the story was easily made to center around an imaginary visit at the home of an unidentified prominent man. There he was supposedly greeted by the man's wife and introduced to an attractive only daughter, in whose presence he smoked a cigarette and accidentally broke a prized ashtray.

The "how" of telling this story seemed primarily to be a task of so relating the fictitious account that it would become superimposed upon his actual experiential past in a manner

that would cause him to react appropriately to it emotionally, to incorporate it into his real memories, and thus to transform it into a vital part of his psychic life.

This could be done, it was reasoned, by taking the objective items contained in the essential content of the story and so weaving a narrative about them that they would stimulate a wealth and a variety of emotions, memories, and associations that would in turn give the story a second and much greater significance and validity than could its apparent content.

To do this would require a careful choice and use of words which would carry multiple meanings, or which would have various associations, connotations, and nuances of meaning which would serve to build up in a gradual unrecognized, cumulative fashion a second more extensive but unrealized meaningfulness for the story.

Also, the words, by their arrangement into phrases, clauses, and sentences, and even their introductory, transitional, and repetitive uses could be made to serve special purposes for building up emphasis or cutting it short, for establishing contrasts, similarities, parallelisms, identifications, and equations of one idea to another, all of which would build up a series of associations and emotional responses stimulated, but not aroused directly, by the actual content of the complex. Additionally, sharp transitions from one idea to another, sequential relationships of various ideas and objects, shifts of responsibility and action from one character to another, the use of words that threatened, challenged, distracted, or served only to delay the development of the narrative were all employed to formulate a story possessing a significance beyond its formal content.

Additionally, it must be noted that the patient had been a hypnotic subject of mine for a long time and that therefore he had had a wealth of experience in responding to both direct and indirect suggestions. Thus, his experiential background was of a character to enable him to react adequately to the indirect, concealed, and disguised suggestions and significances of the fictitious story.

Supplementary to this is the fact that the hypnotist, in administering the complex to the patient, was fully aware of what he hoped each item of the story might mean to the patient. Hence, the hypnotist's voice in administering that complex to the patient would carry a load of meaningful intonations, inflections, emphases, and pauses, all of which, as common daily experience constantly proves, so often convey more than spoken words.

Essentially, the task, as worked out, was comparable to that of composing music intended to produce a certain effect upon the listener. Words and ideas, rather than notes of music, were employed in selected sequences, patterns, rhythms, and other relationships, and by this composition it was hoped to evoke profound responses in the subject. These responses were to be of a type not only hoped for in terms of what the story could mean but which would be in accord with the established patterns of behavior deriving from the patient's experiential past.

How well this was done, aside from the experimental results secured, is a matter for speculation. No proof can be offered that the explanation of the complex offered is correct, or that someone else, using the same words, could not construct an entirely different explanation. Proof, if there is to be any, can only be inferential at the best. However, continued experience with the greater effectiveness of hypnotic suggestions carefully calculated as to structure, as contrasted to the lesser effectiveness of spontaneous suggestions primarily concerned with an obvious content, indicates that this initial effort at an analysis of an interpersonal communication of a particular type is warranted.

One additional preliminary to the presentation of the explanation of the complex relates to the actual process of composing the story. During a period of several weeks the story was rewritten in various wordings many times before it seemed to be satisfactory. Two colleagues read and discussed the proposed complex story and contributed a number of helpful suggestions for the final wording of it. Other colleagues contributed unwittingly by discussing, upon request, the meaningfulness of sentences worded in slightly different ways. Also, items of fact relating to the patient, such as his attitudes toward his parents, conversational clichés, patterns of behavior, and actual experiences, were all kept in mind and worked directly or indirectly into the story at every opportunity so that it might have a special and unique appeal for the patient.

As a method of presenting the explanation, the story as devised will be given in the first column of Table 1 and the explanation, logic, intended significances, hoped-for reactions and responses will be given in the second column in the form of comments. These are listed as they were formulated for the final draft of the complex. No attempt will be made to show preliminary or partial formulations as they were worked out from one draft to the next. Finally, the reader must bear in mind that these explanatory remarks constitute only pre-experimental formulations of what the complex might possibly mean to the subject and that hence they are not necessarily to be taken at face value. They constitute simply a Pre-experimental effort to determine the possible meanings of an intended specific interpersonal communication in a special situation. In a few instances it was possible to confirm the validity of a number of these comments post-experimentally, but for the most part such confirmation was not actually feasible aside from also being precluded by the experimental situation.

Table 1

The Complex	Explanatory Remarks
Now	"Now" relates to the present, the immediate, circumscribed, highly limited present; it will not bear upon the past nor upon the future; it is safe, secure.
as you	"You" is a soft word; the subject is introduced gently.
continue	"Continue" is a most important word, since it

The Complex	Explanatory Remarks
	carries on into the future, it contradicts "now," which relates to the present, and it introduces an indefinite extension into the future. Hence, the subject unwittingly makes a change from the "now" situation into a continuing future situation.
to sleep	Thus he has the time situation changed and at the same moment is given a command to "continue to sleep," a command based upon the past, including the present and extending into the remote future.
I'm	First-person pronoun, which means that anything done is to be done by the hypnotist and that the subject can be safely passive.
going	Going" carries on the future connotation of "continue," but enlarges it by bringing both the hypnotist and the subject into the continuation into the future.
to recall	"Recall" signifies the past, and we are both going into the future, taking with us the past.
to your	Second-person pronoun, emphasizing that we are both going into the future and taking the past with us.
mind	"Mind" is a selected, important, most important part of him, a part of him related to the past.
an	"An" means just one, a certain one, and yet is at the same time so indefinite.
event	"Event" is a specific word; just one event, "an event," and yet, despite its seeming specificity, it is so general that one cannot seize upon it or resist or reject it or do anything but accept "an event."
which occurred	"Occurred" is a narrative word; lots of things occur, especially minor things.
not	If the subject wishes to reject, deny, or contradict, the word "not" gives him full opportunity. He can seize upon it and attach to it all of his resistances to an acceptance of the story; it is literally a decoy word to attract his resistances. The sequences are "occurred not"—in other words, "did not occur" —but, even should his resistances seize upon "not," that

The Complex	Explanatory Remarks
	decoy is legitimately snatched away by the next two words, and thus his resistances are mustered, mobilized, but left unattached and frustrated.
long ago.	Actually “not long ago,” —”not” now destroys itself as a negative word; it is positive in that sequence. Furthermore, it is highly specific, but in a vague, general way; when is “not long ago”? Yesterday? Last week? Also “not long ago” is real, since we do have a “not long ago” in our lives; thus a weight of truth is given which will radiate.
As I	First person again, assuming responsibility.
recount	Previously, I was going “to recall,” but in this phrase I immediately withdraw from that responsibility. Now I am only going to “recount,” and “recount” and “recall” are totally different words. Thus the responsibility for “recall,” which was the initial task, is rejected by the hypnotist, who assumes the responsibility only for recounting. Therefore, if the hypnotist recounts, the subject is thereby compelled to recall. Indeed, if the hypnotist can recount, and there can be no doubt about that, then the subject can, actually can, recall; a sophistical but indisputable establishment of the truth of the story to be told.
this	“This,” like “an,” is a definitive word that cannot be disputed; and readiness to dispute or deny must be held in abeyance.
event	Again a specific word
to you,	Second person; first it was recalled to “your mind,” and now it is recount “to you,” that is, to him as a person. Thus he is introduced so that, in his passive acceptance of the recounting, he, as a person, can assume responsibility.
you will	The subject is called upon to act as a person and at the same time is given a command.
recall	“Recall” completes the shift of responsibility from first to second person, with a final allocation of responsibility for recounting and for recalling.
fully and completely	fully and completely These are distraction words

The Complex	Explanatory Remarks
	since they attract attention not to the task, but to the size or quality of the task. Hence, he must first refuse to do it "fully and completely" before he can refuse to do the task at all, and if he refuses to do it "fully and completely," he is by implication obligating himself to do it at least in part, until he goes through the process of refusing to do it in total. All this takes so much time that there is no opportunity to go through those mental processes permitting a logical rejection of the entire task. Additionally, if he still has resistances to the hypnotic situation, he can mobilize them against these distraction words.
everything	"Everything" is really a threatening word; to tell everything is something one just does not do. So here is an opportunity to mobilize resistance, since, if he is to accept this story, his resistances must first be mobilized as a preliminary to a dispersion. Also, if he refuses to tell "everything," he is thereby affirming that there is something to tell.
that happened.	The command to tell "everything" is now seemingly qualified, since it is not "everything," but just the bald facts of "what happened," not the meanings or personal implications. Again there is an implication of other things.
You	Second person, reemphasizing the subject's role as someone involved.
have had good reason	There is not only a "reason," but a "good reason," at that! We all like to think we have a "good reason"; it vindicates.
to forget	Now the "good reason" becomes inexplicably transformed into a "bad" reason; "good" no longer is "good," but is really a bad sort of thing; the kind of reason one likes to forget. Also, "to forget" explains the need "to recall," and explains the recounting. But what does one forget? Bad things, especially!
this	Explicit word, intended to reemphasize the feeling of specificity.
occurrence,	"Occurred" was a narrative word, and now the word is "occurrence," so often a euphemism

The Complex	Explanatory Remarks
	applied to bad things one forgets.
but	"But" always prefaces unpleasant things; "let's have no 'buts' about it," is so common an expression.
as I recall it,	This phrasing is a reprieve, since the first person assumes the responsibility, but he who can assume responsibility can also assign it. Thus, indirectly, the dominance of the hypnotist is assured, and the next words lead to active work for the subject.
you will remember each and every detail fully.	More than recall is wanted. Previously, it was "you will recall"; now it is more "you will remember"; furthermore, "remember" is in itself a simple, direct, hypnotic suggestion, similar to the suggestion of "sleep" in the opening sentence. Also, what is to be remembered is "each and every detail," so refusal to remember has to be directed to each detail, not to the whole occurrence. Thus, "each" and "every" and "fully" are distraction words, directing refusal or rejection to a quality of performance.
Now	"Now" harks back to the first word of the first sentence, a word that could be fully accepted. Thus, utilization is made of that first attitude.
bear this in mind,	Mind" harks back to the first sentence again for a similar reason.
that while I repeat	"Repeat" is a word which relates to a factual experience in the past, one that really occurred and is known, since otherwise it could not be repeated by someone. Also, the role of the hypnotist is clearly defined and cannot be disputed.
what I know of this event,	"Repeat" and "know" affirm and establish the truth, but they give an avenue of escape, because the qualification of what "I know" implies that there may be much that "I" don't know, and therefore something additional that he does know.
you will recall fully and completely	This phrasing harks back and reaffirms the original allocation of responsibility to "you." "Fully and completely" is again a repeated distraction, reinforcing the previous use of those

The Complex	Explanatory Remarks
	words.
everything	That meaningful, even threatening word again.
just as it happened,	A qualification that limits and comforts since it excludes possible personal implications and meanings.
and more	Further threatening since "more," what "more," is wanted.
than that,	Still carrying the threat.
you will	A hypnotic command carrying compulsion.
re-experience the various conflicting emotions	The thing is now defined as conflicting and as emotional, of which things he had a plenty, all real and, above all, emotional.
which you had at the time	A specific but unidentified "time" in the past, but a time related to "conflicting emotions."
and you will feel	a hypnotic command that he is to feel, which carries a threat since it follows " conflicting emotions."
exactly as you did while this occurrence was taking	The thing is defined and outlined, his course of action indicated to be a revivification, only that, of a past experience—not a confession, just a re-experiencing of something that took place.
Now	Harking back to the opening word, repeated later for its acceptance values immediately after the assignment of a task, and once again repeated here at a similar point.
the particular event	"An event," "an occurrence," now becomes a highly specific item.
of which I am going to tell you is this:	"I" can tell only what little "I know," a casual statement, transitional in its use, reassuring in its implications.
Some time ago	"Not long ago" redefined, but still vague and elusive of contradiction.
you met a man	Indisputably true and acceptable.
prominent	We like to know "prominent" people, an initial appeal to narcissism.
in academic circles	A narrowing of the identification of the man, but safely so!

The Complex	Explanatory Remarks
who manifested an interest in you	A strong appeal to narcissism.
and who was in a position	A tentative threat, because "position," synonym of power, can be used favorably or unfavorably.
to aid you	Narcissism reinforced and reassured, but more than that, the subject now wants to know, to identify, the man, hence is open readily to suggestion.
in securing a certain	Highly specific but not definitive.
research fellowship in which you were much interested.	A true statement in that he was interested in a fellowship, actually any fellowship, but this statement offers no opportunity to take issue or dispute, since each item is progressively qualified, and each qualification requires dispute before the initial premise can be attacked, and his narcissism requires that he accept each time in the suggestions. Thus, resistance is dispersed. Additionally, the man is "interested," the subject is "interested," there is a common denominator, and the reality of the subject's interest radiates to and substantiates the man's interest.
He	A third person taking all responsibility. Therefore, the subject can listen receptively, since the story is about a third person.
made an appointment with you	This is a disputable statement, hence is to be qualified in more and more detailed and specific fashion, thus to preclude any upsurge of resistance or rejection, and each little item to be added must have a cumulative effect that takes the subject ever farther from the essential point.
to see him at his home	A qualification as to place.
and on that day	A qualification as to a specific day that must be selected out of the past.
you called at the designated	"Designated" is so specific, final, absolute, and yet so indefinite.
hour.	A final specific qualification for the appointment, and it is most important to establish that appointment. Thus the subject is led to a home, to "that day," to a "designated hour." With such detail not even a thought can flash obstructively in his mind, since the only measure open to him

The Complex	Explanatory Remarks
	in the hypnotic situation is to reject a "designated hour" of a specific day at a home of an interested man who, narcissistically, he wanted. Thus, an idea has been offered, and its acceptance literally forced. Therefore, an opportunity to resist something about this rapidly growing story must be given him in return for being forced to accept some ideas.
When	A challenging word, anything can happen "when."
you	Second-person active, giving opportunity for him to get set for action.
knocked at the door	A brief item of detail, momentarily obstructing action.
you were met	"You" is second-person passive—thus he is forced from the active to the passive role. "Were met" is a dogmatic declaration which is the opening for all resistance and rejection, an opportunity to interpolate from past experience, a wide-open door for dismissal of the entire story, and thus a chance for him to construct his own account.
not	A negative word, emphatically negative.
by this gentleman	Apparently, it is unnecessary to deny, reject, or dispute the story, since the hypnotist is doing that by the implications of "you were not met." Thus, the subject's resistances have been built up and then lulled into inaction, rendered futile by the negations employed.
but his wife	"But" used a second time, this time in close association with a woman to reinforce possible previous unpleasant associations, in a wife is a sexualized woman. Also, this is another disputable statement, but before he can remobilize his resistances, the to a situation is completely changed by the next words.
who greeted you cordially and was very friendly,	A tremendous appeal is mad3e to his narcissism, already stimulated previously. Only lie to be treated cordially by a "prominent" man's wife.
making you feel	"Feel" means "respond emotionally," a safe, secure situation for responding t narcissism.

The Complex	Explanatory Remarks
	Also, the word is a direct call for narcissistic response. At the same time there is given the simple direct hypnotic command of "you feel."
that her husband had given a good account of you to her.	Full opportunity offered for unrestricted narcissism in a safe, secure fashion. All that has been told now rests upon secure foundation of narcissistic satisfactions. He needs this story.
She explained apologetically	An indirect attack upon his narcissism—is this gracious woman who flattered him now becoming apologetic? That must not be so because whatever that cordial woman does must be right, and he will make it so. Apologies and praise in that combination are not good.
that her husband had been called away	A faint, remote realization that he was alone with a woman who was a wife and hence a recognized sexual object.
for a few moments	A limitation of the danger, and hence he is safe, although alone with a woman.
but that he would return shortly,	"Shortly" is so specifically vague and reassuring.
and had asked that you	"You," the person, introduced again.
be made comfortable	Gracious man, gracious woman, narcissistic satisfactions reinforced.
in the library.	A distraction phrase. Yet, to be made comfortable by a lone woman in the safe confines of a library is like inviting a girl to meet you in the sitting room of your hotel suite—a faint suggestive implication.
You	Second-person active.
accompanied her to this room where	Reduction of possible fear by specificity in mentioning only this room—but what is to happen?
she	A woman active in his company she—something will happen!
introduced you to a charming girl	For him there can be no greater threat in all the world than a charming girl. A terrifying, threatening situation, loaded with tension firmly established by his past.
who-was obviously rather shy and reserved	The threat castrated, and he was master. Thus, his fears were aroused and immediately lessened.

The Complex	Explanatory Remarks
and who, she explained,	First she explained apologetically and unacceptably, now she explains in relation to a threat will these displeasing explanations never end? A direct opportunity for relief of tension, directed against unnecessary social amenities conducted in such a terrifying situation, but serving to introduce another antagonism.
was their only daughter.	A very special kind of daughter, all the more threatening despite the castration. Thus, a useless, only temporary castration was performed, and while it did relieve his tension briefly, that tension has been revived and intensified.
The mother	An immediate shift from the threatening daughter to the displeasing mother, permitting his tension to increase.
then requested your permission	This cordial, gracious, apologetic woman led him into a trap; she was nice, and certainly he would do anything for her, especially since it would change the total situation by letting him deal with the mother and not the daughter.
to go about her work,	Work is a far cry from social pleasures, remote and distant, and thus she was removing herself far from him, leaving him alone with danger.
explaining	That unpleasant word again, first used to rob him of narcissistic pleasure, then to lead him into a danger situation. What now?
that the daughter	Special, precious, only daughter—charming girl. A peculiar threat, challenge, and danger all combined.
would be very happy to entertain you	To be entertained by a charming girl with the mother's connivance!
while you waited.	"Waited" for what? "Waited," a threatening word, expressive of his passive helplessness. He could only wait, and in the past he had so often "waited" in the company of a charming girl.
You assured	"Assured" carries connotations about risks and dangers.
the mother	Who led you into a trap, a danger situation—opportunity for intense resentment and tension

The Complex	Explanatory Remarks
	relief.
that you would be very comfortable	"Comfortable" with a girl? Past history proves the mockery of that.
and even now	Harking back to the first "now" and reutilizing its "present" values.
you can recall	Harking back to the first use of "recall" and thus tying everything tightly together.
the glow of pleasure you experienced	Harking back to "re-experience the various conflicting emotions." If there were conflicting emotions, some were glows of pleasure, and now his situation is one of a conflict, of attractive and shy, of charming and only daughter, of mother coming and not staying and praising and apologizing, pleasure and unpleasure.
at the thought of having the daughter	"Having the daughter," possessing the charming girl-synonymous phrases.
as a hostess	Dance-hall hostess? He had had hostesses before, and now there is given the suggestion that he have the "daughter as a hostess."
as the mother left the room	A distraction by shifting attention away from the immediate threat of the girl, and hence readily accepted even though it leaves him alone with his danger.
you set about conversing	Second person introduced. "Set about" implies action, doing something. "Conversing" is a safe activity, but it is a euphemism, and what thinking one can do as he converses!
with the girl	Alone with a dangerous girl brought to full realization.
and despite her shyness and bashfulness,	Despite those qualities, what else? What danger threatens?
you soon found	Continuation of the threat.
that she was	What was she? An only daughter, a charming girl, a daughter as a hostess?
as attractive conversationally as she was pleasing to the eye.	Safe, yet unsafe, physically pleasing, capable of conversation, capable as a hostess.

The Complex	Explanatory Remarks
You	Second person again.
soon learned	He had learned much about her, too much, and now what more was to be learned about this charming girl so pleasing to the eye?
that she was much interested	Repetition of the word “interested.” In what could she, in this danger situation, be interested?
in painting	“Painting”? Painting the town red? A euphemism?
had attended art school, and was really profoundly interested in art	He had done commercial art to pay his way through college, so there was something in common, a common interest-to be profoundly interested in art would mean that she was interested in his art, and his art was part of him. A part of him?
she	A shift from him to her.
timidly	A dangerous girl being timid? Girl-boy behavior, coy, luring behavior?
showed you	Presented to you.
some vases she had painted.	A symbol innocuously introduced, and with the word “painted” establishing their common interest in doing something.
Finally	This is a threatening word. It establishes a moment surcharged with finality—a grand finale is about to be!
she showed	Previously, she timidly “showed,” but now where is that timidity? The situation has changed!
you a delicate little glass dish	Fragile, precious thing, easily shattered by masculine strength, so like the girl.
which she had painted	Something on which she had lavished attention.
in a very artistic manner	Lavished care in a special sort of way that he and she together could both appreciate.
explaining	That word of previously unsatisfactory connotations.
that she had decorated it as an ashtray for her father,	Charming girl, precious possession, father’s owner-ship and priority.
to be used	There is something in this danger situation to be used!

The Complex	Explanatory Remarks
more as an ornament	An ornament can decorate a pleasing body.
than as an actual ashtray.	It's not an ashtray! It's something different. Thus, the symbolic value is clearly established. It is just called an ashtray, but it is an ornament belonging to her and over which the father exercises some undetermined undefined authority.
You admired it	"It" was what she had; she was attractive, pleasing to the eye.
very greatly.	Redundant superlative! In other words a special significance is to be attached to this symbol, significance in relation to admiration in the presence of a physically attractive girl.
This mention	Some things are just "mentioned," hinted at, not said in a forthright manner.
of using the dish as an ashtray	But it is not a "dish," it is not a vase, it is not even an ashtray-it is just an ornament that belongs to her and to her father in a peculiar sort of way.
made you desirous	One wishes to smoke but becomes "desirous" in the presence of a pretty girl.
of smoking.	A euphemism, a safe, conventional way of giving expression to the feeling of being "desirous," actually a pattern of behavior taken out of his past, since smoking was used by him in his problem situation as a distraction.
Because of her youth	Not "youth" really, though she was fresh and pretty and youthful, but something that "youth" connoted, something not to be expressed.
you hesitated	One may eye an attractive girl and be "desirous" and "hesitate." Thus, a sexual motif becomes more evident. Besides, one does not hesitate to smoke in the presence of youth.
to give her a cigarette.	A symbolic ashtray, an ornament belonging to her in which both she and he were "interested" in a special way, with a father lurking in the background. The words "desirous," "smoking," "youth," "hesitate" all constitute a background for a symbolic cigarette that fits a symbolic ashtray.

The Complex	Explanatory Remarks
Also,	There is something else left unsaid as yet, an implication repeatedly established by transitional words.
you did not know how her father	Father lurking in the background reinforced.
might feel about such things	What are "such things" in the presence of a youthful girl that might arouse a father's ire?
and yet you wanted	A long history of "wanting," "wanting" in the presence of every pretty girl
to observe the courtesies of smoking	A euphemism, since what else can be said?
As you debated	One does not debate about smoking, one debates for deep reasons, one strives against and tries to controvert the forces against him in a debate.
this problem	He had a "problem," a most troublesome problem in relation to girls, and he is "debating" a "problem" in a girl's presence.
you became increasingly impatient.	Not over smoking does one become "increasingly impatient," but only over vital problems.
The girl	"The girl" follows "increasingly impatient," and by that juxtaposition a relationship is established between "the girl" and the feelings described.
did not offer you a cigarette and thus solve your problem	She failed him like all other girls he had known, equating her with those other girls who did not solve his "problem."
and you kept wishing	"Wishing" just "wishing" in direct connection with a girl who had failed to solve his "problem," an old, old story for him.
that you might	If only he "might," really "could" do something.
offer her a cigarette.	"They satisfy," was one of his clichés, and he did want satisfaction. The conventional and the sexual motifs intermingled—satisfaction in relation to a girl, a symbolic ashtray, being "desirous" and his "problem."
Finally	Another final moment, with implications of other things.
in desperation	Strong, bitter, frustrated emotions constitute desperation, and it does not derive from being deprived of a cigarette.

The Complex	Explanatory Remarks
you asked her permission	The role of being miserable, a suppliant, incapable of self-determined action.
to smoke,	A long history of smoking in his "problem" situation to cover up and conceal his disability.
which she granted very readily,	A permissive, willing girl, readily granting favors—another item taken out of his past history.
and you took a cigarette	That was all he could do, and which he had so often done in the past.
but did not offer her one.	She bad no pleasure, she was unsatisfied. Past history still being utilized.
As you smoked	He couldn't do anything else, as be bad proved many times.
you looked about for an ashtray and the girl, noticing your glance,	Did she notice? Did all those girls of the past notice your glance, your look? "For an ashtray and the girl," making them in this juxtaposition a single object to be looked for. Also, another cliché was "ashes hauled."
urged	Not only permissive, but urgent, active, aggressive.
you to use the ashtray she had designed	An "ashtray she bad designed" for what'? She bad only decorated it for father.
for her father.	Father's special thing, unused by him and not, intended for his use, but only an ornament over which be exercises an undefined authority.
Hesitantly	Again he "hesitates," but more than that, the word "hesitantly" implies insecurity, uncertainty, even fears.
you did so	"Hesitantly, you did so—in other words, disposed of "ashes" in a forbidden object.
and began talking on various topics.	A technique of self-distraction and of distraction for the girl often employed in the past.
As you talked you became aware of a rapidly mounting impatience	"Mounting" is a word he often used with special significance. He was always "impatient to mount" before "something happened" that meant the end of the attempt to succeed. Incongruous words!
for her father's return.	"What choice is there between "father

The Complex	Explanatory Remarks
Shortly you became so impatient	This only another "impatient" situation, thereby it is equated with other "impatient" situation.
that you could not enjoy smoking any longer,	Past history repeated. Was that why the slogan "they satisfy" was his cliché?
and so great was you impatience and distress	'Those words can describe only something more vital than smoking. They are pertinent to past experiences.
that instead of carefully putting out your cigarette and then dropping it in the ashtray, you simply dropped the lighted cigarette	'The whole performance was of no value—it was futile, useless, hopeless, fraught with distressing emotion. "lighted cigarette" and ashes just dropped futilely.
into the ashtray and continued to converse with the girl.	Past history, in that he could only conclude by conversing with the girl.
The girl apparently	"Apparently" carries a weight of hope.
took no notice of the act	There are acts, and then there is "the act," and this was an act that preceded his despairing resignation to mere conversation with a girl, a girl who "took no notice," a parallel of many previous instances.
but after a few minutes you suddenly heard a loud crack,	"'The crack that never heals" was a paraphrase from a song often employed by him to vent sadistic reactions.
and you immediately realized that the cigarette you had dropped into the ashtray had continued burning and had heated the glass unevenly, with the result that it had cracked in pieces.	He had often bitterly described his repeated efforts and failures on a single occasion as an attempt "to take a crack in pieces."
You felt very badly	Redundancy, strained superlative to carry extreme emotional weight.
about this, but the girl	"This" is one thing, "the girl" is another—juxtaposition of two items that are to be equated.
very kindly and generously	Permissive, granting, urgent, now maternally kind and forgiving—copies from past experience.
insisted that it	An unnamed "it."
was a matter of small moment	Past history again, carrying the same load of bitter ironic significance. What he did was of "small moment."
that she had not yet given the	Further ironic truth.

The Complex	Explanatory Remarks
ashtray	
to her father	First maternal, now the girl speaks for her father, thus combining maternal and paternal attitudes in her forbearance.
that he would not know anything	"Not anything," a secret was to be dept, a guilty secret.
about it	Still an unnamed "it."
and that he would not be disappointed.	A seriously tense situation does not warrant such a mild word as "disappointed." "Disappointed" is a euphemism and at the same time signifies that the situation warrants the mockery implied by "small moment."
Nevertheless,	"Nevertheless" implies the existence of certain other facts.
you felt exceedingly guilty	Fitting words, but not for the superficial content.
about your carelessness in breaking the ashtray.	A euphemism, since exceeding guilt does not attach to an ashtray.
and you wondered	How many times had he "wondered" in similarly emotionally charged situations?
about how her father	Man of power, authority, prior rights.
would feel about it	Not think about "fee," since this was a matter for profound emotion.
if he ever learned of it.	"Ever learned" —a continuing threat implied.
Your concern was plainly evident,	How many times in the past had his concern been evident?
and when the mother	Maternal retribution, forgiveness, or what?
came into the room you tried	You really did try, you've always tried, but it always ends the same old way.
to explain, but she graciously	Forgiveness, not retribution, always forgiveness as in the past.
reassured you and told you that it really did not matter.	"Small moment" ironically brought home by the one who should be most bitter.
However, you felt most uncomfortable about it,	A conventional way of saying something too vital to be put into words.
and it seemed to you that the girl felt badly too.	Like other unsatisfied girls who masked their disappointment by maternal behavior, who did not reveal that they had been "badly" used.

The Complex	Explanatory Remarks
Shortly after this a telephone call was received from the father stating that he was called away for the rest of the day	A reprieve, a postponement.
and asking your permission to see you on a later day.	"Your permission," when he has been wronged and violated in relation to his only daughter. The whole situation now radiates beyond the room, reaches out into the fabric of the social situation, the educational situation, infringes upon and enters into everything, and continues to a "later day." Hence, it is not ended yet, but reaches indefinitely into the future.
You left the house very gladly, feeling most wretched about the whole situation	That was all it was, a "whole situation." A pun upon another cliché he employed when distressed about his disability.
and realizing at the time that there was nothing you could really do about it.	A final, despairing repetition of the teachings of the past.
Now after you are awakened,	The original "now" situation continuing into the immediate future with the repetition of the word "now" reestablishing the original receptive attitude.
this whole situation	Pun repeated in relation to the immediate future.
will be on your mind. You will not consciously know what it is but nevertheless, it will be on your mind, it will worry you and govern your actions and your speech although you will not be aware that it is doing so.	Hypnotic suggestion, with careful emphasis upon the second-person pronoun.
I have just told you of a recent experience of yours, and as I recounted it to you, you recalled it in detail, realizing the whole time that I gave you a fairly accurate account of the situation, that I gave the essential story.	A brief summary of first- and second-person activities with allocation of responsibilities and definition of roles reiterated.
After you awaken, the whole situation will be on your mind, but you will not be conscious of what it	A final shifting of all action upon the second person and repetition of hypnotic suggestions.

The Complex	Explanatory Remarks
is, you will not even be aware of what it might be, but it will worry you and it will govern your speech and your actions.	
Do you understand?	A final command, request, and plea that in itself signifies that there is much to be understood.

CONCLUDING DISCUSSION

That all of this labor was warranted in devising a complex is, at first thought, questionable. Previous experience (Huston et al, 1934) had disclosed that complexes could be devised easily which would exert significant influences upon the behavior of hypnotic subjects. However, such influences were found to be uncertain, unreliable, and unpredictable. Additionally, that same investigation, as well as other experimental work had shown that hypnotic subjects could reject complexes for even minor reasons or mere whims.

In this particular experiment, however, the total situation made heavy demands. Not only was the subject to accept the complex and to have his behavior influenced by it, but he was also to be induced to develop an artificial neurosis which would in some way parallel his actual neurosis. Thus, the experimental situation required of the subject a highly specific type of behavioral reactions, determinable only by the personality structure of the patient, and which would be expressive of responses at a symbolic level to the implications rather than to the actual content of the story.

Just what forms such responsive symbolic behavior would take was entirely a matter of speculation. For example, phobic reactions about smoking were anticipated, but it was not realized these phobic reactions would lead to a ready acceptance of a cigarette for smoking and then result in a fearful dusting of the ashes into his trousers' cuff, with a subsequent spontaneous equating of this specific behavior with the consequences of a premature ejaculation. Such symbolic equating of two different types of behavior in relation to his trousers can be explained only in terms of the intended special meanings of the complex story, and hence, the results suggest that, at least in this type of interpersonal communication, the method by which a story is told may be even more important than its content.

GENERAL INTRODUCTION

For nearly 200 years there has been a slowly growing scientific interest in hypnotism. Along with this interest there has also existed much antagonism, misunderstanding and actual fear of the phenomenon because of the difficulties involved in reaching any clear understanding of it. However, the developments in psychology, psychiatry, and psychoanalysis within the last 50 years are now serving both directly and indirectly through the elaboration of new and useful concepts to place hypnotism on a secure scientific basis free from the hampering, superstitious misconceptions that have characterized so long the general attitude toward this definite psychological phenomenon.

At the present time many of the leading psychological laboratories are subjecting hypnosis to controlled scientific study. In the last 20 years slightly more than 400 articles have been written on the subject in French, English, and German. About one-third of these articles were written in the first half of the last 20 years, and they dealt either with vague generalities or limited aspects of the subject. The articles for the last 10 years amounting to two-thirds of the total, show a markedly different approach to the subject. Not only has the volume of the work doubled, but the approach to the problems of hypnotism has been placed more and more on the scientific basis of controlled laboratory analysis and experimentation in an effort to identify the essential nature of hypnotic manifestations. The immediate outcome of this type of scientific study has been the realization of the investigative and explorative values of hypnosis as an instrument applicable to the laboratory study and analysis of the psychological aspects of human behavior, neurophysiology, and mental disease.

HISTORICAL PERSPECTIVE

Before discussing these aspects of the subject, hypnotism may be considered first in a brief historical review. Although actually known for centuries, even by primitive savages, hypnotism made its semiscientific debut about 1775 in a study by Mesmer, after whom it was originally termed “mesmerism.” Mesmer had no realization of its psychological nature but regarded it as a force of a cosmic type possessed of decided value in the medical treatment of certain types of patients. Mesmer’s misunderstanding of his discovery, together with the general antagonism of the public to any new and incomprehensible phenomenon, led to the development of many superstitions and fearful beliefs, some of which are excellently portrayed in the story of “Trilby,” especially in the

characterization of Svengali. These fears and superstitions are now beginning to die, although they are frequently given new life in the cinema, the tabloid newspaper, and the comic strip.

Following Mesmer were three outstanding English physicians: Elliotson, who began his work in 1817 by employing mesmerism as a definite therapeutic aid in hospital and private practice; Esdaile, who, stimulated by Elliotson's success and writings, began to employ it medically in India in a government hospital chiefly as an anesthetic agent in surgery; and finally, James Braid, who in 1841 recognized its psychological nature and first placed mesmerism, which he renamed "hypnotism," on a scientific basis.

Since Braid, many outstanding clinicians have been interested in the subject, the foremost of whom was Charcot. Much of Charcot's work, however, served only to retard the development of definitive knowledge in this field. His misidentification of hypnosis with hysteria has led to many serious misconceptions of hypnosis, and even today the false belief is held that hypnosis and hysteria are the same. Fortunately, however, the increasing clinical literature is correcting this mistaken idea.

Perhaps the next significant, though passing, figure in the development of the clinical applications of hypnosis was Freud, who with Breuer initiated its employment as an investigative psychological instrument in the treatment of mental patients. However, he soon discarded it as a method because of certain limitations which he encountered through his use of it as a direct and immediately corrective and therapeutic agent instead of as an indirectly educative measure in therapeusis—developing, instead, certain of the discoveries he had made through his use of hypnosis.

Since this first application of hypnosis as a clinical instrument for the study of mental disorders, the development of psychology as a science has served greatly in providing concepts and methods of study and analysis permitting a more comprehensive application of hypnosis as a clinical instrument for both normal and abnormal forms of behavior. Accordingly, the problem of the study of hypnotism and its applications was taken over by both abnormal and clinical psychologists and psychiatrists.

With this recognition of hypnotism as constituting a definite problem for investigation by the relatively young sciences of psychology and psychiatry, there has come to be an increasing appreciation of the possibilities it offers in both fields, first as a laboratory instrument in the study of the nature of human behavior, and second as an explorative and perhaps therapeutic agent in dealing with mental disorders.

Naturally, the greater contribution to date has been in the field of the clinical psychologist, who has taken hypnosis out of the province of abnormal psychology and has employed it to reopen certain questions in psychology formerly considered fairly well outlined. This hypnotic experimentation by the clinical psychologist has served greatly, both directly and indirectly, to contribute new significance to such concepts as learning and forgetting, reasoning, sensation, attention, feeling and emotion, association, conditioning, and personality development, to develop new approaches to old questions,

and to permit the repetition of established work under varied psychological conditions, thereby serving to make it more informative.

In consequence of the general development of clinical psychology, psychiatry has profited extensively. As pointed out by Whitehorn and Zilboorg (1933), in the ten years from 1921 to 1930, there has been a complete change in the character of psychiatric literature, with a decrease of clinical descriptive articles and a more than doubling of the psychological studies. With this influx of psychological trends, psychiatry has come to look upon hypnosis not only as a limited therapeutic approach but rather as a useful instrument for the study of mental disorders and as an actual means of approaching an understanding of causal factors in the laboratory analysis of its problems.

GENERAL CONSIDERATIONS AND TECHNIQUE

However, before taking up the question of the laboratory use of hypnosis, it may be best to mention briefly certain general considerations and then to proceed to the problem of the technique of hypnosis. First of all are those considerations included in certain general questions always asked, foremost among which is the question of who may be hypnotized. The reply to this is that any really *cooperative* subject may be, regardless of whether he is a normal person, a hysterical neurotic, or a psychotic schizophrenic patient. Next, it has no harmful effects nor does it lend itself, as the cinema and the tabloid newspapers would have one believe, to the promotion of criminal activities (Erickson, 1932, 1934). Thirdly, despite its outward appearance, it has no actual relation to physiological sleep but is simply a psychological phenomenon (Bass, 1931). Finally, it is not supernatural but a normal though little understood psychological manifestation, readily and easily controlled by the experienced worker.

Concerning the technique of trance induction little information is available in the literature, and hence each hypnotist necessarily develops his own. The actual accounts of hypnotic procedure given in the literature are inadequate and misleading. Because of this lack of information regarding the essential refinements of technique, much of the early hypnotic work attempted by investigators leads to poor or unsatisfactory results, and this in turn accounts for much of the discredit accorded to hypnotic work.

Usually the understanding is that hypnosis may be induced by repeated suggestions of fatigue, drowsiness, and sound sleep, and that when the subjects give evidence of being asleep, they are ready for hypnotic procedure. Actually, these subjects may be in a trance, giving every evidence of this fact, but in reality it is too often a type of trance permitting only limited use of hypnotic suggestion. The employment of hypnosis as a therapeutic agent or as a laboratory method of experimentation requires, for valid results, a training process extending over several hours. In this training procedure subjects may be hypnotized, awakened, rehypnotized, and reawakened repeatedly, with each of the trance and waking states employed to teach them by slow degrees a facility of control over mental faculties and an organization of responses that increases the degree of dissociation between consciousness and subconsciousness, thus establishing in effect but not in actuality a dissociated hypnotic personality. Only by building up in each subject a

capacity to function in an organized, integrated fashion while in the trance state can extensive complicated therapeutic or experimental work be done.

Because of the difficulties and labor involved in integrating various forms of hypnotic behavior, the variations in time and effort required in training individual subjects and hence the impossibility of establishing any standard of routine, and the general failure to realize the need for an integration of hypnotic responses, there are inadequate, ineffective, and often misleading results from hypnotic work.

Since the scope of this paper does not permit a detailed account of the refinements of technique, it may be best to summarize with the statement that an effective technique is one based upon repeated, long-continued hypnotic trances in which the subject reaches a stuporous state. In this trance stupor the subject is taught, by slow degrees, to obey suggestions and to react to situations in an integrated fashion. Only in this way can there be secured an extensive dissociation of the conscious from the subconscious elements of the personality which will permit a satisfactory manipulation of those parts of the personality under study.

UTILIZATION OF HYPNOTIC PHENOMENA

To proceed now to a consideration of the utilization of the various phenomena of the hypnotic state, it may be best to select those having a significant bearing upon psychiatric problems and to indicate their various investigative possibilities.

One of the important trance manifestations occurring in nearly every well-hypnotized subject is catalepsy. In the stuporous trance this catalepsy may not be distinguishable from the cerea flexibilitas of the stuporous catatonic patient. Numerous attempts have been made to understand the physiology and psychology of the waxy flexibility of the schizophrenic patient, and many studies with drugs, especially bulbocapnine on animals, have been made without clarifying the problem. The apparent identity of hypnotic catalepsy with the catalepsy occurring in mental disease suggests the advisability of approaching the neuropsychiatric problem contained in this familiar sign of mental disease by exhaustive studies of its hypnotic parallel, since the hypnotic catalepsy can be induced, directed, and controlled, and thus subjected to thorough physiological and psychological study as a phenomenon complete in itself and not as a minor part of a major constellation where many other factors may be present. Perhaps it is too optimistic to consider hypnotic catalepsy as identical with the catalepsy of mental disease, but it nevertheless offers an opportunity for a complete study of a closely parallel phenomenon that can be studied thoroughly at the convenience of the investigator. Approaches to this problem have been made at Yale (Williams, 1930) and various other universities, but further and more clinically oriented work is needed. Aside from the psychiatric aspects, the investigation of this problem should contribute much to a knowledge of muscle tonus and neurophysiology. It is conceivable that an understanding of hypnotic catalepsy would contribute materially to a better knowledge of certain of the phenomena of catatonia.

Another hypnotic phenomenon which has a direct bearing upon psychiatric problems is the amnesia which develops for all trance events following profound hypnosis. Thus, subjects in deep trance may perform any number of complicated actions and yet have no knowledge of their actions upon awakening from the trance (Erickson, 1934), and indeed, they may even be unaware of the fact that they have been in a trance.

That the whole problem of amnesia in itself constitutes a nuclear part of many psychiatric questions, particularly in considering the domination of the personality by long past and forgotten experiences, is readily realized. The same sort of amnesic phenomena found in the psychiatric patient is to be found in hypnotic amnesia, with the exception that the hypnotic amnesia can be controlled, manipulated, directed, removed, and even reestablished at the desire of the investigator. Thus, there is an opportunity to synthesize or to manufacture amnesic states, and then to analyze their effects upon the personality; then to restore the memories, studying the processes by which associations can be built up and forgotten experiences reintegrated into the conscious life of the personality. In brief, one can, by hypnosis, manufacture a state of amnesia, making it all-inclusive or limiting it to certain considerations, studying and analyzing that amnesia fully, with the entire possibility at any time of removing it in part or in full, making differential analyses at each step of the procedure.

In addition to this laboratory approach to the dynamics of amnesia, there is also a clinical application of hypnosis to the problem of amnesia as encountered in psychiatric practice. Recent literature contains a number of accounts of patients who have forgotten their identity or who have forgotten some experience of vital importance to them. In ordinary psychiatric practice the meeting of such a problem is almost entirely one of painstaking but often futile trial-and-error procedure. By means of hypnosis, as has been demonstrated particularly by Beck (1936) and by Erickson (1933, 1937; Erickson & Kubie, 1939), psychological situations can be created in the trance state, dormant associations awakened by hypnotic suggestion, and the amnesic material reconstructed. An example of the varying techniques which may be employed may be found in Erickson's *The Investigation of a Specific Amnesia* (1933), concerning a young woman who had forgotten the identity of a Christmas gift. By means of the employment of automatic writing, crystal-gazing, and dream suggestion the amnesic data was obtained. All of these are techniques which cannot be used in the waking state, but in the peculiar psychic state of hypnotic sleep they can be most effectual. The development of clinical techniques in the hypnotic exploration of amnesias should serve materially to advance knowledge concerning the development of amnesias, the repressive forces at work, and the mental mechanisms involved in their development and in their removal.

Another type of experimental hypnotic work employing certain characteristic phenomena of the trance state has been the utilization of hypnotic suggestibility as a means of testing in a laboratory the postulated fundamental causes of mental disease. Luria in his book *The Nature of Human Conflict* (1932), Huston, et al. (1934), Erickson (1935) in various studies of hypnotically induced complexes, and Brickner and Kubie in their study, *A Miniature Psychotic Storm* (1936), have all shown the significant value of hypnosis as a means of paralleling or duplicating on a miniature scale the major phenomena of mental

disorders. All of these workers were concerned with the production of psychoneurotic and emotional disturbances in normal subjects similar to the complex manifestations of actual mental disorder as a means of reaching an understanding of the processes involved.

Utilizing the marked suggestibility found in hypnotic states, Luria (1932) and Huston and his coworkers (1934) suggested disagreeable experiences, which, upon acceptance, would give rise to significant internal conflicts from which could derive severe neurotic and emotional symptoms. This procedure was followed by the administration of a word-association test accompanied by voluntary and involuntary motor responses to determine the presence in both hypnotic and waking states of evidences of internal conflict. Subsequently, hypnotic psychotherapy was employed to remove these internal conflicts, and re-administration of the word-association test and its accompaniments disclosed the disappearance of the previous evidence of internal psychic distress. Briefly, these workers demonstrated the possibility of producing in normal subjects miniature artificial psychoses which would serve to govern their personality reactions, which could be removed at the will of the investigator, and which presumably might parallel in their structure actual mental disorders. Erickson's study (1935) demonstrated the possibility of developing in a subject an artificial neurosis characterized by compulsions, phobias, and obsessions, in such a fashion that an actual neurosis already present in the subject became a part of this induced neurosis, with psychotherapy of the artificial neurosis serving to remove the original difficulty.

Brickner and Kubie (1936), interested in the dynamics of compulsive behavior, undertook a study in which a hypnotic subject was given posthypnotic suggestions leading to compulsive and obsessive behavior. By this means they were able to observe the slow genesis and final working out of an abnormal type of behavior, identifying each element of the reaction pattern as it appeared and relating it to accepted theoretical concepts. Such studies as these reveal the possibilities for subjecting various types of human behavior to a complete study in a state of isolation. Before Luria's work (1932) the whole psychological and psychiatric concept of a complex was a clinical assumption, but as a result of the experimental work mentioned above, laboratory proof and methods for such proof are now available to show that a complex is an experimentally demonstrable concept signifying certain psychic phenomena and furthermore, that a complex can be induced in a subject, its effects upon the personality postulated and then corrected by direct observation, and that it can then be removed by psychotherapy and its effects upon personality reactions abolished (Huston et al., 1934). Like-wise, my own study (1935) and that of Brickner and Kubie (1936) have shown some of the fundamental processes entering into the development of compulsive, obsessive, and phobic behavior, demonstrating clearly the cause-effect relationships of definite experiences and their direct manifestations in behavior patterns.

Still another type of hypnotic work which gives great promise psychiatrically lies in the neurophysiological changes which may be induced in the profoundly hypnotized subject. Sears (1932) has reported some extensive studies on hypnotic anesthesia wherein the subject has had localized anesthesias induced comparable to the anesthesias that develop particularly in such psychoneuroses as hysteria and various conversion syndromes. This

work is highly suggestive of the possibilities of reducing many of the conversion symptoms found in mental disorders to laboratory problems accessible to investigation in a controlled fashion.

An even farther-reaching aspect of this possibility may be found in the work reported to the American Psychiatric Association in May, 1936 (Erickson, 1938), which gave an account of the production by means of hypnotic suggestion of a state of deafness which gave every evidence of being a neurological deafness and yet which could be removed and reestablished readily and easily by appropriate suggestion. Similar in character are two other investigations concerning the effect of hypnosis upon psychophysiological and neurophysiological functioning in the sensory fields as shown by the hypnotic induction of color blindness (Erickson, 1939), and the hypnotic induction of hallucinatory color vision accompanied by pseudonegative afterimages (Erickson & Erickson, 1938). That deafness and color blindness comparable in degree and character to that found in organic conditions can be induced by hypnotic techniques suggests strongly the value of hypnotic techniques for psychophysiological and neurophysiological research.

However, one of the greatest advantages of hypnosis as applied to psychiatry seems to me to be the possibilities it affords in the development of significant psychological situations permitting definite control and study of personality reactions. Thus, by hypnotic suggestion one can create definite psychological environments permitting an adequate study of personality reactions within those situations and free from other and disturbing elements. For example, should it be desired to make a study of the effects of a state of affective depression upon behavior in general, hypnotic subjects can be placed in a state of profound depression which will serve to govern their conduct in any number of ways. At the same time this depression can be removed and direct contrasts made between depressed behavior and normal behavior. An account of such experimental work can be found in the investigations mentioned earlier (Huston et al., 1934; Luria, 1932).

Just as situations can be created permitting a study of the genetic development of behavior patterns, so can hypnosis be applied to the calling forth of even long-forgotten patterns of response. To make this clear, let us consider the psychiatric concept of regression, which may be defined as a reversion to simpler and earlier forms of behavior—a thing that we see daily in the “second childhood” of senile patients and in the “regression” of schizophrenic patients. Platonow (1933) approached this problem, and his work has been repeated (Erickson, 1939), by suggesting to profoundly hypnotized adult subjects that they were children and had not yet reached the years of adult life. To those subjects, in that suggested state of childhood, intelligence tests were administered, and it was found that there had occurred an actual evocation of the simpler and earlier forms of response, both intellectual and muscular, with an amnesia for things learned subsequent to the suggested age level.

Control studies with normal subjects in the waking state asked to respond as children disclosed the impossibility of normal adults responding genuinely at a childhood level. Personal work on this problem has shown that normal adults may be “regressed” by hypnotic suggestion literally to a state of infancy, with this regression including not only

intellectual and emotional patterns of response but even muscular reflex responses. Just how significant this laboratory regression of normal subjects will prove is still a question warranting much more investigation; how much value it will be in reaching an understanding of the regression found in psychoses is still another question. But at least it does offer the best and most promising approach to date to one of the most significant and difficult of psychiatric problems.

Along this same line hypnotic regression can be employed profitably in the elucidation of another important psychiatric problem—namely, that of the abreaction or the reliving of past experiences. In this procedure subjects are reoriented or regressed to a previous period of their lives and allowed to relive as a current experience some long-past event. An example of such investigatory work is to be found in a report published in the *Archives of Neurology and Psychiatry* (Erickson, 1937). A patient who had been drugged and beaten to unconsciousness had recovered from his injuries but had developed an amnesia for the experience. Several years later, during hypnosis, he was reoriented to that period of his life and allowed to relive that experience as if it were actually happening at the time. By this procedure a complete account was obtained, together with a redevelopment of unconsciousness characterized by a loss of reflexes, and with a duplication of the original confused mental state. In brief, the patient was enabled to re-experience in the hypnotic state a profound traumatic experience which had long been forgotten. The application of this procedure in the securing of adequate psychiatric data on patients is at once apparent, and it is highly suggestive of the possibilities for reorienting patients to those periods of their lives wherein their original maladjustments and abnormalities first appeared. With such reorientation there is then the possibility of attacking directly the problems of psychotherapy involved.

Still another application of hypnosis to psychiatry lies in the development of an experimental approach to the study of psychic dynamisms. We all realize that personality reactions and emotional attitudes may manifest themselves directly or indirectly, consciously or at a level at which people are unaware of their conduct, or if they become aware of their conduct, may be unaware of their motivations. To date our knowledge of mental mechanisms has been based on the observance of their occurrence and the explanation of their appearance on a post hoc, propter hoc basis, relating the dynamism to those events which have preceded it, and then verifying the conclusions by noting whether or not the insight afforded by knowledge of the relationships serves to elucidate the nature of the response.

By the application of hypnosis the entire approach to the problem of psychic dynamisms can be changed. For example, the existence of unconscious mentation or subconscious thinking has long been accepted, but its proof has rested on observations made after its appearance. Recent experimental work (Erickson, 1938) shows that it is possible to create a psychological situation and to declare that a person subjected to such a situation would be forced to react in a certain way that would lead to a demonstration of unconscious mentation. In the experimental work mentioned a normal hypnotic subject was instructed to write a simple sentence, complete and meaningful in itself and which could be read by anyone else and found to have that meaning; and yet, in an unnoticeable way, it would

contain a significance apparent only to the subject's unconscious mind. The subject achieved this difficult task by writing her guess concerning the length of time required to perform a certain act. The subject as well as the entire group present read the writing as "30 seconds." Yet, upon indirect questioning and the employment of automatic writing, it was found that the writing actually read 38 seconds, written with some scrawling of the word thirty and the transformation of the letter y into the numeral 8. Thus, two trains of thought, simultaneously operative, were recorded by different types of symbolic thinking, one of which was kept from the awareness of the subject's conscious mind. In this same report, with another hypnotic subject, it was possible to carry on a written conversation having a conscious import but which was developed entirely in accord with an import known only to the unconscious mind of the subject and to the investigator without the subject becoming aware consciously of the actual nature of the conversation.

One other important consideration needs to be mentioned—namely, posthypnotic behavior, since this phenomenon enters so intensively into both experimental and therapeutic use of hypnosis. Briefly defined, posthypnotic behavior is that which occurs in response to hypnotic commands and subsequent to the trance state in which it is suggested. Through its utilization therapeutic efforts are made to direct, influence, and control behavior favorably and to enable patients to meet their various problems adequately. Similarly, it is used experimentally in the laboratory as a measure of manipulating a subject psychologically to permit a study of the dynamics of behavior, and its field of usefulness there is now being realized (Erickson & Erickson, 1941).

CONCLUSION

Within the limits of this report it has been possible only to sketch briefly a few of the applications of hypnosis to psychiatry. Many important considerations have been omitted. It has been my purpose only to indicate certain possibilities for definitive research in psychiatry by the use of hypnosis. That the eventual results of such research will be good or bad cannot yet be stated, but at least it can be said that hypnotic techniques applied to psychiatric problems give every promise of leading to better understandings of troublesome questions. In addition to this is the fact that hypnosis itself constitutes a form of psychic behavior worthy of understanding. And it is only reasonable that a thorough understanding of one type of mental behavior should contribute materially to an understanding of many problems of mental disorder.

Hypnosis in Medicine

Milton H. Erickson

Reprinted with permission from *The Medical Clinics of North America*, May, 1944, New York Number.

Hypnosis or hypnotism is a psychological phenomenon of exceeding interest to both layman and scientist. Its history is as old as that of the human race, and it has been utilized by the most primitive of peoples, ancient and modern, in the practice of religious and medical rites to intensify belief in mysticism and magic. The striking character of this psychological manifestation, its inexplicable and bewildering phenomenology, and the seemingly miraculous results it produces—together with its long use for the bewilderment of the observer—have served to surround it with an aura of the supernatural and the unreal. As a consequence, the attitude of the general public toward this phenomenon, now scientifically established, has been, and too often still is, one of superstitious awe, misunderstanding, incredulity, antagonism, and actual hostility and fear. This attitude is perpetuated by the exploitation of hypnosis by the charlatan and the stage performer and the well-intentioned but mistaken and inadequate utilization by inexperienced experimenters and medical men.

The scientific history of hypnosis began about 1775 with Anton Mesmer, whose name is still attached to it, but unfortunately, even this scientific beginning was founded on a mystical belief that it was constituted of a peculiar cosmic fluid with healing properties.

Mesmer's use of hypnosis began with his discovery that suggestion in various forms could be used to induce a condition resembling sleep in certain types of patients, and that, in this state, therapeutic suggestions could be given them to alleviate and even remedy their complaints and symptoms. Unfortunately, Mesmer failed to recognize the purely psychological character of his discovery and attributed it to a cosmic force he termed "animal magnetism." Although Mesmer successfully treated large numbers of patients on whom orthodox medical procedures had failed, he fell into disrepute because of the mysticism with which he surrounded his therapy. Nevertheless, his discovery and utilization of it served to lay a foundation for the therapeutic use of hypnosis and for a recognition of the validity of psychotherapy as a medical procedure.

Since Mesmer's time there has been a succession of scientific men, chiefly medical, who have contributed greatly to its scientific growth. Elliotson, the first British physician to use a stethoscope, used hypnosis effectively about 1817 in his medical practice and published extensively on its suitability for certain types of patients. Esdaile, through Elliotson's writings, became so interested that he succeeded in having a government hospital built in India primarily for the use of hypnosis, where he extended its use to all types of patients, especially surgical.

In 1841 James Braid, an English physician who bitterly opposed "mesmerism," was induced to make a physical examination of a mesmerized subject. He recognized both the validity of the phenomenon and its psychological character, with the result that he coined the terms *hypnosis and hypnotism* and initiated the first scientific studies of hypnosis as a psychological condition of extensive medical and scientific significance.

Since then, clinicians first and psychologists later, among them many outstanding scientists, have contributed increasingly to a better understanding and utilization of hypnosis as a scientific tool and as a medical procedure of immense value for certain types of patients. Particularly has interest been developing rapidly during the last 25 years among psychiatrists and psychologists. During the last 15 years there has been an increasing wealth of publications dealing with the effective use of hypnosis in the fields of psychiatry and experimental psychology.

Regrettably, however, there is still a persistence of outmoded ideas and concepts of hypnosis which vitiate experimental studies and therapeutic efforts. For example, some psychologists are still publishing studies based upon techniques and psychological concepts belonging to the 19th century, and some medical men still employ it for direct symptom relief rather than as an educative procedure for the correction of personality disorders.

As yet the scientific study of hypnosis is still in its infancy despite the development of a healthy, intense interest in it as a scientific problem of merit. There is still lacking an adequate general appreciation of the need to integrate hypnotic studies with our present-day concepts and understandings of personality, of inter- and intrapersonal relationships, and psychosomatic interrelationships and interdependencies.

GENERAL QUESTIONS

In any discussion of hypnosis certain general questions arise concerning who may be hypnotized, the possible detrimental effects of hypnosis, its possible antisocial use, the nature of the hypnotist-subject relationship, the controllability of the hypnotic state, the relationship between hypnotic sleep and physiological sleep, and the possibility that hypnosis may crystallize or precipitate abnormal or pathological conditions in subjects that otherwise might have remained indefinitely dormant.

Because of space limitations reply to these questions must necessarily be brief and dogmatic, and the reader is referred to the following references upon which reply is based: Brickner & Kubie, 1936; Bass, 1931; Beck, 1936; Erickson, 1933, 1935, 1937a, 1938a, 1938b, 1939a, 1939c, 1943b, 1943c; Erickson & Erickson, 1941; Erickson & Brickner, 1943; Erickson & Hill, 1944; Erickson & Kubie, 1939, 1941; Farber & Fisher, 1943; Fisher, 1943; Gill & Brenman, 1943; Harriman, 1941, 1942a, 1942b; Liebman, 1941; Raeder, 1933; Sears, 1932; Vogel, 1934; White, 1941.

Briefly, there are no *injurious* or *detrimental effects* upon the subject other than those that can develop in any other normal interpersonal relationship; hypnosis cannot be used for

antisocial or criminal purposes—most subjects can be induced to commit make-believe or pretended crimes, but pretenses should not be accepted as realities; the hypnotist-*subject relationship* is entirely one of voluntary cooperation, and no subject can be hypnotized against his will or without his cooperation; the hypnotist-subject relationship is analogous to that which exists between physician and patient, lawyer and client, minister and parishioner. Furthermore, a subject can be a hypnotist and a hypnotist can be a subject; they can work with each other in alternating roles, and often do in experimental work. Belief that hypnosis is a matter of a weak will dominated by a strong will is entirely a misconception. The best subjects are highly intelligent, normal people; the feebleminded and the psychotic and many psychoneurotics are either difficult or impossible to hypnotize.

Since hypnosis depends primarily upon cooperation by the subject, the control of the trance state rests largely with the subject. No subjects can be kept in a trance for an unreasonable length of time without their full cooperation, and the removal of the hypnotist from the hypnotic situation by one means or another disrupts the interpersonal cooperation necessary for the continuance of the trance. Thus, no subject can be left accidentally or intentionally in a trance for an indefinite period.

The relationship between the hypnotic trance and *physiological sleep* is one of appearance only. Hypnosis is a psychological phenomenon with secondary physiological manifestations, and sleep is physiological with secondary psychological manifestations. Blood distribution, muscle tonus, motor behavior, and reflex behavior in the trance state are not the same as in physiological sleep, and the two phenomena primarily serve entirely different purposes. Physiologically, there is much more resemblance between the hypnotic and the waking states than with physiological sleep.

As for hypnosis *crystallizing or precipitating abnormal or psychopathological conditions*, this is a post hoc observation. The relationship is temporal and not causal, as in the case of mental illness first noticed following a routine appendectomy.

Finally, as for *detrimental effects* of hypnosis, none have been observed in personal experience with hundreds of subjects, some of whom have been hypnotized hundreds of times. Furthermore, as every experienced hypnotist knows, the great difficulties involved in producing changes in the personality of a desired therapeutic character make evident the illogic of assuming that the time- and situation-limited hypnotic trance can bring about significant harmful effects, when earnestly desired beneficial effects are so hard to achieve.

THE TECHNIQUES OF HYPNOTIZING

The technique of inducing hypnosis, contrary to long-established and traditional superstitious ideas of eye fixation, crystal balls, and passes of the hand, is primarily a function of the interpersonal relationship existing between the subject and the hypnotist.

Hypnosis is not a mystical, magical thing that follows a definite rule-of-the-thumb or a special abracadabra. Practically all normal people can be hypnotized, though not necessarily by the same person, and practically all people can learn to be hypnotists. Hence any technique that permits the hypnotist to secure adequate and ready cooperation in this highly specialized interpersonal relationship of hypnosis constitutes a good technique. The able hypnotist is the one who is able to adapt technique to the personality needs of each subject. Thus, some subjects want to be dominated, others coaxed, still others to be persuaded. Some subjects want to dominate the situation and place the hypnotist in the role of an assistant who merely guides. Some prefer to be hypnotized by a wealth of repetitious suggestions, and there are those who like to resort to an introspective experiencing of the process of going into a trance. Sometimes the situation is one of authority-subservience, or it may be one of father-child, or again physician-patient, and often that merely of two equals intensely interested in an important problem.

Properly, hypnotists should have a good appreciation of their own personality and capabilities so that they may adapt themselves to the specific personality needs of each subject. In the majority of instances, especially in medical hypnosis, the physician-patient relationship is ideal and satisfies adequately the personality needs of the subject.

The actual procedure best employed when the problem is not controlled experimental work consists of giving the subjects a preliminary explanation of what they may expect, thereby correcting any misapprehensions they may have. At the same time this suggests indirectly to them their course of behavior and response. This is followed by a series of suggestions to the effect that they will get tired and sleepy, that they will wish to sleep, and will feel themselves going to sleep, that they will notice increasing lassitude of the body and an increasing feeling of comfort and satisfaction as they continue to sleep until they fall into a deep, sound, restful sleep. Every effort should be made to make the subjects feel comfortable, satisfied, and confident about their ability to go into a trance, and the hypnotist should maintain an attitude of unshaken and contagious confidence in the subject's ability. A simple, earnest, unpretentious, confident manner is of paramount importance, unless one wishes to be a vaudeville performer. Only then are histrionics warranted.

Once the hypnotic trance has been induced, there is need to keep a subject in the trance until the necessary work has been completed. This is best done by instructing the subjects to sleep continuously, to let nothing disturb them, to enjoy their trance state, and above all to enjoy their feeling of comfort, satisfaction, and full confidence in themselves, their situation, and their ability to meet adequately and well any problem or task that may be presented to them.

The awakening of the hypnotic subject is a simple procedure, even with those subjects who willfully insist upon remaining in the trance. Usually, simple instruction to awaken is sufficient. If the subject resists awakening, simple persuasive suggestions will suffice.

Of great importance in inducing trance states and trance behavior is the allotment of sufficient time for the subject to make those neuro- and psycho-physiological changes

necessary for certain types of behavior. To rush or force a subject often defeats the purpose.

HYPNOTIC PHENOMENA

While certain phenomena are characteristic of the hypnotic trance, their manifestations vary with the individual subject and with the depth of the trance—that is, whether light or deep hypnosis. Even so, phenomena usually found in deep hypnosis may, in the individual subject, occur in light hypnosis and vice versa, depending upon the subject's personality and psychological needs at the time. There is no absolute rule—hence, efforts to describe accurately various levels of trance depth are chiefly of academic interest.

Most normal people develop light hypnosis easily, and at least 70 percent of all subjects, with adequate training—by which is meant repeated hypnosis and thus continued practice in going into the hypnotic state—can develop deep trances.

For medical purposes either the light or the deep trance may be satisfactory, depending upon the nature and the character of the therapeutic goal to be achieved. Also, should the light trance be unsuitable, recourse may at once be had to the progressive induction of a more profound trance. Experience is the only able teacher of what type of trance is necessary, and failure to secure results in the light trance can always be corrected by resorting to the deep trance.

The phenomena of the trance of most interest to the medical man are several. Foremost of these is *rapport*, a condition in which the subject responds only to the hypnotist and is seemingly incapable of hearing, seeing, sensing or responding to anything else unless so instructed by the hypnotist. It is in effect a concentration of the subject's attention upon, and awareness only of, the hypnotist and those things the hypnotist wishes included in the trance situation, and it has the effect of dissociating the subject from all other things. The hypnotist may transfer this rapport by appropriate suggestions.

Catalepsy is a second phenomenon which illustrates clearly the tremendous psychosomatic significance of hypnosis. This is a peculiar state of muscle tonus which parallels *cerea flexibilitas* of the stuporous catatonic patient. The subject holds his arm up in the air, maintains any awkward position given him by the hypnotist, and shows a failure of normal fatigue reactions. Concomitant with it are a loss of the swallowing reflex, a dilatation of the pupils, a loss of facial mobility, and a definite slowing of all psychomotor activity. Yet, upon instructions by the hypnotist, the subject can perform adequately at a motor level equal to the waking capacity and often at a level that transcends it.

Sensory changes, or alterations in sensory behavior, of both a positive and a negative character are frequent and often undetected. Blindness and deafness to things not included in the hypnotic situation often develop to a degree that resists clinical tests. There also occur spontaneously anesthesia, analgesia, and other types of sensory disturbances. Additionally these sensory phenomena can be induced by appropriate

suggestion. A detailed account of these types of psychosomatic manifestations has been reported (Erickson, 1943). Their presence is often of great importance in therapy, since they serve so well to make subjects appreciate their trance depth and to direct the hypnotist's attention to unexpected psychosomatic implications that need to be considered in the hypnotic procedure.

Amnesia and other memory alterations constitute another type of hypnotic phenomena of extreme interest to the medical practitioner. Usually after a deep trance subjects have a more or less complete amnesia for all trance events. This amnesia can be controlled by the hypnotist through instruction to the subjects, or the subjects themselves can deliberately set about recovering the amnestic material. In either instance the forgotten memories may be recovered in full or in part according to the instructions given or in accordance with each subject's needs. This amnesia is of profound importance in psychotherapy since it permits the therapist to deal with painful memories without arousing the subject's waking resistance and defensive reactions.

In contradistinction to hypnotic amnesia is the capacity of the hypnotic subjects to develop *hypermnesia*—that is, increased memory ability—and to recover memories of past experiences long forgotten and actually inaccessible in the waking state. Traumatic, painful, forgotten experiences and memories that often constitute a point of origin in serious personality disturbances are frequently readily accessible under hypnosis, can be easily recalled by the patient, and a foundation laid in the trance state for their integration into the waking life of the patient. The importance of the recovery of lost memories in psychotherapy is fully established, and hypnosis often proves a royal road to those memories, although it still leaves the task of integrating that memory into the waking life of the patient a painstaking task for the therapist. In addition to this recovery of past forgotten memories, hypnosis can enable subjects to recover memories of lost experiences in phenomenal and minute detail ordinarily not possible. By such hypermnesia minor clues to a personality disturbance or emotional conflict otherwise not accessible become available.

Based to some degree upon the mechanisms of amnesia and hypermnesia is another phenomenon termed *regression*. By this is meant the capacity of hypnotic subjects, upon suitable suggestions and instructions, to develop an amnesia for a definite period of life and to revivify and reestablish the memories and patterns and habits of an earlier period. Thus, a 25-year-old subject can be induced to develop a profound amnesia for all events of his life subsequent to the age of 15 years and to reassume his actual modes and habits of behavior and response belonging to his 15-year-old level of development.

The actual technique of so reorienting a subject to an earlier age level is complicated and difficult, and the process easily results in errors unless extreme care in suggestion is exercised, nor can regression behavior be accepted too readily and uncritically. However, experimental and therapeutic studies have disclosed the feasibility and usefulness of this procedure, and in addition have shown that profound psychosomatic changes accompany the process. Two such instances are given in the issue of *Psychosomatic Medicine* previously mentioned.

Suggestibility, necessarily a primary feature of hypnosis, is always present and constitutes the basic consideration upon which the trance and its attendant phenomena are based. Additionally, suggestibility plays another role after the trance is induced, in that any desired behavior can be suggested to the subject and an adequate performance can be secured, provided that the suggestions are not offensive to the subject. Thus, in the medical situation, the recovery of memories, the development of amnesias, identifications, and anesthesias, the causing of dreams, emotional conflicts, hallucinations, disorientation, and so forth can be produced in the patient during the course of therapy as a measure of meeting problems, developing insights, and reorganizing the psychic life.

Automatic writing and *crystal-gazing*, two somewhat comparable phenomena, both long known but superstitiously regarded, are easily elicited in the trance state and are often of great value in psychotherapy. In response to suggestion the subject writes automatically and without awareness and thus may be induced to uncover amnesic material or to disclose necessary information otherwise inaccessible or which the personality is not yet strong enough to face. Or the subject may see vividly and clearly in a crystal the enactment of long-forgotten traumatic experiences and thus achieve a realization of their actuality and reality to him as a person.

Posthypnotic suggestion is one of the most significant of all hypnotic phenomena. By this measure subjects can be given instructions in the trance to govern their future behavior, but only to a reasonable and acceptable degree. Thus, the subject may be instructed that at some future date he is to perform a certain act. At the specified time the subject executes his bidding, but believes his performance self-ordered and spontaneous. As a therapeutic measure, posthypnotic instructions are of great value, but if improperly used they are ineffectual and futile. They need to be used primarily as a measure of providing the patients with an opportunity to develop insight and to integrate their behavior.

Somnambulism is another form of hypnotic behavior always significant of a deep trance state. In this condition subjects behave and respond as if they were wide awake and may even deceive observers with their seeming wakefulness. This state is the most suitable for the deeper forms of psychotherapy and can be induced by repeated hypnosis in at least 70 percent of all subjects.

THE VALUES OF HYPNOSIS

To the medical doctor, the values of hypnosis in medical science are of first importance. That hypnosis can contribute to the scientific study of human behavior, normal and abnormal, is self-evident, since it permits experimentation and investigation not ordinarily feasible and under conditions difficult or even impossible to obtain in the waking state. Thus, it possesses values of a basic character in the development of a more adequate scientific understanding of the medical problems arising from disturbances in

human behavior and adjustment. These values alone would warrant continued hypnotic work.

Additionally, hypnosis possesses other values of paramount interest to the physician as an individual. Foremost of these is the education it gives the physician in understanding, sympathizing and dealing effectually with that vast array of emotional conflicts, fears, anxieties, uncertainties, psychoneurotic complaints and psychosomatic. disturbances that constitute so large a part of the problems presented to every medical practitioner. These are problems that cannot be treated with drugs or surgery nor with the simple statement that "there is nothing wrong with you physically."

Such patients are in need of therapy, therapy of the class that falls under the heading of the "art of medicine." This is essentially a physician-patient relationship that permits the physician to enable the patient to capitalize upon every positive thing he has to reach a satisfactory adjustment in life rather than become psychologically invalided.

The physician who learns hypnosis and thus learns how and when and why to give suggestions effectively to hypnotic subjects is literally taking a postgraduate course in how to suggest to patients the attitudes, insights, understandings, and methods of behavior that will enable them to adjust more adequately in life. In the general practice of medicine it is not only the drug dispensed but the physician's manner of handling the patient that constitutes the actual turning point in the patient's illness, his attitude toward himself and toward life. The entire history of medical practice emphasizes the tremendous factor of the human relationship, and physicians who have trained themselves in hypnosis have acquired special experience that stands them in good stead in building up their art of medicine, even though they may not utilize hypnosis directly.

As an actual medical therapeutic procedure, hypnosis possesses definite and demonstrated values. Certain early psychoneuroses, behavior problems, personality maladjustments, circumscribed neuroses, and psychosomatic disturbances are frequently susceptible to intelligently conceived hypnotic psychotherapy. Such therapy, however, should not be directed merely to the alleviation of a symptom or to the forcing of the patient to adopt better adjustment patterns. Therapeutic effects thus achieved are short-lived and account for the majority of failures. Successful hypnotic psychotherapy should be systematically directed to a reeducation of patients, a development of insight into the nature of their problems, and the promotion of their earnest desires to readjust themselves to the realities of life and the problems confronting them. Too often hypnosis is employed simply to relieve a symptom, and there is a failure to capitalize upon the peculiar intense, effective physician-patient relationship engendered by the hypnosis which constitutes the actual point of departure in effecting a psychotherapeutic reordering of the patient's life adjustment and a healthy integration of the personality.

Another field of application now just developing for the utilization of hypnotic therapy lies in the treatment of the acute psychiatric war disturbances occurring in front-line action. Under these conditions present findings indicate that the induction of a deep trance, the building of an intensely satisfying interpersonal relationship between the

physician and each patient and then permitting the patients to verbalize in this protected situation their fears and anxieties, their horror and distress, and then to take inventory of themselves, of their self-confidence, their abilities, their ambitions and desires is effecting a high percentage of recovery—as, indeed, might logically be expected.

ILLUSTRATIVE CASE HISTORY

To illustrate the actual application of hypnosis to a specific medical problem, the following case history is presented. This account has been selected because it demonstrates clearly both the medical and the psychological aspects of a total problem reflected in a single symptom which could easily have been the point of departure for a serious, prolonged neurotic disturbance, and also because the account permits the reader to recognize readily the psychological significance and the rationale of each step in the therapy employed. The total time spent in treating the patient was slightly over three hours. Such an expenditure of time was warranted by the nature of the case and justified by the results obtained, and it illustrates the need in hypnotic therapy to allot time as freely as is done in surgery.

That so systematic and elaborate a procedure of hypnotic therapy was necessary for the patient described is open to question. Perhaps a simpler approach would have succeeded, but adequate therapy of the patient was the goal sought, and there was no thought of experimentation to determine how economical of effort the therapist might be in handling this particular problem. Failure in attempts at hypnotic therapy always increases the difficulty of further efforts at therapy. Hence, for the benefit of the individual patient, extensive care and effort is always warranted.

The patient, a woman in her middle thirties, was referred to me by her physician for hypnotic therapy because of hysterical urinary retention of fourteen days' duration, and an increasing neurotic reaction of fright, terror, and panic over her condition. The history secured contained the following significant facts.

She had been recently married after having despaired of marriage for many years because of her belief that she was not physically attractive. Following a brief honeymoon, she had developed an acute nonspecific urethritis and cystitis, which, because of her educational background in medical science, had frightened her seriously. The infection yielded rapidly to medication, but during the course of her treatment she had been catheterized several times. This had embarrassed and distressed her greatly. Just before her discharge from the hospital as recovered, her husband received notice to report for induction, a notification arriving much sooner than had been anticipated. She reacted to this with intense grief but soon composed herself and began to rearrange her plans for the future.

Some hours thereafter she had found herself unable to void. Repeated futile efforts over a period of several hours had increased her anxiety and discomfort seriously and she had to be catheterized. Thereafter catheterization twice daily for two weeks was necessary, since various measures of encouragement, reassurance, and sedation failed. The patient responded to this with increasing alarm and terror because of her helplessness. Nor was

the general situation helped by the patient's own realization that her symptom might be hysterical, since she regarded hysteria as much worse than an organic disability.

The actual therapeutic procedure was simple. She was given an evening appointment so that ample time free from interruption would be available. The history furnished by her physician was confirmed and elaborated by a casual, comfortable questioning and discussion of the patient's problem as a means of alleviating her anxiety.

She was then sent to the lavatory with firm instruction to discover if her symptoms still persisted and to make certain that she really needed treatment. Thus, she was given the first real doubt about the continuance of her difficulty. To have sent her to the lavatory with instruction to void would have courted therapeutic failure, since inability to obey such a command would seemingly have demonstrated my incapacity to handle her problem. But to be sent to discover if she really needed treatment had the effect of convincing her of my complete confidence in my therapy and of my unwillingness to use it unless actually required. She returned to report that her symptom was still present, whereupon she was asked if she wished me to proceed with therapy. Upon her assent, the explanation was offered that before therapy would be undertaken at all, it would be necessary to discover how capable a hypnotic subject she was as a preliminary to dealing with her problem therapeutically. She expressed some disappointment at this delay in therapeutic hypnosis, but recognized the desirability of permitting me to follow my own procedure.

Accordingly, a light trance was induced and simple hypnotic phenomena elicited, and this was followed by the induction of a fairly deep trance during which the patient was called upon for a continued manifestation of hypnotic phenomena. This procedure was simply a means of teaching her effectively that she could execute hypnotic instructions readily and adequately and constituted a process of building up her confidence in her ability to obey any instructions given to her.

She was then sent to the lavatory in the trance state with firm instructions *not* to empty her bladder but instead to have a bowel movement. However, with careful emphasis, these instructions were qualified by further suggestion that she probably would *not* have a bowel movement, since she really *did not need* to have one, and this idea was stressed repeatedly. Thus, by implication she was given to understand effectively that excretory activity was not a matter of response to hypnotic suggestion, however strong, but a *function of an actual bodily need that could be aided by hypnotic suggestion*. Additionally, the failure to urinate in this situation would have a new and important meaning to the personality—namely, one of obedience to the hypnotist's instructions and not one of personal inability. Also, in relation to the bowel movement, the patient would have the perverse satisfaction, characteristic of neurotic behavior, of failing to obey the therapist's instructions in relation to an unimportant consideration and not in relation to her actual symptom.

The patient obeyed instructions as intended, whereupon the suggestion was offered that she might like to discuss in detail, while still in the trance state, her general immediate

life situation. She agreed, and there followed a detailed, systematic, comprehensive, psychotherapeutic discussion and appraisal of her deprecation of her appearance, her despair about ever getting married, her sexual adjustment, her infection and the fears it engendered, her husband's impending induction, and the neurotic utilization of invalidism to escape problems. Every effort was made to give the patient insight into her situation and to organize her thinking constructively so that she would be able to face her problems adequately instead of retreating from them into neurotic illness. However, at no time was any direct psychological interpretation made of her urinary retention. In fact, it was not even mentioned specifically. Instead, reliance was placed upon the patient's own thinking and intelligence to make the proper psychological interpretation of her symptom when she became ready for that realization.

When the patient seemed to have adequate understanding of her situation and its probable significance to her personality, return was made indirectly to her symptom. In the guise of casual conversation she was reminded of the practice of little children at play to suppress the need for urination until the last possible moment and then to rush frantically to the bathroom where any unexpected delay would result in a wetting of their clothes.

As soon as the patient understood this general statement, she was asked with much urgency to tell me approximately how long it would take her to reach her home after I dismissed her, what route she would follow, an approximation of the distance from the pavement to the front door, the location and the length of the stairway leading upstairs, and how far down the upstairs hallway the bathroom was located.

When the patient had given this information as accurately as she could she was given a rapid series of urgent, strongly persuasive suggestions to the effect that:

1. She would leave for home feeling generally comfortable and at ease and not thinking about anything specific but just simply absorbed in quietly enjoying the ride home.
2. That during the last 20 minutes of the trip home there would come to her mind vague fears that she might wet herself, which she would promptly suppress, only to have them recur with increasing frequency and insistency until finally they would become an annoying and even distressing conviction that if she did not arrive home soon she would surely wet herself.
3. That the last five minutes of the trip home she would spend in a state of feverish anxiety and that she would be unable to think of anything except whether she would be able to hold out long enough to rush through the door, up the stairway, and into the bathroom where she then could relax completely and be comfortable all over.
4. That when she was relaxed and was comfortable all over, she could then have a full recollection and understanding and memory of all those things she needed to know to meet her life situation without handicaps.

These suggestions were given repetitiously, urgently and with great rapidity until it was certain the subject understood them sufficiently well to execute them. Then, after

instruction to have amnesia for all trance events and suggestions, she was awakened and promptly dismissed. Her husband, who had accompanied her, was instructed to drive home quietly, commenting only on the beauty of the night, acceding to any demands of his wife that he drive faster but to keep within the speed limits, and asking no questions of any sort.

Subsequent reports from the husband, the patient, and the referring physician disclosed the effectiveness of these suggestions and success of the therapy, both in relation to her symptom and her adjustment to her husband's military status. Inquiry a year later disclosed no recurrence of her problem.

CONCLUSION

To summarize, the age-old attitude of superstitious awe, fear, incredulity, and antagonism toward hypnosis is now being rapidly replaced by an appreciation of its scientific values. In its place is a growing, constructive recognition of hypnosis as both a therapeutic medical procedure and a means of acquiring a sympathetic understanding and appreciation of human nature and behavior requisite to the adequate practice of psychotherapy and the art of medicine.

Hypnotic Techniques for the Therapy of Acute Psychiatric Disturbances in War

Milton H. Erickson

Read at the Centenary Meeting of The American Psychiatric Association, Philadelphia, Pa., May 15-18, 1944 and reprinted with permission from the *American Journal of Psychiatry*, 1945, 101, 668-672.

Ever since the first primitive medicine man attempted to use hypnosis in some form to treat his savage patients, there has persisted a general tendency to regard hypnosis, its techniques, its methods, and its applications as something beyond the ken of common man, as mysterious, magical, and occult, based upon and derived from special powers, a ritual of mystical passes and an abracadabra of verbal commands. Only recently has the rapid growth of scientific interest in hypnotism made possible the recognition of hypnosis as a special and highly significant intrapersonal state or condition clinically important, deriving from interpersonal relationships and valuable for both intra- and interpersonal significances. Also, there has been a progressive realization that practically all normal people as well as many of those suffering from certain types of mental disturbances can be hypnotized under proper circumstances; and, similarly, that anyone reasonably interested and intelligent can learn to hypnotize even as anyone can learn to do surgery. Special talents and abilities, other than a reasonable degree of aptitude, are necessary only to achieve historical prominence. In other words, the field of hypnosis is open to any person willing to qualify by interest, study and experience, and the intelligent use of hypnosis depends essentially upon a background and foundation of personal interest and training.

The technique for the induction of hypnotic trances is primarily a function of the interpersonal relationships existing between subject and hypnotist. Hence, hypnotic techniques and procedures should vary according to the subject, circumstances, and the purposes to be served. Furthermore, since hypnosis is dependent fundamentally upon the subject's cooperativeness and his willingness to be hypnotized, any technique eliciting the necessary cooperation is adequate in this highly specialized interpersonal relationship. Indeed, competent hypnotists avoid any rigidity in technique and properly adapt it to the personality needs of their subjects in the immediate situation.

A variety of individual approaches may be employed, but they need to be directed especially to the development in the subject of full confidence and security in the hypnotist, his willingness to participate in any legitimate procedure and his readiness to yield to an experience which is understandable, though perhaps painfully, of value to him as a personality. To this end, some subjects need to feel themselves dominated by the hypnotist, others want to be coaxed or persuaded, some wish to go into the trance as a result of joint cooperative endeavor, and there are those who wish, or more properly need, to be overwhelmed by a wealth of repetitious suggestions guiding every response

they make. The actual interpersonal relationship established between subject and hypnotist may be one purely of authority-subservience, of father-child, or more frequently physician-patient. In the armed forces, however, hypnotists occupy a position of special vantage. They combine the significant prestige of both an officer and a physician, and this is further enhanced by the training of the ranks in habitual, unquestioning obedience, which leads easily to the ready acceptance of hypnotic suggestions. However, in this regard, much more is to be accomplished when medical officers minimize their authoritarian status as officers and deal with their patient primarily at a medical level, thereby transforming their authority into additional prestige as a physician concerned not with authority but with professional interest and effort.

Another important consideration in inducing trances, especially among members of the armed forces, where group relationships predominate, is the utilization of the group situation itself. Even among civilians, where greater emphasis is placed upon individualism, the induction of a trance in the group situation, aside from the exceptional case, decreases the time and effort required and leads to a more rapid and better training of the individual subject. Especially is this true when a trained or unusually capable subject is used as an object lesson for the group. Even those subjects who resist hypnosis in a group situation respond privately much more readily after having observed group trance behavior. The use of drugs to induce hypnotic trances is often feasible in excited, fearful, emotionally unstable, disturbed, or unconsciously uncooperative patients. Alcohol, paraldehyde, the barbiturates, and even morphine can be used, although alcohol is the drug of preference because of its rapid transient effects, its relief of inhibitions and anxieties, and the absence of narcotic effects. Although in certain cases narcotic drugs are decidedly useful, there is always the possibility of narcotic effects masking or excluding hypnotic responses. However, experience and clinical judgment are the means of learning how and when to use drugs as an adjunct to hypnosis.

Trance states for therapeutic purposes may be either light or deep, depending upon such factors as the patient's personality, the nature of the problem, and the stage of therapeutic progress. Sometimes light hypnosis is all that is needed even in a severe problem, and sometimes deep hypnosis is required for a relatively mild disturbance. Clinical experience and judgment are the best determinants, and there is always the possibility of recourse to the other type of trance in case of failure to achieve results.

Another highly significant general consideration in the medical use of hypnosis, often overlooked or completely disregarded, is its striking usefulness even when it is not the indicated therapeutic procedure. This usefulness lies in its effectiveness in building up patient morale and in establishing a physician-patient relationship of profound trust, confidence, and security that so often constitutes a vital factor in helping the patient to adjust adequately to the problems of invalidism. Especially is this so when the invalidism involves serious psychic distress, anxiety, and fear such as characterize the acute psychiatric disturbances of war.

An illustrative example, cited from personal experience to demonstrate the usefulness of hypnosis when not the indicated therapy, is the instance

of a recovered drug addict hospitalized for major surgery. She developed an acute anxiety state, was unable to sleep, and refused sedative or narcotic medication because of her intense fear that it might lead to a recurrence of her drug addiction. Sympathetic interest, reassurance, and postponement of the operation for another day failed to lessen her panic reactions. The induction of a hypnotic trance with extensive posthypnotic suggestions governing sleep; the development of an emotional feeling of comfort, security, and trust; and the induction of subsequent trances resulted in an uneventful pre- and post-operative course of events.

The actual technique for inducing hypnotic trances varies greatly from one hypnotist to another and from one subject to the next. No set, rigid technique can be followed with good success since, in medical hypnosis, the personality needs of the individual subject must be met, and such is the purpose of hypnosis rather than the mere induction of a trance. Additionally, there is an equally important need for the hypnotist to use that technique which permits him to express himself most satisfactorily and effectively in the special interpersonal relationship which constitutes hypnosis.

The procedure most uniformly successful in initiating hypnosis consists in prefacing the actual induction of the trance by a simple, informative discussion of hypnosis as a scientific medical phenomenon, taking care to develop the patient's interest in it as a personal experience. During such discussion patients should be given opportunity to express their attitudes, fears, misconceptions of hypnosis; simple, unpersuasive explanations, corrections, and reassurances can be offered. Also, such a discussion is an effective means of giving the intended subjects a wealth of information and suggestions to govern their own hypnotic responses.

The group approach is an effective manner of accomplishing this, despite its seemingly time-taking and laborious nature. My procedure, which is also being used by several former associates now in the army and employing hypnosis therapeutically for acute psychiatric war disturbances, consists in presenting before a group of 10 to 30 interested persons, among whom are intended hypnotic patients, a comprehensive lecture and a demonstration of hypnosis, using first a trained subject and then volunteer subjects.

The results obtained are invariably profitable. A favorable and appreciative attitude toward hypnosis is engendered; new subjects useful in the future are secured; fears, doubts and misconceptions are dispelled; and the intended hypnotic patients develop a most helpful, satisfying sense of comfort and confidence in hypnosis.

How successful this approach may be is shown by the following instance. After a lecture and demonstration before a group of 15 persons, 12 of whom were intended for future intensive hypnotic work, it was possible to begin the proposed work with all 12 subjects without further individual preparation. While such success is not always to be achieved, the sense of belonging to the group, the freedom to participate or merely to observe, the visual instruction afforded, and the opportunity to identify with the subjects employed are potent factors in securing the confidence, cooperation, and rapport necessary to hypnotize

the individual subject. While this approach is not always applicable, my tendency is to rely upon it as often as possible.

The procedure of the trance induction with the individual subject is relatively simple after the preliminary establishment of rapport and confidence. A series of suggestions is given to the effect that the subjects will feel themselves relaxed, tired and sleepy, that they will become increasingly tired and will wish to sleep and will feel themselves beginning to go to sleep, and that as this continues they will want, with progressive intensity, to enjoy more and more the comfort and satisfaction of a deep, sound, restful sleep in which their only desire is to sleep with no other interest than to enjoy that sleep.

A second step of technique I have found of immense value, and which I usually employ concomitantly with the sleep suggestions, is the development of the subject's own feeling of active participation in the process of going into a trance. The reason for this is that in medical hypnosis there is a great need for the patient to participate actively in any reorganization of his psychic life. Hence his behavior should not be limited to the level of passive receptiveness and responsiveness so often mistakenly assumed to be all that hypnosis permits.

To secure active participation, hand levitation suggestions are given as the first step. That is, the subject is told that, as he goes to sleep, his hand will gradually and involuntarily begin to lift up in the air. This he may not notice at first, but when he does become aware of it, he will find himself tremendously interested and absorbed in sensing and enjoying that effortless, involuntary movement of his hand and arm. Thus, the subject is given the opportunity of observing his hypnotic response as a personal experience that is occurring within himself. There follow suggestions that soon the direction of the hand movement will change, that he is to be greatly interested in discovering what the new direction may be. This suggestion does result in an alteration of the hand movement, an alteration recognized by the subject as not determined in direction by specific hypnotic suggestions but determined by the continuing processes within himself as a hypnotic subject. This gives him a growing realization of his active participation in a progressive intrapsychic experience in which he plays an undefined but definite directive role governed by forces within him.

This can be followed by suggestions directing the subject's attention to those other possible psychosomatic manifestations characteristic of hypnotic behavior, reported upon previously (Erickson, 1943a, b, c, d) with the result that the subjects become absorbed in sensing their own psychosomatic phenomena as a personal experience in which they are active. Thus the situation is transformed from one of passive responsiveness for the patient to one of active interest, discovery, investigation, and participation in these changes produced by hypnosis. This is further enhanced by his realization that these changes in him are the result of his response to hypnosis itself and that they are occurring within him and are not forced upon him by specific suggestions. Thus, from intrapsychic evidence he has full opportunity to understand hypnosis as a significant and vital personality experience.

The crucial step of bridging the gap between light hypnosis and a deep trance can often be accomplished easily by letting the subject assume the entire responsibility for this further progress instead of resorting to the use of overwhelming, compelling suggestions by the hypnotist.

The method I usually employ is to suggest that the subject continue to sleep more and more deeply and to his own satisfaction and that, as he does so, his hand—automatically, involuntarily, and perhaps without his knowledge—will slowly move up and touch his face. However, his hand will not and must not touch his face until he is in a deep trance. Then, the touching of his face will be merely a signal for his own realization that he is in a profound trance.

Thus, suggestions are given to the subject, but the execution of them, the rapidity and time of response, and their effectiveness are made the responsibility of the subject, and they are contingent upon processes taking place within him and related to his own needs. In this way the suggestions are made to serve a more important function than that of eliciting passive obedience to the hypnotist. Consequently, hypnosis becomes a vital personality experience in which the hypnotist plays primarily the role of an instrument, merely guiding or directing processes developing within the subject.

This measure of securing the hypnotic subject's participation in the development of responses to suggestions is of value not only in inducing trances but also in eliciting hypnotic behavior of all sorts, whether simple experimental phenomena or therapeutic objectives. Indeed, in medical hypnosis the result obtained should derive primarily from the subject's activity and participation since it is his needs and problems that must be met.

Too often the unwarranted, unsound assumption is made that, because hypnosis can be induced by suggestion, whatever develops from the trance must be completely the result of suggestion and is only expressive of suggestions, that hypnosis as a special psychological state is in itself of no importance, and that what the hypnotist says, does, and understands is all-important. However, in the hypnotic situation the factor of paramount importance is hypnosis as a potent personality experience of peculiar and special importance to the subject.

This discussion of technique should demonstrate that the hypnotic subject can participate actively in his own hypnotic trance in an indefinite but nonetheless significant manner, and in direct relation to his own needs; and that hypnotic technique oriented to this understanding can reasonably offer the hypnotic patient an opportunity to deal with his own needs and problems in accord with his own psychological structure and experiences.

The reasons for this exposition of hypnotic technique are several. Personal experience with acute personality disturbances and the experience of former associates now in the army employing hypnosis for the therapy of acute psychiatric war disturbances suggest the value of much more extensive utilization of hypnosis as a therapeutic procedure. Also, hypnosis lends itself readily to easy and repeated use and requires no equipment

other than training and experience. Additionally, it gives the patient an opportunity to re-associate and reorganize the psychological complexities and disturbances of his psychic life under special conditions that permit him to deal with his problems constructively, free from overwhelming distress.

In the actual application to acute psychiatric disturbances hypnosis can reasonably be expected to offer several therapeutically significant advantages.

Experience to date with narcosis therapy, which is proving a most useful procedure, has indicated the great importance of the interpersonal relationship of physician and patient. In this connection hypnosis as a means of building up a favorable rapport between patient and physician can scarcely be equaled.

Experience also shows that narcosis therapy without verbalization by the patient of his fears and anxieties is ineffective. The hypnotic state can give the patient this same important avenue of self-expression without the handicap of narcotic effects and even make possible for him the verbalization of traumatic material otherwise repressed and unavailable to him.

Also, properly oriented, hypnotic therapy can give the patient that necessary understanding of his own role in effecting his recovery and thus enlist his own effort and participation in his own cure without giving him a sense of dependence upon drugs and medical care. Indeed, hypnosis offers the patient a sense of comfort and an attitude of interest in his own active participation in his therapy.

Probably of even greater significance is the opportunity hypnosis gives the patient to dissociate himself from his problems, to take an objective view of himself, to make an inventory of his assets and abilities, and then, one by one, to deal with his problems instead of being overwhelmed with all of them without being able to think clearly in any direction. Hypnosis offers an opportunity to control and direct thinking, to select or exclude memories and ideas, and thus to give the patient the opportunity to deal individually and adequately with any selected item of experience.

Finally, hypnosis offers both to the patient and the therapist a ready access to the patient's unconscious mind. It permits a direct dealing with those unconscious forces which underlie personality disturbances, and it allows a recognition of those items of individual life experience significant to the personality and to which full consideration must be given if psychotherapeutic results are to be achieved. Hypnosis alone can give the ready, prompt, and extensive access to the unconscious, which the history of psychotherapy has shown to be so important in the therapy of acute personality disturbances.

Hypnotic Psychotherapy

Milton H. Erickson

Reprinted with permission from *The Medical Clinics of North America*, May, 1948, New York

Since the most primitive times hypnosis has been employed almost universally in the practice of religious and medical rites to intensify belief in mysticism, magic, and medicine. The impressive, bewildering character of hypnotic manifestations and the profoundly inexplicable, seemingly miraculous psychological effects upon human behavior achieved by the use of hypnosis, have served to bring about two general contradictory attitudes toward it. The first of these is the unscientific attitude of superstitious awe, fear, disbelief and actual hostility, all of which have delayed and obstructed the growth of scientific knowledge of hypnosis.

The second attitude is one of scientific acceptance of hypnosis as a legitimate and valid psychological phenomenon, of profound importance and significance in the investigation and understanding of human behavior, and of the experiential life of the individual. This attitude had its first beginnings with the work of Anton Mesmer in 1775, who tempered his scientific approach to an understanding of hypnosis by mystical theories. Nevertheless, Mesmer did succeed in demonstrating the usefulness and effectiveness of hypnosis in the treatment of certain types of patients otherwise unresponsive to medical care. Thus he laid the foundation for the therapeutic use of hypnosis and for the recognition of psychotherapy as a valid psychological medical procedure.

Since then there has been a long succession of clinically trained men who demonstrated the usefulness of hypnosis as a therapeutic medical procedure and as a means of examining, understanding and reeducating human behavior. Among these was James Braid, a Scotch physician who, in 1841, first discredited the superstitious mystical ideas about the nature of hypnosis, or "mesmerism," as it was then called. Braid recognized the phenomenon as a normal psychological manifestation, coined the terms of "hypnosis" and "hypnotism," and devised a great variety of scientific experimental studies to determine its medical and psychological values.

Following Braid, many outstanding scientists, including both clinicians and later psychologists, accepted his findings and contributed increasingly to the scientific development of hypnosis despite the hampering heritage of traditional misconceptions, fears, and hostilities that have surrounded it and still do among the uninformed.

As yet, a scientific knowledge of hypnosis is still in its infancy. Theories of its nature are too general and too inadequate. Methods of application constitute a problem warranting extensive investigation. A general appreciation of the need to integrate hypnotic studies

with current knowledge is only slowly developing. The types of disorders for which it is best suited are still undetermined. New variations in techniques need to be developed.

As for the utilization of hypnosis in psychotherapy, this too, is still in its infancy. Traditions and traditional ways of thinking, the rigid self-sufficiency of various schools of psychotherapy, and the human tendency to fear the new and untried have hampered studies in this field. Only during the past 25 years has there been an increasing number of studies demonstrating hypnosis to be of outstanding value in investigating the nature and structure of the personality, in understanding normal and abnormal behavior, in studying interpersonal and intrapersonal relationships and psychosomatic interrelationships. Also, there have been extensive developments in the utilization of hypnosis as an effective instrument for psychotherapy. During the Second World War there was a tremendous increase in the recognition and utilization of hypnosis as a valuable form of psychotherapy.

Any discussion of hypnotic psychotherapy or hypnotherapy requires an explication of certain general considerations derived directly from clinical observation. In the following pages an effort will be made to indicate some of the misconceptions, inadequate understandings, oversights, and failures of differentiation that hamper or militate against the acceptance and usefulness of hypnotherapy. Also, material will be given to illustrate techniques, and explanations of their use will be given.

DIFFERENTIATION BETWEEN TRANCE INDUCTION AND TRANCE STATE

One of the first considerations in undertaking hypnotic psychotherapy centers around the differentiation of the patient's experience of having a trance induced from the experience of being in a trance state. As an analogy, the train trip to the city is one order of experience; being in the city is another. To continue, the process of inducing a trance should be regarded as a method of teaching patients a new manner of learning something, and thereby enabling them to discover unrealized capacities to learn, and to act in new ways which may be applied to other and different things. The importance of trance induction as an educational procedure in acquainting patients with their latent abilities has been greatly disregarded.

Both the therapist and the patient need to make this differentiation, the former in order to guide the patient's behavior more effectively, the latter in order to learn to distinguish between conscious and unconscious behavior patterns. During trance induction the patient's behavior is comprised of both conscious and unconscious patterns, while the behavior of the trance state should be primarily of unconscious origin.

The failure of such distinction or differentiation between the induction and the trance often results in patients attempting to perform the work of the trance state in the same fashion as they learned to develop a trance. That is, without proper differentiation, patients will utilize both conscious and unconscious behavior in the trance instead of

relying primarily upon unconscious patterns of behavior. This leads to inadequate, faulty task performance.

Although patients can, and frequently do, make this distinction spontaneously, the responsibility, though often overlooked, rests properly with the therapist. To ensure such differentiation, the trance induction should be emphasized as a preparation of the patient for another type of experience in which new learnings will be utilized for other purposes and in a different way. This education of patients can be achieved best, as experience has shown, by teaching them how to become good hypnotic subjects, familiar with all types of hypnotic phenomena. This should be done before any attempt is made at therapy. Such training, while it postpones the initiation of direct therapy, actually hastens the progress of therapy since it gives the patient wider opportunities for self-expression. For example, the patient who can develop hypnotic hallucinations, both visual and auditory, manifest regressive behavior, do automatic writing, act upon posthypnotic suggestions, and dream upon command is in an advantageous position for the reception of therapy.

As for the trance state itself, this should be regarded as a special, unique, but wholly normal psychological state. It resembles sleep only superficially, and it is characterized by various physiological concomitants, and by a functioning of the personality at a level of awareness other than the ordinary or usual state of awareness. For convenience in conceptualization, this special state, or level of awareness, has been termed "unconscious" or "subconscious." The role in hypnotic psychotherapy of this special state of awareness is that of permitting and enabling patients to react, uninfluenced by their conscious mind, to their past experiential life and to a new order of experience which is about to occur as they participate in the therapeutic procedure. This participation in therapy by the patients constitutes the primary requisite for effective results.

ROLE OF SUGGESTION IN HYPNOSIS

The next consideration concerns the general role of suggestion in hypnosis. Too often the unwarranted and unsound assumption is made that, since a trance state is induced and maintained by suggestion, and since hypnotic manifestations can be elicited by suggestion, whatever develops from hypnosis must necessarily be completely a result of suggestion and primarily an expression of it.

Contrary to such misconceptions, the hypnotized person remains the same person. His or her behavior only is altered by the trance state, but even so, that altered behavior derives from the life experience of the patient and not from the therapist. At the most the therapist can influence only the manner of self-expression. The induction and maintenance of a trance serve to provide a special psychological state in which patients can reassociate and reorganize their inner psychological complexities and utilize their own capacities in a manner in accord with their own experiential life. Hypnosis does not change people nor does it alter their past experiential life. It serves to permit them to learn more about themselves and to express themselves more adequately.

Direct suggestion is based primarily, if unwittingly, upon the assumption that whatever develops in hypnosis derives from the suggestions given. It implies that the therapist has the miraculous power of effecting therapeutic changes in the patient, and disregards the fact that therapy results from an inner re-synthesis of the patient's behavior achieved by the patient himself. It is true that direct suggestion can effect an alteration in the patient's behavior and result in a symptomatic cure, at least temporarily. However, such a "cure" is simply a response to the suggestion and does not entail that reassociation and reorganization of ideas, understandings, and memories so essential for an actual cure. It is this experience of reassociating and reorganizing his own experiential life that eventuates in a cure, not the manifestation of responsive behavior which can, at best, satisfy only the observer.

For example, anesthesia of the hand may be suggested directly, and a seemingly adequate response may be made. However, if the patient has not spontaneously interpreted the command to include a realization of the need for inner reorganization, that anesthesia will fail to meet clinical tests and will be a pseudo-anesthesia.

An effective anesthesia is better induced, for example, by initiating a train of mental activity within the patient himself by suggesting that he recall the feeling of numbness experienced after a local anesthetic, or after a leg or arm went to sleep, and then suggesting that he can now experience a similar feeling in his hand. By such an indirect suggestion the patient is enabled to go through those difficult inner processes of disorganizing, reorganizing, reassociating, and projecting of inner real experience to meet the requirements of the suggestion, and thus the induced anesthesia becomes a part of his experiential life instead of a simple, superficial response.

The same principles hold true in psychotherapy. The chronic alcoholic can be induced by direct suggestion to correct his habits temporarily, but not until he goes through the inner process of reassociating and reorganizing his experiential life can effective results occur.

In other words, hypnotic psychotherapy is a learning process for the patient, a procedure of reeducation. Effective results in hypnotic psychotherapy, or hypnotherapy, derive only from the patient's activities. The therapist merely stimulates the patient into activity, often not knowing what that activity may be, and then guides the patient and exercises clinical judgment in determining the amount of work to be done to achieve the desired results. How to guide and to judge constitute the therapist's problem, while the patient's task is that of learning through his own efforts to understand his experiential life in a new way. Such reeducation is, of course, necessarily in terms of the patient's life experiences, his understandings, memories, attitudes, and ideas; it cannot be in terms of the therapist's ideas and opinions. For example, in training a gravid patient to develop anesthesia for eventual delivery, use was made of the suggestions outlined above as suitable. The attempt failed completely even though she had previously experienced local dental anesthesia and also her legs "going to sleep." Accordingly, the suggestion was offered that she might develop a generalized anesthesia in terms of her own experiences when her body was without sensory meaning to her. This suggestion was intentionally vague since the patient, knowing the purpose of the hypnosis, was enabled by the vagueness of the

suggestion to make her own selection of those items of personal experience that would best enable her to act upon the suggestion.

She responded by reviewing mentally the absence of any memories of physical stimuli during physiological sleep, and by reviewing her dreams of walking effortlessly and without sensation through closed doors and walls and floating pleasantly through the air as a disembodied spirit looking happily down upon her sleeping, unfeeling body. By means of this review she was able to initiate a process of reorganization of her experiential life. As a result she was able to develop a remarkably effective anesthesia which met fully the needs of the subsequent delivery. Not until sometime later did the therapist learn by what train of thought he had initiated the neuro-psycho-physiological processes by which she achieved anesthesia.

SEPARATENESS OF CONSCIOUS AND SUBCONSCIOUS LEVELS OF AWARENESS

Another common oversight in hypnotic psychotherapy lies in the lack of appreciation of the separateness of the possible mutual exclusiveness of the conscious and the unconscious (or subconscious) levels of awareness. Yet all of us have had the experience of having a word or a name "on the tip of the tongue" but being unable to remember it so that it remained unavailable and inaccessible in the immediate situation. Nevertheless, full knowledge actually existed within the unconscious, but unavailably so to the conscious mind.

In hypnotic psychotherapy too often suitable therapy may be given to the unconscious, but with the failure by the therapist to appreciate the tremendous need of either enabling the patient to integrate the unconscious with the conscious or of making the new understandings of the unconscious fully accessible, upon need, to the conscious mind. Comparable to this failure would be an appendectomy with failure to close the incision. It is in this regard that many armchair critics naively denounce hypnotic psychotherapy as without value, since "it deals only with the unconscious." Additionally, there is even more oversight of the fact, repeatedly demonstrated by clinical experience, that in some aspects of the patient's problem direct reintegration under the guidance of the therapist is desirable; in other aspects the unconscious should merely be made available to the conscious mind, thereby permitting a spontaneous reintegration free from any immediate influence by the therapist. Properly, hypnotherapy should be oriented equally about the conscious and unconscious, since the integration of the total personality is the desired goal in psychotherapy.

However, the above does not necessarily mean that integration must constantly keep step with the progress of the therapy. One of the greatest advantages of hypnotherapy lies in the opportunity to work independently with the unconscious without being hampered by the reluctance, or sometimes actual inability, of the conscious mind to accept therapeutic gains. For example, a patient had full unconscious insight into her periodic nightmares of an incestuous character from which she suffered, but as she spontaneously declared in the trance, "I understand those horrible dreams, but I couldn't possibly tolerate such an

understanding consciously." By this utterance the patient demonstrated the protectiveness of the unconscious for the conscious. Utilization of this protectiveness as a motivating force enabled the patient subsequently to accept consciously her unconscious insights.

Experimental investigation has repeatedly demonstrated that good unconscious understandings allowed to become conscious before a conscious readiness exists will result in conscious resistance, rejection, repression and even the loss, through repression, of unconscious gains. By working separately with the unconscious there is then the opportunity to temper and to control the patient's rate of progress and thus to effect a reintegration in the manner acceptable to the conscious mind.

ILLUSTRATIVE CASE HISTORY

A 28-year-old-married man sought therapy because he believed implicitly that he did not love his wife and that he had married her only because she resembled superficially his mother, to whom he was strongly attached. In the trance state he affirmed this belief. During hypnotherapy he learned, in the trance state, that his marital problem had arisen from an intense mother-hatred disguised as over-solicitude and that his wife's superficial resemblance to the mother rendered her an excellent target for his manifold aggressions. Any attempt to make his unconscious understandings conscious confronted him with consciously unendurable tasks of major revisions in all of his interpersonal relationships and a recognition of his mother-hatred, which to him seemed to be both intolerable and impossible.

In psychotherapy other than hypnotic, the handling by the patient of such a problem as this would meet with many conscious resistances, repressions, rationalizations, and efforts to reject any insight. The hypnotherapeutic procedures employed to correct this problem will be given in some detail below. No attempt will be made to analyze the underlying dynamics of the patient's problem, since the purpose of this paper is to explicate methods of procedure, new techniques, the utilization of mental mechanisms, and the methods of guiding and controlling the patient's progress so that unconscious insight becomes consciously acceptable.

Early in the course of this patient's treatment it had been learned that he did not consciously dare to look closely at his mother, that he did not know the color of his mother's eyes or the fact that she wore dentures, and that a description of his mother was limited to "she is so gentle and graceful in her movements, and her voice is so soft and gentle, and she had such a sweet, kind, gracious expression on her face that a miserable neurotic failure like me does not deserve all the things she has done for me."

When, during hypnotherapy, he had reached a stage at which his unconscious understandings and insights seemed to be reasonably sufficient to permit the laying of a foundation for the development of conscious understandings, he was placed in a profound somnambulistic trance. He was then induced to develop a profound amnesia for all aspects of his problem and a complete amnesia for everything about his mother and his wife, except the realization that he must have had a mother. This amnesia included also

his newly acquired unconscious understandings. There are special reasons for the induction of such a profound amnesia or repression. One is that obedience to such a suggestion constitutes a relinquishing of control to the therapist of the patient's repression tendencies. Also, it implies to the patient that if the therapist can repress, he also can restore. In undertaking hypnotherapy it is important in the early stages to have the patient develop an amnesia for some innocuous memory, then to restore that memory along with some other unimportant but forgotten memory. Thus, an experiential background is laid for the future recovery of vital repressed material.

The other reason is that such an amnesia or induced repression clears the slate for a reassociation and reorganization of ideas, attitudes, feelings, memories, and experiences. In other words, the amnesia enables patients to be confronted with material belonging to their own experiential lives but which, because of the induced repression, is not recognized by them as such. Then it becomes possible for those patients to reach a critical objective understanding of unrecognized material from their own life experience, to reorganize and reassociate it in accord with its reality significances and their own personality needs. Even though the material has been repressed from both the working unconscious and the conscious, personality needs still exist and any effort to deal with the material presented will be in relationship to their personality needs. As an analogy, the child on a calcium-deficient diet knows nothing about calcium deficiency or calcium content but, nevertheless shows a marked preference for calcium-rich food.

After the induction of the amnesia, the next step was a seemingly casual, brief discussion of the meaning of feminine names. Then it was suggested that he see, sitting in the chair on the other side of the room, a strange woman who would converse with him and about whom he would know nothing except for a feeling of firm conviction that her first name was Nelly. Previous hypnotic training at the beginning of hypnotherapy had prepared him for this type of experience.

The patient's response to that particular name, as intended, was that of a hallucination of his mother whom he could not, because of the amnesia, recognize as such. He was induced to carry on an extensive conversation with this hallucinatory figure, making many inquiries along lines pertinent to his own problem. He described her adequately and objectively. He was asked to "speculate" upon her probable life history and the possible reasons there for. He was asked to relate to the therapist in detail all that Nelly "said" and to discuss this material fully. Thus, careful guidance by the therapist enabled him to review objectively, critically, and with free understanding a great wealth of both pleasant and unpleasant material, disclosing his relationships to his mother and his comprehension of what he believed to be her understandings of the total situation. Thus he was placed in a situation permitting the development of a new frame of reference at variance with the repressed material of his life experience, but which would permit a reassociation, an elaboration, a reorganization, and an integration of his experiential life.

In subsequent therapeutic sessions a similar procedure was followed, separately, with two other hallucinated figures, "spoken of" by Nelly as her son Henry and his wife Madge, neither of whom the patient could recognize because of his induced amnesia.

The hypnotic session with Henry was greatly prolonged since Henry "told" the patient a great wealth of detailed information which the patient discussed with the therapist freely and easily and with excellent understanding. The patient's interview with the hallucinatory Madge was similarly conducted.

Of tremendous importance in the eventual therapeutic result was the patient's report upon the emotional behavior he "observed" in the hallucinated figures as they related their stories, and his own objective, dispassionate appraisal of "their own emotions."

To explain this procedure it must be recognized that all of the material the patient "elicited" from the hallucinatory figures was only the projection of the repressed material of his own experience. Even though a profound repression for all aspects of his problem had been induced, that material still existed and could be projected upon others, since the projection would not necessarily lead to recognition. To illustrate from everyday experience, those personality traits disliked by the self are easily repressed from conscious awareness and are readily recognized in others or projected upon others. Thus, a common mental mechanism was employed to give the patient a view of himself which could be accepted and integrated into his total understandings.

The culminating step in this procedure consisted in having him hallucinate Nelly and Henry together, Madge and Henry, Nelly and Madge, and finally all three together. Additionally, he was induced to develop each of these various hallucinations in a great number of different life settings known from his history to be traumatic, such as a shopping trip with his wife which had resulted in a bitter quarrel over a minor matter, a dinner table scene, and a quarrel between his wife and his mother.

Thus the patient, as an observant, objective, judicious third person, through the mechanisms of repression and projection, viewed freely, but without recognition, a panorama of his own experiential life, a panorama which permitted the recognition of faults and distortions without the blinding effects of emotional bias.

In the next session, again in a profound somnambulistic trance, he was emphatically instructed to remember clearly, in full detail, everything he had seen, heard, thought, and speculated upon and appraised critically in relationship to Nelly, Henry, and Madge. To this he agreed readily and interestedly. Next he was told to single out various traumatic incidents and to wonder—at first vaguely, and then with increasing clarity—whether or not a comparable incident had ever occurred in his life. As he did this, he was to have the privilege of remembering any little thing necessary in his own history. Thus he was actually given indirect instructions to break down by slow degrees the induced amnesia or repression previously established.

The patient began this task slowly, starting with the simple declaration that a cup on the table, in a dinner scene he had hallucinated, very closely resembled one he had had since childhood. He next noted that he and Henry had the same first name, wondered briefly what Henry's last name was, then hastily observed that Madge and Henry evidently lived

in the same town as he did, inasmuch as he had recognized the store in which they quarreled so foolishly. He commented on Nelly's dentures and, with some reluctance, related his fears of dentists and of losing his teeth, and being forced to put up a "false front." As he continued his remarks, he became more and more revealing. Gradually he tended to single out the more strongly emotional items, spacing them with intervening comments upon relatively innocuous associations. After more than an hour of this type of behavior, he began to have slips of the tongue, which he would immediately detect; he became tense, and then, upon reassurance by the therapist, would continue his task. For example, in comparing Nelly's light-brown eyes with Madge's dark-brown eyes, he made the additional comment, "My wife's eyes are like Madge's." As he concluded his statement, he showed a violent startle reaction and, in a tone of intense surprise, repeated questioningly. "My wife?" After a moment's hesitation he remarked to himself, "I know I'm married. I have a wife. Her name is Madge. She has brown eyes like Madge. But that is all I know. I can't remember any more—nothing—nothing!" Then, with an expression of much anxiety and fear, he turned to the therapist and asked pleadingly, "Is there something wrong with me?"

Shortly he discovered the similarity between Nelly and his mother, then continued, with excellent understanding, by appraising Nelly as an unhappy neurotic woman deserving normal consideration and affection. This led to the sudden statement: "That applies to my mother too—Good God, Nelly is my mother, only I was seeing her for the first time—her eyes are brown—like Madge's. My wife's eyes are brown—her name is Madge—Madge is my wife."

There followed then a whole series of fragmentary remarks relating to traumatic situations, of which the following are examples:

"The fight at the store—that coat she bought—we almost broke our engagement—birthday cake—shoestring broke—Good God, what can I ever say to her?" After each utterance he seemed to be absorbed in recalling some specific, emotionally charged event in detail. After about 20 minutes of this behavior he leaned forward, cupped his chin in his hands, and lost himself in silent reflection for some minutes, terminating this by asking in a questioning manner, "Nelly, who is Nelly?" but immediately absorbed himself in reflection again. For some time longer he sat tense and rigid, shifting his gaze rapidly here and there and apparently thinking with great feeling. About 15 minutes later he slowly relaxed and, in a tired voice, declared. "That was hard. Henry is me. Now I know what I've been doing, what I've been doing here, and been doing all my life. But I'm not afraid anymore. I don't need to be afraid—not anymore. It's an awful mess, but I know how to clean it up. And I'm going to make an appointment with the dentist. But it's all got to take a lot of thinking—an awful lot, but I'm ready to do it."

Turning to the therapist he stated. "I'm tired, awful tired."

A series of questions and answers now disclosed that the patient felt satisfied, that he felt comfortable with the rush of new understandings he had experienced, that he knew that he was in a trance, and that he was at a loss to know how to let his conscious mind learn

what he now knew in his unconscious. When asked if he wanted some suggestions in that regard, he eagerly indicated that he did.

He was reminded of how the induced amnesia had been broken down by the slow filtering out of ideas and associations by outward projection where he could examine them without fear or prejudice and thus achieve an understanding. With each new understanding he had experienced further reorganization of his experiential life, although he could not sense it at first. This, as he could understand, was a relatively simple task, involving nothing more than himself and his thinking and feelings. To become consciously aware of his new understandings would involve himself, his thinking, his everyday activities, his own personal relationships, and the interpersonal relationships of other people. This, therefore, would be an infinitely more difficult task. Upon full understanding of this, an agreement was reached to the effect that he would continue to be neurotic in his everyday life, but as he did so, he would slowly and gradually develop a full conscious realization of the meaningfulness of his neuroticisms, first of the very minor ones and then, as he bettered his adjustments in minor ways, to progress to the more difficult problems. Thus, bit-by-bit, he could integrate his unconscious learnings with his conscious behavior in a corrective fashion which would lead to good adjustment.

The above paragraph is but a brief summary of the discussion offered the patient. Although he believed he understood the explanation the first time, it is always necessary, as experience has shown repeatedly, to reiterate and to elaborate from many different points of view and to cite likely incidents in which unconscious insights can break through to the conscious before patients really understand the nature of the task before them. A possible incident was cited for him by which to learn how to let unconscious learning become conscious. On some necessary trip to the store where the quarrel had occurred he would notice some clerk looking amused at something. He would then experience a strong feeling of amusement for no known reason, wonder why, discover that his amusement was tinged with a mild feeling of embarrassment, suddenly recall the quarrel with his wife in its true proportions, and thus lose his conscious resentments. A few other such incidents were also suggested and, as subsequently learned, were acted upon. He was then awakened from the trance and dismissed.

The patient's first step to effect a conscious integration, in accord with his trance declaration, was to visit, with much fear, his dentist, thereby discovering, in the dental chair, how grossly exaggerated his fears had been. Next, he found himself humming a song while putting on his shirt, instead of examining it compulsively for wrinkles, as had been his previous habit.

Examination of all the family photographs initiated a process of identification of himself, his mother, and his wife. He discovered for the first time that he resembled his father strongly and could not understand why he had previously believed so fully that he was the image of his mother. By way of the photographs he discovered the dissimilarities between his wife and his mother, and that dentures had actually altered his mother's facial appearance.

At first his adjustments were made singly and in minor matters, but after a few weeks larger and larger maladjustments were corrected. Usually, these were corrected without his conscious awareness until sometime later, a measure which had been suggested to him. For example, he had always visited his mother regularly at the hour of her favorite radio program, and he had always insisted on listening to another program which he invariably criticized unfavorably. Unexpectedly, one day, he became aware that, for several weeks, he had been making his visits at a different hour. With much amusement he realized that his mother could now listen to her favorite program, and, at the same time he experienced the development of much insight into the nature of his attitudes toward his mother.

During this period of reintegration he visited his therapist regularly, usually briefly. Sometimes his purpose was to discuss his progress consciously, sometimes to be hypnotized and given further therapy.

One of his last steps was to discover that he loved his wife and always had, but that he had not dared to know it because he was so convinced in his unconscious that any man who hated his mother so intensely without knowing it should not be allowed to love another woman. This, he now declared, was utterly unreasonable.

The final step was postponed for approximately six months and was achieved in the following manner.

Walking down the street, he saw a stranger swearing fluently at a receding car that had splashed water on him. He felt unaccountably impelled to ask the stranger why he was swearing in such a futile fashion. The reply received, as reported by the patient, was, "Oh, it don't do no good, but it makes me feel better, and besides, it wasn't the driver's fault, and my swearing won't hurt him."

The patient related that he became obsessed with this incident for several days before he realized that it constituted an answer to the numerous delays in the execution of many half-formulated plans to stage a quarrel with his mother and "have it out with her." He explained further that an actual quarrel was unnecessary, that a full recognition of his unpleasant emotional attitudes toward his mother, with no denial or repression of them, and in the manner of the man in the street, would permit a true determination of his actual feelings toward his mother. This was the course he followed successfully. By following the example set by the stranger, he successfully established good relationships with his mother.

The remarkable parallelism between this final step and the hypnotic procedure of having him project his experiential life upon hallucinatory figures is at once apparent. It illustrates again the value of the hypnotic utilization of the dynamics of everyday behavior.

COMMENTS

In presenting this case material, the purpose has not been to give an understanding of the dynamics involved in the patient's illness nor of the varied nature of his maladjustments. Rather, the purpose of the entire paper is that of demonstrating the values of hypnotic psychotherapy, methods of application, and techniques of utilization. A most important consideration in hypnotherapy lies in the intentional utilization, for corrective purposes, of the mental mechanisms or dynamics of human behavior.

Repressions need not necessarily be broken down by sustained effort. Frequently their maintenance is essential for therapeutic progress. The assumption that the unconscious must be made conscious as rapidly as possible often leads merely to the disorderly mingling of confused, unconscious understandings with conscious confusions and, therefore, a retardation of therapeutic progress.

The dissociation of intellectual content from emotional significances often facilitates an understanding of the meaningfulness of both. Hypnosis permits such dissociation when needed, as well as a correction of it.

Projection, rather than being corrected, can be utilized as a therapeutic activity, as has been illustrated above. Similarly, resistances constituting a part of the problem can be utilized by enhancing them and thereby permitting the patient to discover, under guidance, new ways of behavior favorable to recovery. The tendency to fantasy at the expense of action can be employed through hypnosis to create a need for action.

SUMMARY

In brief, there are three highly important considerations in hypnotic psychotherapy that lend themselves to effective therapeutic results. One is the case and readiness with which the dynamics and forms of the patient's maladjustments can be utilized effectively to achieve the desired therapy.

Second is the unique opportunity that hypnosis offers to work either separately and independently, or, jointly with different aspects of the personality, and thus to establish various nuclei of integration.

Equally important is the value of hypnosis in enabling the patient to re-create and to vivify past experiences free from present conscious influences, and undistorted by his maladjustment, thereby permitting the development of good understandings which lead to therapeutic results.

Hypnosis in General Practice

Milton H Erickson

Reprinted from *State of Mind*, 1957, 1

Hypnosis can help you in treating almost any patient. Divested of the mystery which it holds for the uninitiated, this long-known psychological phenomenon has a definite place in general medical practice.

As every doctor knows, it is not enough to prescribe and advise correctly—the patient himself must put the recommended regime into action. Whether he does or not will depend on many things, among them his understanding of himself, his illness and the required treatment, plus the degree of rapport he has with his physician. Here's where hypnosis can be a valuable therapeutic aid.

In a hypnotic state the patient gains a more acute awareness of his needs and capabilities. He is freed from mistaken beliefs, false assumptions, self-doubts and fears which might otherwise stand in the way of needed medical care. Whether he really is sick or just believes that he is (which, by the way, can be equally damaging), the new insights he gets through hypnosis improve his attitude toward his condition. Rapid development of a sound relationship with the doctor is also facilitated, since trust and confidence in others is based, to a large extent, on a real understanding of one's self.

HYPNOTIC RESPONSIVENESS STIMULATES COOPERATION

Another significant change occurs while the patient is hypnotized. He becomes much more responsive to ideas and is able to accept suggestions and to act upon them more readily than in his ordinary state of awareness. The patient's increased responsiveness under hypnosis helps the doctor to secure the kind of cooperation that is essential to successful medical treatment.

To repeat: all patients who come to you seeking the help, the inspiration, and the motivation they need to recover and maintain recovery can benefit from hypnosis. There is the obstetrical patient who is entitled to the easiest possible delivery and the allaying of her anxiety; the surgical patient who fears a needed operation; the dermatological or allergic patient who cannot stand the itching of his skin; the rheumatoid arthritic patient who progressively handicaps and limits himself, the patient with minor illness who invalids himself completely; the obese patient who "tries" but does not cooperate; the patients with unhealthy habits ranging from thumb-sucking to alcoholism. I could go on indefinitely, but I think I can better make my point by citing two case histories which illustrate widely different applications for hypnosis in general practice.

HYPNOSIS AIDS DIAGNOSIS

The first case concerns a middle-aged nurse who had an extremely domineering personality. She had been referred to me by another physician to whom she had complained of fatigability, insomnia, weakness, and vague gastric pains. She had accepted referral somewhat reluctantly and by the time she appeared in my office had already diagnosed her problem herself as "globus hystericus." She demanded that hypnosis be used as a therapeutic approach and only grudgingly consented to give her case history. From her description of her physical complaints it appeared to me that her self-diagnosed ailment was in reality a symptom displacement. I offered the suggestion that she might have a peptic ulcer and that she go to see an internist. This she flatly refused to do unless I employed hypnosis on her. In a light trance, she was persuaded to have an X-ray, and the report disclosed that she did, in fact, have a peptic ulcer. She told me that she had been given a wealth of medical advice and prescriptions, all of which, she announced, she intended to reject.

Another somewhat deeper trance was induced in which she was given a whole series of suggestions to the effect that she could dominate the entire situation (which was important to her) by taking control of therapy herself. I told her she could do this by utilizing fully and cooperatively all advice and instructions given her, by assuming a comfortable and happier attitude toward her situation and by realizing that such an attitude would free her of tensions. She was further advised that she had no real need for her presenting complaint of "globus" and that she could dismiss it now that she had radiographic confirmation of her true condition. A month later she went to the internist for a reexamination and was delighted with his announcement that she was symptom-free, with no X-ray evidence of an ulcer.

She returned to me twice more for trance induction, to be continued in her "own handling of her physical problems," as she put it.

HYPNOSIS "KILLS" PAIN

Another middle-aged woman came under my care for quite a different reason. This patient was suffering from metastatic carcinoma of the lung and was experiencing continuous, excruciating pain which required constant sedation with narcotics. She was well aware of the fact that she had only a few weeks to live and bitterly resented the comatose state induced by the narcotic medication.

Her husband sought my help in the hope that a hypnotic anesthesia could be induced which would free his wife of both the pain and the narcotic so that she could spend her remaining days with her family.

The woman willingly endured pain for some 12 hours to rid herself of the effects of the narcotics so that I might hypnotize her. Because of her tremendous motivation, it was possible to induce in her a profound trance state. A deep hypnotic anesthesia was achieved and she was given posthypnotic suggestions to the effect that each day this would be renewed and strengthened. As a result, she was released from the narcotic-

induced comatose state and enjoyed five weeks of contact with her family before she expired. During this time she experienced no more than a slight dull ache and feeling of heaviness in her chest.

WHERE CAN YOU LEARN HYPNOSIS?

Assuming that what I've said has convinced you that hypnosis has a place in your practice, you will want to know where you can learn it.

A few universities, scattered around the country, teach formal courses in hypnosis. But for the most part you will have to get your training from people who are experienced in hypnosis and willing to teach it. Such training is best accomplished in situations where more than one person's knowledge and experience is presented, since every patient poses problems that need understanding from more than one point of view.

Preferably, hypnosis should be taught under multidisciplinary auspices as it is by an independent group in Chicago, which includes psychiatrists, obstetricians, general practitioners, dentists, and psychologists. I look forward, however, to the time when more professional schools will offer courses in hypnosis in a concentrated form that does not take doctors away from their practice for too long.

For as the age-old attitude of superstitious awe, fear, incredulity, and antagonism toward hypnosis is replaced by an appreciation of its scientific values, it will become an even more important therapeutic aid and a valuable tool in practicing the art of medicine.

Hypnosis: Its Renascence as a Treatment Modality

INTRODUCTION

Hypnosis Is as Old as Medicine and Almost as Old as Man

Civilizations now belonging to the ancient past reveal that the primitive use of hypnosis was incorporated into the healing arts of the earliest civilizations. These civilizations arose, flourished, and fell, only to be buried under the ruins of newer civilizations that succeeded one another in man's march out of the past. As man continued to think, to behave, to desire, so did he continue to use the art of hypnosis. Throughout history there has been an ever-continuing need to cast the magic spell, to bring healing sleep to the sick, and inner peace to the wounded.

Down through the ages priests and priestesses rendered their services to the ailing and troubled in Temples of Sleep, built upon the ruins of other Temples of Sleep belonging to previous civilizations. The Chinese, Hindus, Greeks, and Egyptians all had temples where suggestion and hypnosis were administered to lessen hurt and suffering. Undoubtedly, there are ancient civilizations yet-to-be-discovered that used hypnosis expressed in magical sleep, rites, and incantations. For men forever remain men with needs in common.

A rebirth of medical interest in hypnosis, although short-lived, began following World War I. The Germans in World War I exhausted their supply of chemical anesthetics and used hypnosis as an anesthetic agent. After the war, particularly in England, hypnosis was used as a calming and re-educative influence in what was then called "shell shock." By the 1930s a new type of study of hypnosis was evolving. This was the use of hypnosis as a means of investigating psychological and physiological behavior. This was done first by the author, who was then one of Clark L. Hull's students. Subsequently, Hull became seriously interested in hypnosis and proceeded to demonstrate that hypnosis could be subjected to laboratory examination and study just as can other forms of human behavior. Publications originating first in his laboratory, then elsewhere, disclosed that hypnosis could be evaluated by measurable changes brought about in the physiology of the person on whom it was employed, and that by inducing changes in the person's behavior, there could be an investigation of the various forces and experiences that constitute the foundation of personality.

During World War II physicians and psychologists who had learned something about hypnosis found that it could be used not only as an anesthetic, as the Germans had shown in World War I, but to investigate the particular experiences that resulted in "combat fatigue." Further, it could be employed to reeducate the patient to a better understanding of his actual capabilities and potentialities in meeting the stresses of war. Thus, many battle casualties were salvaged. When World War II ended, many of the men from the psychological, medical, and dental fields, returning to civilian life, realized that there should be much more extensive teaching of hypnosis.

Enterprising men from the professions of medicine, dentistry, and psychology organized teaching teams and traveled throughout the country conducting seminars on hypnosis. These teams included people well-founded in psychosomatic medicine, general medicine, psychiatry, obstetrics, surgery, psychology, and dentistry. They lectured before medical societies, psychological groups, or other organizations. Properly, the qualifications for admission to these seminars was the possession of a proper academic degree. Very slowly, scientific interest continued to grow. The result was that here and there a psychology department, a physiological department, or a dental school permitted investigative work by means of hypnosis.

In 1949 the Society of Clinical and Experimental Hypnosis was organized by a small group of scientifically trained men in New York City. The organization promoted the development of hypnosis and founded a journal in that field.... In 1957 came the founding of the American Society of Clinical Hypnosis.... which affiliated with, and stimulated the growth of numerous comparable societies throughout the world. It also aroused the interest of qualified individuals interested in hypnosis. Thus, there arose a progressive and compelling interest in hypnosis as a valuable modality in the healing arts and in the field of psychological investigation of human behavior. Iatrogenic well-being rather than iatrogenic illness became a new center of interest.

Little is really known of the actual potentials of human functioning. Hypnosis offered for scientific exploration a different field of conscious awareness, an unexplored approach to puzzling medical problems, a new awareness that scientific studies could be approached in a different way. In brief, a new field of scientific investigation had been opened.

Hypnosis, as an adjunct to the practice of medicine, has opened new fields of exploration in the study of human behavior and is changing the concepts of psychological and physiological potentialities. That it will be productive is unquestionable. But how productive, and in what way, no one can yet say.

HYPNOSIS BY DEFINITION

A Special State of Conscious Awareness

Today there are still those who think of hypnosis as a healing sleep, a magical force, a kind of demoniacal power, as has been thought for thousands of years.

But what is hypnosis as we understand it scientifically today? It is certainly not physiological sleep, even though it may seem to resemble it and may even be used to produce physiological sleep. It is not some special power or magic, nor is it some barbaric force arising from evil sources. It is, in simple terms, nothing more than a special state of conscious awareness in which certain chosen behavior of everyday life is manifested in a direct manner, usually with the aid of another person. But it is possible to be self-induced. Hypnosis is a special but normal type of behavior, encountered when attention and the thinking processes are directed to the body of experiential learnings acquired from, or achieved in, the experiences of living.

In the special state of awareness called hypnosis the various forms of behavior of everyday life may be found—differing in relationships and degrees, but always within normal limits. There can be achieved no transcendence of abilities, no implantations of new abilities, but only the potentiation of the expression of abilities which may have gone unrecognized or not fully recognized.

Hypnosis cannot create new abilities within a person, but it can assist in a greater and better utilization of abilities already possessed, even if these abilities were not previously recognized.

Using Hypnosis in Medical Practice

The rationale for the use of hypnosis in the healing arts is the beneficial effect of restriction of the patient's attention to those items of behavior and function pertinent to his well-being.

To clarify by an example, lay a wooden plank 25 feet long and 20 inches across on the level ground. Anybody in a state of ordinary, conscious awareness can walk that 25 feet easily. But place that same plank at an elevation of 200 feet in the air and the problem of walking its length becomes greatly changed for the person, even though the actual task is unchanged. In the ordinary state of conscious awareness performance is too often limited by considerations which may actually be unrelated to the task. Walking that wooden plank with transparent flooring on both sides, but the ground plainly visible 200 feet below, would still remain a nerve-racking task for many persons who could do it easily on the ground. Ideas, understandings, beliefs, wishes, hopes, and fears can all impinge easily upon a performance in the state of ordinary, conscious awareness-disrupting and distorting even those goals which may have been singly desired. But in a state of hypnosis the field of conscious awareness is limited and tends to be restricted to exactly pertinent matters, other considerations being irrelevant. To cite another illustration, a badly burned patient is in desperation for pain relief. He does not want to be presented with ideas and suggestions about his pain. He is not interested in taking fluids and food. He has no appetite as a result of his suffering. He cannot sleep because of pain, fear, and anxiety about the outcome of his condition.

Under hypnosis, by contrast, the badly burned patient is open to suggestion. He is as ready to accept suggestions of hypnotic anesthesia and analgesia as he would be to accept

morphine. He is also ready to accept suggestions of thirst and hunger and to respond readily to them, something that would be impeded by drug administration, as would likewise the elimination of toxins be retarded by medication for pain. Further, he enjoys natural, physiological sleep rather than a narcotic sleep.

Even if hypnosis fails to bring full relief, the symptomatology can be greatly reduced, thus lessening the amount of medication that can interfere with toxin elimination.

In the writer's own experience the shock response of a seven-year-old child to severe scalding of one arm, her shoulder, chest, and side, was utilized in inducing a hypnotic trance. Local dressing of the burned areas, but no general medication, resulted in full recovery within three weeks. Further hypnosis after the initial session was not required, since the original posthypnotic suggestions continued to remain effective throughout the hospitalization.

In another instance, which took place some years ago, a male patient in his early twenties, who had been committed to the mental hospital three years previously, was diagnosed as suffering from catatonic schizophrenia. His clinical course in the hospital came to be almost completely predictable. There would be a week during which he would show rising tension and anxiety, and always within eight days he would reach a peak of highly disturbed violent behavior, requiring either physical restraint or seclusion, and during which time no interpersonal contact could be made. This period would last four to six weeks. There could then be a six- to eight-day period during which his disturbed behavior would subside, and always within eight days he reached a state of passive, inaccessible behavior, but was unable to give any clear account of the reasons for, or the nature of, his disturbed behavior. This state of behavior would then continue for seven to nine weeks, whereupon the disturbed cycle would begin again.

During one period of remission approximately 25 hours were spent in training this patient to be a somnambulistic hypnotic subject, the purpose being purely experimental and investigative. He was given special posthypnotic suggestions to which he was "always to respond."

At the beginning of the third week of the next disturbed period following his hypnotic training, the patient was still in full physical restraint and, so far as could be determined, was still completely inaccessible by ordinary methods, requiring tube feeding and being completely incontinent. The patient was approached, his wrist was grasped gently, and he was addressed by the name of "John," an agreed-upon name assigned to him during previous hypnotic trances and to be used only in the trance condition. After he had been called by the name "John" three times at five-second intervals, each time his wrist being gently squeezed, he appeared to recognize the writer and asked what was wanted. Then he almost immediately seemed to become aware of his restraints and asked what had happened. He was told simply that it was desirable to have him talk to the medical students—a procedure of much previous experience during remission states. "John" stated that he was not feeling well, that he was full of "awful feelings" and fears and anxiety, and he expressed doubt that he could talk to the students. He also asked why he

was called “John” instead of his real name Frank. This signified that he was not in a hypnotic trance, a development not anticipated, since it was hoped and expected that he would “come out” of his disturbed state into a trance state. Nevertheless, with much urging he was persuaded to take a shower, to dress, and to talk to the students. He was told that he was free to ask to be put back into restraint if he found his emotional distress becoming too much for him. Hesitantly, he agreed.

After two hours with the students, Frank stated that he was “getting sick” and asked to be put in restraint as rapidly as possible. He even assisted in an anxious, hurried manner in the securing of the restraints. When this was completely accomplished, he was so informed. Immediately he renewed his previous disturbed behavior of screaming, shouting, and struggling violently, again completely inaccessible.

The next week, the fourth week in his disturbed cycle, the same procedure was followed and similar contact was obtained.

By the fifth week it was recognized that he was in a state of beginning remission, which was achieved within a week’s time. It was not considered desirable to intrude upon this spontaneous abatement of his symptoms.

During the succeeding eight-week period of remission he was used repeatedly to demonstrate hypnotic trances, and he was still a most competent subject. Unfortunately, the most intensive questioning could secure no information regarding his disturbed period experiences. He did not even seem to understand that he had had a disturbed period, but he knew that a period of time, for which he could not account, had elapsed.

During the next period of disturbed behavior it was learned that he could again be approached by the previously established posthypnotic cues of a gentle grasping of his wrist and calling him by the name of “John” three times. This could be done at intervals of four or more days. There were two failures when such an attempt was made on the third day after a successful approach. Hence, all approaches thereafter were never more frequent than four days apart.

None of the other psychiatrists was willing to follow the writer’s example. Several medical students succeeded easily, but this was not a fair test since I was present. But in general the use of hypnosis as an easy approach to a disturbed psychotic patient, unapproachable by any other method, was frowned upon and discouraged, and only my rank on the professional staff made it possible for me to perform these “unorthodox” experiments.

Encouraged by this experience with Frank, I attempted a similar procedure in six other schizophrenic patients, both catatonics and hebephrenics. Similar results were obtained with these patients, three of them recovering sufficiently to be sent home. All returned to the hospital within three years’ time, acutely disturbed in behavior. Nevertheless, each responded again to the posthypnotic cues given them in their previous hospitalization and shortly left the hospital.

Hypnosis was also employed successfully with three violently excited manic-depressive patients who showed brief remissions sufficiently long to permit hypnotic training. With them, as with the schizophrenic patients, extremely violent, excited episodes of disturbed behavior could be briefly interrupted for two to four hours before it would be necessary to restore the restraints or to return them to the seclusion rooms.

In the writer's experience this manner of dealing with disturbed psychotic behavior could be accomplished only by hypnosis. Even though the percentage of successes was much lower than the percentage of failures, the elicitation of reasonable normal behavior by hypnosis from acutely disturbed psychotic patients indicates, in a limited way, the remarkable effectiveness of this "special state of conscious awareness." It also indicates an important area warranting continuing research and investigation.

The problem yet remaining is to ensure that the members of the medical profession fully realize that the thinking, the emotions, and the past experiential learnings of each person play a significant role in his psychological and physiological functionings.

HYPNOSIS IN MEDICAL PRACTICE: THREE CASE HISTORIES

The following case histories illustrate how the potentials within a person can restore well-being. Hypnosis isolates the person from his immediate conscious surroundings—and so directs attention within one's self and to one's own actual potentialities. This is as important as the conventional scientific laboratory, because it is the laboratory that exists within the person.

Edward C.

Edward was one of two children. His sister was six years his senior. His father was employed in an industrial plant. Upon graduating from high school Edward secured employment in the same plant. He was quiet, thoughtful, had few friends and these were merely casual. He had no interest in girls, although he had taken two or three to a movie (but never the same girl twice). He was neither friendly nor unfriendly. One day while at work he suddenly became violently disturbed. He had to be subdued by his fellow workers until the police came to put him in handcuffs and leg irons and take him to the psychopathic ward of a city hospital. From there he was committed to the mental hospital. The psychiatric staff made a diagnosis of schizophrenia, catatonic type.

On the ward Edward sat quietly in a chair. He would listen attentively when spoken to, but would never reply. However, about three times every 24 hours he became violently disturbed. He would rush wildly through the dormitory, crawling under and over beds, around beds, shoving them away from the wall. The disturbances would last from 10 to 20 minutes, whereupon, covered with perspiration, he would return to his chair or, at night, to his bed. There was never a word of explanation received from Edward about these episodes. More than a dozen physicians endeavored repeatedly to interview the

patient or to elicit some verbal response from him. Each interview was a failure—and this had been going on for three years.

Finally this writer decided to use hypnosis. I employed a technique of relaxation, with suggestions of tiredness, fatigue, sleep, and attentiveness to what was said. Within the course of 20 minutes Edward gave every evidence, physically, of being in a hypnotic trance. He showed catalepsy, would nod his head affirmatively or shake it negatively when asked various questions. It was soon determined that he would like to tell about his difficulties, but did not know how. This information was obtained by laborious questioning, answered by head movements. I explained that I was going to help him, and that this help would consist of having him sit quietly in a chair and have a dream. (A dream could be acceptable, since it was an inner experience, and direct communication is not.) This dream might occur during the coming night, but it was explained that I would like to have it occur within the next hour if that were agreeable. Edward nodded affirmatively. He was told that he was to dream informatively about his problem, about the reason why he was in a mental hospital. It was suggested that he relate the content of this dream after it occurred. He was asked to think this over for a half-hour while still in a hypnotic trance. I explained that I would return to him and ask him if he would dream that informative dream within the hour after I returned. Edward nodded his head to express his agreement. He was then left sitting in his chair in a trance. Half an hour later I returned and asked Edward if he were willing to have his dream within the next hour, and after the dream to relate it verbally. Edward nodded his head affirmatively. I took a comfortable seat near the patient and waited for 15 minutes to pass, the time Edward had said it would take before he would have his dream. Almost exactly 15 minutes passed when Edward suddenly became extremely tense and began to perspire freely. His muscles quivered. He clenched his jaws. These movements persisted for about 20 minutes. Then Edward relaxed and sighed deeply. I asked him, “Are you through dreaming,” He replied, “Yes, it was awful, just awful.”

I asked him to narrate the dream fully, if he could. He nodded his head affirmatively and also stated, “I can, but take me by the hand because I will get awful scared.” Edward related his dream. He imagined himself being suddenly thrown into complete darkness and being seized by a terrible force. “It drags me, it yanks me, it pulls me, it twists me, it turns me. It hauls me through great piles of barbed wire, through heaps of stabbing knives. It jerks me first one way and then another. It pulls me up and it pulls me down, and all the time I am being stabbed. I can’t see anything. I just feel awful pain. It goes on and on and on. And I am so scared.”

I asked if there was anything I could do to comfort him. Edward replied that nobody could help him, that nothing could help him, that all he could do was sit and wait. I then asked him to sit quietly and comfortably, to rest for two or three hours, and to let nothing happen to him. During that period he was told to awaken and to go to lunch as usual. Later that same day Edward was approached again. He was silent, but looked attentively at me—his first real effort in three years to respond to a psychiatrist. I asked if he were willing to let me hypnotize him again. Edward nodded and reached out his hand. I took a careful grasp of his hand and induced a trance within a few minutes. As soon as catalepsy

indicated that Edward was in a hypnotic state, I asked if he were asleep. He answered, “I am sound asleep, I am resting comfortably, I am all alone except for your voice. I like it this way.” Edward was then asked, “Are you willing to have another dream?”

He answered, “No.” I persisted, “I would like you to have another dream because I think I can help you by your having this dream again.” Edward answered, “If it will help, I’ll try.” Sick people do want to try—usually they don’t know how. Edward was asked to listen most attentively, slowly and laboriously. He was told that he was to dream that same dream that he had dreamed previously. He shook his head and said, “No! No!” I continued, “I want a different setting, a different set of conditions. I want it to be the same dream with a totally different set of characters, because you can call those barbed wire heaps and the thorn bushes and the heaps of stabbing knives ‘characters.’ This time I want it to be the same dream with the same emotions, but with a different cast of characters. Will you do this for me, Edward, knowing that it really is for you?”

After some minutes of thought Edward asked how soon to start. I asked, “After five minutes will it be all right to begin the dream?” There was a slow, reluctant “Yes.” The minutes were counted—one, two, three, four—and about 50 seconds later Edward tightened his fingers on my hand very forcibly and showed the previous behavior—tense, quivering muscles, diffuse perspiration, and shuddering of his body. Again, this lasted about 20 minutes. Then Edward suddenly relaxed and sank weakly in his chair. He stated in reply to a question, “It is all over now. It was the same dream. Hold my hand carefully. I will tell you, but don’t make me dream it again.”

Edward began to tell his dream. A sudden terrible darkness had enveloped him, and the same awful power seized him. But this time it dragged him and yanked him and pulled him and twisted him and turned him and shoved him down a never-ending canyon. All the way there were earth slides and great boulders fell on him or knocked him hither and yon. He bumped from one side of the canyon to the other, and dirt filled his eyes and mouth, and great stones fell on his legs. Sometimes he was hauled up over a landslide only to be covered by a second landslide. And so on, and so on. Edward concluded his description, “It was just the same as the other dream except it was a canyon. That is all there is to it. Now let me rest.” I thanked him and waked him. Again he sat there—silent and attentive, but unresponsive. He would neither nod nor shake his head. I saw Edward on the next day. He responded only by averting his face. The following day he was again approached. Again he turned away. This continued for a week. It was also noted that the nurses’ records disclosed that Edward had not been having his periodic disturbed episodes. Then, 12 days later, Edward had his usual disturbed episode. When I approached him that afternoon, Edward did not turn his face away, but made no response to questions until he was asked if he were willing to go into a hypnotic trance. To this he nodded yes. The hypnotic state was induced in a couple of minutes. I asked, “Did those dreams help you?”

Edward said, “Yes. Those dreams are what happened on the ward, in the dormitory. They are just the same.” I asked, “Would you like to have another such dream?” He replied, “No,” reluctantly. I told him that his negative answer was not emphatic. It almost seemed

as if he wanted to say yes. He was asked to explain. He said, “Those dreams are awful, just awful. What happens on the ward is just awful. But after those first two dreams, nothing happened again. I know it will, but I don’t want it.” I asked, “Since those first two dreams were helpful, maybe another dream would give you a few days’ relief. Are you willing to try?” Fearfully, hesitantly, he finally said yes.

Again I explained to him, “I want you to have the same dream again, but with a different cast of characters. Not barbed wires or stabbing knives or huge boulders such as you had before. I want it to be the same dream with a different cast of characters. Will it be all right to start the dream in five minutes? I will hold your hand carefully.” Edward said weakly, “Yes.” This time I was very careful in taking hold of Edward’s fingers because I had experienced the forcefulness of his grip. About five minutes later he showed the behavior previously manifested. Again it lasted about 20 minutes. As he finally relaxed, breathing heavily, I asked him, “Can you tell me about the dream?” He said, “Yes.” “All right, tell me now.” Edward related a dream of being in “a jalopy” that was filled with broken glass. It was a big jalopy, and there were four people in it. He was one of the four. The others didn’t get hurt as the jalopy went down a mountain road with hairpin turns. It was falling down the mountainside, always landing on the road below. It was going at frightful speeds. He couldn’t see the people. He just knew they were awful people, and all that glass around him. It filled up that whole jalopy. He was in the glass on the seat. None of the glass touched the others, but each time the jalopy jumped, the glass hit him. It went on and on and on until, all of a sudden, the darkness stopped and the dream ended. I thanked Edward quietly, told him to awaken and feel as rested as he could. He awakened, but as usual he did not speak. When spoken to, he merely looked attentive. He was obviously fatigued, and his shirt was soaked with perspiration. There were no disturbed episodes for the next six days. On the seventh day Edward moved his chair up to the door which I customarily used to enter the ward. As I opened the door, Edward reached up with his hand, took my hand, and pulled me down into the chair beside him. I asked, “Do you want something, Edward?” Slowly he nodded yes. I asked, “Do you want to go into a trance?” After some moments he said softly, “Yes.” Thus, for the first time in over three years, he had voluntarily asked for help—thanks to hypnosis.

Excitedly, I hypnotized him again. The trance state developed very rapidly, and I asked Edward to “explain.” In essence his explanation was, “Those dreams are all the same. Just something different, but they mean the same. They scare me. They hurt me. They are awful. But when you make me have the dreams, I don’t have to have the dreams on the ward. But today I am going to—and I don’t want to. So maybe you had better have me dream.” (Development of first real insight.) Again, the laborious explanation was given. “Dream the same dream with the same meaning, the same emotional significance, but with a different cast of characters. This time maybe it won’t be so dark. Maybe you can see a bit more clearly. It won’t be pleasant, but maybe it won’t hurt so much. So go ahead as soon as you can and have your dream.” Within four minutes the dream developed; 20 minutes later, streaming with perspiration, Edward said, “It was the same dream. It was bad. It was awful bad. But it didn’t hurt so much. I was walking through a forest. The sky got blacker and blacker until I couldn’t see anything. Then the wind began blowing. I could hear the crashing of the lightning, but I couldn’t see it. There was thunder. The

wind would pick me up and throw me against the trees. I went crashing against the forest, on and on for miles. Just as the dream ended, I thought I saw a house. But I am not sure." (Beginning of identification.)

Edward was asked when he thought he would have the next dream. He replied, "Not this week. Maybe next week." I asked if he would let me know. He answered, "Every day walk past me. When I want the dream, I will take your hand." (Three long years and now trust in another person!) Edward was asked to relax, to feel as comfortable as possible, and then to awaken. Upon arousing from the trance state, Edward was asked if he would like to talk. He nodded affirmatively. When I repeated the question, he shook his head no. For the next 10 days I dutifully walked past Edward. It was not until the 11th day that he reached up and took my hand as before. The nurse's note showed that Edward had had no disturbed episodes. As I sat down on the chair beside him, Edward did not wait, but developed a trance immediately. I asked if he thought he was going to have a disturbed episode. He said, "Yes, one is coming soon. I want you to help me."

Again he was asked to dream the same dream, but to dream it with less pain, less discomfort, and to dream more clearly—to see the characters more plainly. His fingers tightened on my hand, and the dream developed immediately. The observed behavior was essentially the same. The duration was again about 20 minutes. His recovery from the dream was a bit more difficult. There was much shuddering, much gasping for breath. He fended me off with his hands. He was asked to explain. He said, "I was walking along a strange street. It was very shady. The sun wasn't very bright. I came to a hideous house. I knew I didn't want to go in, but something awful hit me on the back and knocked me inside. It was an awful room. Then something that looked like a woman hit me with something that looked like a great big broom. Then something that looked like a man seemed to jump on me. Then another woman kept hitting me with a red hot iron. I tried to get away. I ran from one room to another, but they always followed me. I couldn't get away. Finally I came to the last room. I couldn't see who these people were. They were huge; they were monsters. All of a sudden the sun shone and I was out in the street. Then I was here in the chair beside you." I asked, "Is there anything more you can tell me?" His answer was no. "But I know there is something awful dreadful that is coming up in my mind. I am awfully afraid. Will you come every day and speak to me?" I told him I would. Each day Edward met me at the door to the ward and walked with me on rounds. Questions I asked him were answered only by a nod or a shake of the head. There was no verbalization. On the fourth day Edward took me by the hand and led me to a chair. For the first time he spoke, saying loudly, "I want help right away! Now!" (After three years of inaccessibility, Edward, through hypnosis, could volunteer communication.) A spontaneous trance developed immediately. I told him again to dream the same dream with the same cast of characters, but this time to make the dream "nearer," "clearer," "more understandable, but not too understandable." It was explained to him that he was not to understand the importance of the dream, but only that the characters were to be clearer.

The usual dream sequence ensued. There was much less physical agony manifested. The perspiration was markedly decreased. Edward related his dream as follows: "Out of

somewhere, I don't know where, I was yanked into what seemed to be a hospital. There was a huge, awful, towering nurse, who was in charge. I was thrown into a bathtub. I was washed. They used steel brushes. They yanked me out. They dried me with towels made of ropes with knots in them. I was jerked here and there. Then another nurse, not as big as the first one, grabbed me by the hair and waved me around in the air and banged me on the floor, knocking me against the beds. Then she threw me in a great big bed right between two awful people. One of them seemed to be a woman. She was covered all over with awful sores, like cancers. She didn't seem to have any clothes on. Her teeth were awful. Her eyes were awful. Her fingers were claws. I tried to get away from her. The only way I could move was toward another person, who seemed to be a man. There were many terrible things about him. I don't know how terrible. I was afraid to look. They kept knocking me on the head to make me look. The man kept yelling at me. I couldn't get out of bed. I tried to explain it wasn't my fault. This went on and on. All of a sudden it ended. I was sitting beside you."

I asked if he wanted to remember this dream when awake. Edward said, "No, I just can't, I can't. Don't make me." I asked him when he thought he should have the next dream. In reply he asked, "Will the next dream tell me? But I am afraid to know." "If you want to," I answered. "Think it over for three or four days. Don't rush. Don't hurry. You and I can handle it. Really handle it." I asked him if he were ready to awaken. He answered, "Yes, but say something when I am awake, something nice." He aroused readily upon suggestion and said, "It seems to me that you are going to say something, but I don't know what." I replied very cautiously, "Do you know, Edward, you have come a long way. You are almost ready to be well. You are almost ready not to be afraid. You are almost ready to know something." Edward answered, "I don't know what you are talking about." He was assured that all was well.

Three days later Edward was found pacing the ward restlessly, with much tension. He seemed relieved at seeing me. As I approached, he said, "I think you had better do something for me today. I am awfully afraid, but I think you can do something for me. Something that has got to be done. I think I am ready." I led him to a quiet end of the ward and seated him. Immediately he developed a deep trance and spontaneously stated, "I think I am ready." I told him, "Well, since you think you are ready, have the same dream with the same cast of characters. But let them have a meaning that you can recognize, that you can accept, that won't scare you. I'll be here. If things get too bad, I can stop everything. I want everything to go ahead. But I'll stop things if you need them stopped." Instantly Edward stated, "All right. I am beginning a dream. I am beginning a dream. I am in the hospital. It is this hospital. There is a nurse. She is the head nurse. She looks awful mean. There is a patient. He looks like my father. He is the one in the corner bed on the west side. He looks like my father. The first time I saw him, I wanted to kill him. I wanted to kill the nurse. There is another nurse. She is nasty, too. She looks like my sister. They are taking care of a patient. That awful, great big patient. The head nurse and the other nurse are taking care of a patient. He is kicking. He is trying to get away. They are holding him tight. They put him in bed. They tell him to stay there. That patient is awful afraid. That's funny. That patient is me. I look awful scared. That big patient looks just like my father. The head nurse looks just like my sister. I know what it is all

about. I can tell you now. But I wish you would wake my up and let me tell you, because I will be able to listen when I tell you. Wake me up now, right now."

He was awakened. He was tremulous. There was a rush of words. "It is this way, Doctor. My father and mother and sister came from a foreign country. Everybody respected my father there. Everybody respected my mother, my sister. They were big shots. They came here to America. Then it all happened. Everybody made him a dumb foreigner. That is all he was—a dumb foreigner. I was born here and learned to speak English. Everybody made fun of my father. They laughed at my mother. They laughed at my sister. They even laughed when I spoke. Then my family would get mad at me and beat me up. They took it all out on me. That is why I never had any friends. They would call me `that dumb foreign kid.' But I wasn't dumb. I couldn't have friends. I went to grade school, and they all called me the dumb foreigner. I studied hard, but I couldn't be friends. Every day my father would get drunk. He worked in a factory. Sometimes he wouldn't work. We were on welfare. Then he got a job, and I went to high school. It didn't do me any good. Every time I came home they'd drag me all around calling me a dumb immigrant. They talked about me. They made fun of me. They said I thought I was smart because I could talk English. They yelled and they screamed at me. My father would knock me down. My mother would hit me with anything. My sister was a big woman. She yelled and screamed that she couldn't get married. Every day it went on. I kept studying by myself. Then, when I got through high school, I went to get a job. When I gave my name, they said I was foreign, just like my father. Nothing I could do changed it. I got shoved around at the factory where I worked. I wanted to make friends. I wanted a girl. But everybody knew my name. I was a dumb foreigner. Things kept getting blacker and blacker. Then, all of a sudden, they got awful black. That is what my first dream was about. I was dragged through everything—every insult, every hurt, everything mean, because I was born in America. I wasn't really a foreigner. I was an American. That was what all my dreams were about. That canyon. That's the immigrant section of the city. Why weren't former nationalities forgotten? All the old folks hate it. They don't like being dumb immigrants. Those people in that awful jalopy going down the mountain road. Once we took our secondhand car and drove out in the country. All the time my father was calling me a dumb foreign kid just born in America. My mother and sister were saying it, too. I thought the ride would never come to an end. They said it was a picnic. I got my mother mixed up with the head nurse. That patient was my father. For years I wanted to commit suicide. I have been afraid because I wanted to live. I couldn't stand being alive. I can keep on telling you all these things, Doctor, because you are the first one who I have ever told anything. Some way you made it possible to talk to you. I never could tell anybody. Now I want to talk to you all about this. I am an American. I don't care about what my mother does or what my sister does. I just want to be an American. I tried to be like them and I couldn't. I tried to be the way I wanted to be, and now I know. I can be me."
Within two months, after almost daily discussions of the matter, Edward decided to change his name. He secured his father's permission to shorten his name. He discussed his emotional reaction to his parents, to his sister. He felt sorry for them. He felt helpless so far as they were concerned, but he knew he could help himself.

The years have passed. Edward never needed to return to a mental hospital. He made a good adjustment. He married an American girl of similar foreign extraction. He feels sorry for his father who drank himself to death, for his mother who died eventually of cancer, for his sister who despairingly committed suicide. Edward regrets all this. He is proud of his children. Through hypnosis Edward learned the thing so vital in human living—how to communicate.

Ann R.

Ann, 21, entered the office hesitantly, fearfully. She had been hesitant and fearful over the telephone. She expressed an absolute certainty over the telephone that I would not like to see her. Accordingly, she was urged to come. As she entered the office, she said, "I told you so. I will go now. My father is dead, my mother is dead, my sister is dead, and that is all that's left for me." She was urged to take a seat, and after some rapid thinking I realized that the only possible understanding this girl had of intercommunication was that of unkindness and brutality. Hence, brutality would be used to convince her of sincerity. Any other possible approach, any kindness, would be misinterpreted. She could not possibly believe courteous language. I realized that rapport would have to be established—and established very quickly. She would have to be convinced, beyond a doubt, that I understood and recognized her and her problem and was not afraid to speak openly, freely, unemotionally, but truthfully.

Her history was briefly taken. Then she was asked the two important questions. "How tall are you and how much do you weigh?" With a look of extreme emotional distress she answered, "I am 4 feet 10 inches. I weigh between 250 and 260 pounds. I am just a plain, fat slob. Nobody would ever look at me except with disgust."

This offered a suitable opening. She was told, "You haven't really told the truth. I am going to say this simply so that you will know about yourself and understand that I know about you. Then you will believe, really believe, what I have to say to you. You are not a plain, fat, disgusting slob. You are the fattest, homeliest, most disgustingly horrible bucket of lard I have ever seen, and it is appalling to have to look at you. You have gone through high school. You know some of the facts of life. Yet here you are, 4 feet 10 inches tall, weighing between 250 and 260 pounds. You have got the homeliest face I have ever seen. Your nose was just mashed onto your face. Your teeth are crooked. Your lower jaw doesn't fit your upper jaw. Your face is too damned spread out. Your forehead is too hideously low. Your hair is not even decently combed. And that dress you are wearing polka dots, millions and billions of them. You have no taste, even in clothes. Your feet slop over the edges of your shoes. To put it simply—you are a hideous mess. But you do need help. I think you know now that I won't hesitate to tell you the truth. You need to know the truth about yourself before you can ever learn the things necessary to help yourself. But I don't think you can take it. Why did you come to see me?"

She answered, "I thought maybe you could hypnotize me so I could lose some weight." I answered her with, "Maybe you can learn to go into a hypnotic trance. You are bright enough to graduate from high school. Maybe you are bright enough to learn how to go

into hypnosis. I would like to have you go into hypnosis. It's an opportunity to say a few more uncomplimentary things to you. Things I don't think you could possibly stand to hear when you are awake. But in the trance state you can listen to me. You can understand. You can do something. Not too darn much, because you are horribly handicapped. But I want you to do everything I tell you to do because the way you have gobbled up food to make yourself look like an overstuffed garbage pail indicates that you need to learn something so you won't be so offensive to the human eye. Now that you know that I can tell you the truth, just close your eyes and go deeply into a trance. Don't fool around about it, just as you don't fool around in making yourself a disgusting eyesore. Go into a completely deep, hypnotic trance. You will think nothing, see nothing, feel nothing, do nothing, hear nothing except my voice. You will understand what I say—and be glad that I am willing to talk to you. There is a lot of truth I want to tell you. You couldn't face it in the waking state. So sleep deeply in a deep hypnotic trance. Hear nothing except my voice, see nothing, think nothing except what I tell you to do. Just be a helpless automaton. Now, are you doing that? Nod your head yes and do exactly as I tell you, because you know I'll tell you the truth. The first thing I am going to do is to get you—rather order you—to tell me certain facts about yourself. You can talk even though you are in a deep trance. Answer each question simply but informatively."

"What is important about your father?" Her answer was, "He hated me. He was a drunk. We lived on welfare. He used to kick me around. That's all I ever remember about my father. Drunk, slapping me, kicking me, hating me."

"And your mother?" "She was the same, but she died first. She hated me worse than my father did. She treated me worse than he did. They only sent me to high school because they knew I hated high school. All I could do at high school was study. They made me live in the garage with my sister. She was born defective. She was short and fat. She had her bladder on the outside of her body. She was always sick. She had kidney disease. We loved each other. We only had each other to love. When she died of a kidney disease, they said, `Good.' They wouldn't let me go to the funeral. They just buried the only thing I loved. I was a freshman in high school. The next year my mother drank herself to death. Then my father married a woman worse than my mother. She didn't let me go in the house. She would bring slop out to the garage and make me eat it. Said I could eat myself to death. I would be good riddance. She was a drunk like my mother. The social worker didn't like me, either, but she did send for some medical examinations. The doctors didn't like to touch me. Now my stepmother and my sister were all dead. Welfare told me to get a job. I got a job scrubbing floors. The men make fun of me there. They offer each other money to have sex relations with me, but nobody will. I am just not, good for anything. But I would like to live. I have got a place where I live. It is an old shack. I don't earn much—eat corn meal mush and potatoes and things like that. I thought maybe you could hypnotize me and do something for me. But I guess it isn't any use."

In a most unsympathetic, peremptory fashion she was asked, "Do you know what a library is? I want you to go to the library and take out books on anthropology. I want you to look at all the hideous kinds of women men will marry. There are pictures of them in books in the library. Primitive savages will marry things that look worse than you. Look

through book after book and be curious, horribly curious. Then read books that tell about how women and men disfigure themselves, tattoo themselves, mutilate themselves to look even more horrible. Spend every hour you can at the library. Do it well and come back in two weeks."

Ann was awakened from her trance with this posthypnotic suggestion and left the office in the same cringing fashion as she had entered it. Two weeks later she returned. She was told to waste no time—to go into a trance, a deep one, immediately. She was asked if she found some pictures unpleasant to her. She spoke of finding pictures of the steatopygous women of the Hottentots, and of duckbilled women, and giraffe-necked women, of keloid scarification in some African tribes, of strange rituals of disfigurement. She was then instructed to go to the corner of the busiest section of the city (in a waking state) and there watch the peculiar shapes and faces of the things that men marry. She was to do this for one whole week, and then the next week she was to look at the peculiar faces and peculiar shapes of the things that women will marry, and to do this wonderingly.

She obediently returned, went into a trance and stated with simple wonderment that she had actually seen women almost as homely as she was who wore weddings rings. She had seen men and women who seemed to be man and wife, both of whom were hideously fat and clumsy. She was told that she was beginning to learn something.

Her next assignment was going to the library to go through all the books she could on the history of cosmetology—to discover what constituted desirable beauty to the human eye.

Ann made a thorough search and entered the office without cringing, but still clad in her polka dot dress.

Her next assignment was to go to the library and look through books dealing with human customs, dress, and appearance—to find something depicted that was at least 500 years old and still looked pretty. Ann returned, developed a trance immediately upon entering the office, sat down, and spoke eagerly, relating what she had seen in books. She was then told that her next assignment would be very hard. For two weeks she was to go first to one women's apparel store and then another, wearing her frightful polka dot dress. She was to ask what she really ought to wear—to ask so earnestly and so honestly that the clerks would answer her. She reported after this assignment that a number of elderly women had called her "dearie" and explained to her why she should not wear millions and millions of polka dots. They told her why she should not wear dresses that Were unbecoming—that served to exaggerate her hideous fatness. The next assignment was to spend two weeks in obsessive thinking: Why should she, who must have been born weighing less than 20 pounds, have added such enormous poundage? Why had she wrapped herself up in blubber? From that assignment she reported she couldn't reach any conclusions.

Again, in the trance state, she was given another assignment. This time to discover if there were really any reason why she had to weigh what she did ... to be curious about what she might look like if she weighed only 150 pounds and were dressed appropriately

... to awaken in the middle of the night with that question in mind, only to fall asleep again restfully. After a few more trances in which she reviewed all her assignments, she was asked to recall, one by one, each of her assignments and to see whether they applied to her.

Ann was seen in two-week intervals. Within six months she came in, with great interest, to explain that she could not find any reason why she should weigh so much—or why she should dress so atrociously. She had read enough on cosmetology, on hair dressing, and makeup. She had read books on plastic surgery, on orthodontia. She asked piteously, in the waking state, if she could be permitted to see what she could do about herself. Within another year's time Ann weighed 150 pounds. Her taste in clothes was excellent. Ann had a much better job. She was enrolling in the university. By the time she graduated from the university, even though she still weighed 140 pounds, she was engaged to be married. She had had two teeth that had developed outside of the dental alignment removed and replaced. Her smile was actually attractive. Ann had a job in dress designing as a fashion artist for catalogs and newspapers. She brought her fiancé to meet me. She came into the office first and said: "The darn fool is so stupid. He thinks I'm pretty. But I am never going to disillusion him. He's got stars in his eyes when he looks at me. But both you and I know the truth. I have difficulty in keeping below 154 pounds and I am afraid I am going to reach more. But I actually know that he loves me this way. You will find Dick the handsomest man in the state."

She brought Dick into the office and winked at me. Then she left. As the door closed behind her, Dick turned to me and said, "Isn't she just a beautiful dream?" The writer agreed as he looked at "the handsomest man in the state." He was fully as homely as Ann—manly more so. His features had been thrown together—but did not seem to fit together. Yet Ann truly thought he was the handsomest man in the state—even the nation.

They have been married for 15 years. They have three handsome children, two boys and a girl. This writer has looked the children over. They show every promise of growing up to be physically attractive in every way. Dick still thinks that Ann is a beautiful dream. Ann winks at me with amusement as she states, "That handsome fellow actually thinks I'm pretty." Economically they are successful. Socially they are successful. Ann talks freely of her therapy since she remembers everything that was said to her. She has stated more than once, "When you said those awful things about me, you were so truthful. I knew that you were telling me the truth, that I could trust you. I am so glad you told me the truth. But if you hadn't put me in a trance, I wouldn't have done any of the things you made me do. I just wonder—how did Dick grow up? His parents must have praised and flattered him. Yet, being handsome, it hasn't affected him in any way."

To know how to communicate with patients is all-important in medicine, in all branches of life. Semantics are important, but communication is basic. Hypnosis needs to be recognized as a science of intercommunication.

Sandra W.

Having first telephoned for an appointment, this rather beautiful 38-year-old woman entered the office and asked, “Do you use hypnosis?” She was answered, “If I find it necessary and helpful.” She proceeded to take a seat and explained, “I think it is necessary in this case. Most people won’t believe this, but I am sure you will. I am troubled by nude young men that float in the air just above my head. See them up there next to the ceiling? Wherever I go they follow me. No matter what street I walk on, they are always in the air just above me. They never do anything. They just float.

“Now there is a second thing I want you to do. Quite often I like to float up into the sky and travel around the world on a cloud. Some people think I am just sitting quietly in a chair. Actually, I am up on a cloud floating around the world. Sometimes, instead of doing that, I go down to the bottom of the Pacific Ocean, where I have a beautiful castle made of glass. I spend a day or two, sometimes even a week, there. It’s so lovely to look out at the fish that are swimming all around my castle. I cannot tell these things to people. They don’t understand. They call me crazy. My ex-husband got a divorce because he wanted to put me in the State Hospital. I don’t want to go there because I am able to work and support myself. I just don’t want to have people interfering with me. Now, if you use hypnosis, can you do something about those nude young men? And can you protect me from criticism when I go down to the bottom of the Pacific ... or when I float around the world on a cloud?

“By the way, Doctor, are you sure you are ethical? I notice that over there in that corner of the office you have a half-dozen nude dancing girls. I don’t want my young men to associate with them. It wouldn’t be moral. So would you keep control over your nude young women? I hope that all you do is let them dance for you.”

This was the introductory meeting with a young woman who suffered from schizophrenia, catatonic type. She was working as a secretary for a real-estate firm for the summer and handling her work most satisfactorily.

“I’ve been married twice, but I didn’t tell either of my husbands about the nude young men or of going around the world or to the bottom of the ocean. After we were married I told them about everything. George was so mad about it he beat me up something terrible. Bill just acted plain awful. He called in some psychiatrist. They said I was psychotic and they wanted to commit me to the State Hospital. They took me to court for a hearing. I figured that the fuss must be about those nude young men ... and taking trips around the world ... and my castle on the bottom of the ocean that disturbed Bill so often. So I just flatly denied all those things and I wasn’t committed. Bill got a divorce.

“I have been teaching school regularly during the school year and always take a secretarial job during the summers. I have only been married twice so far. But neither of my husbands seemed to understand. It is awful worrisome teaching school—keeping the children’s attention so that they won’t notice those young men. It is so embarrassing when I take a bath, but I have gotten used to it. They won’t even let me go to the bathroom alone. So I always wait until night, and then I don’t turn on the light.

"One summer I told my employer about the nude young men. The next day I was fired and he gave me a check for two weeks. I never could understand that. He seemed to be such a sensible man." I came to you for help. What I want you to do is to hypnotize me. I don't want to be troubled by these nude young men. They are mine as those nude dancing girls are yours. I want to keep right on making my trips around the world. But lately I have been staying in my apartment for as much as week at a time—to take a trip around the world on the cloud or go down to the bottom of the Pacific and spend time in my castle. I want you to change things hypnotically. Don't take away my young men. Don't stop me from going around the world. Don't stop me from going down to the Pacific. Just see to it that I keep these things, but don't let them interfere with my everyday life. Now I am ready to go into a trance."

Indeed the patient was. In less than five minutes she gave every evidence of being in a profound somnambulistic trance. She was asked to remain in the trance and to talk freely. Her statement was rather peculiar. She said, "That poor girl that is really me is just plain psychotic, but she doesn't know it. She is hallucinating. She is going to the library and she has read up on catatonic schizophrenia. She is really afraid. She is covering up with you. She does not even know how afraid she is. Don't you ever let her find out how afraid she is because she might do something awful. Sometimes she has thought of suicide. Several times she has taken an overdose of sleeping pills. She just doesn't have anybody she can confide in. She thinks maybe you are all right, and will you be awfully kind to her? And you won't think bad about her because, even though she is psychotic, she is normal. Now and then she goes to bed with men, even if she isn't married to them. She wouldn't want you to know that. There are a lot of things she doesn't want you to know about her until she trusts you completely. You will have to do something about those nude young men. She is giving too much time to them. She is taking too much time to travel around the world ... too much time to go down to her castle at the bottom of the ocean. She really enjoys and believes that the castle and the trip around the world exist. She enjoys looking down at Hong Kong and other cities. Do you think you can do anything for her?"

The somnambulistic patient was assured that, with her help, something could be done for "this psychotic girl. She is really me, you know." Instructions were offered. She listened carefully.

Slowly and systematically an explanation was given her of dreams. Normal dreams that everybody has, in which one dreams of falling off a mountainside. Falling and falling and falling forever, it seems. Finally, after what seems to be hours of falling, you hit bottom and wake to discover that you have only fallen out of bed. Yet, it seems as if one has been falling for days and weeks and months and years. It was suggested that she employ this same normal mechanism of behavior and, at any time, climb onto a cloud and feel herself floating gently around the world. She was to feel as if it were taking days and weeks and even months, maybe even years. Yet in actual clock time this will be accomplished in a minute or two or three. She smiled very happily and asked—couldn't she do that in her trips to the bottom of the sea, too? She was told she could even stay

three months and the clock on her kitchen shelf would only show that she had been gone a minute.

Ready agreement was expressed, and the somnambulistic patient said that this arrangement could prove most satisfactory. But she asked most gently about the nude young men. The writer explained that he had a rather large closet attached to his office and that he could let the young men float in there. They could remain in the closet and that any time, night or day, she would be at liberty to come to the writer's house (the office is in the writer's home) and look in the closet to see if they were still there.

The patient continued to teach school for several years, and was a most competent teacher. At first, at least twice a week, she would drop in the writer's office and ask if she could look in the closet. She was always satisfied. The frequency of these visits decreased. Finally she was making them only once in three months. Then once in six months. Then approximately once a year. During this period of time she made many trips around the world on the cloud. She took great pride in being able to make a three-month trip in three minutes' time ... in being able to stay months in her castle at the bottom of the Pacific in only three minutes of kitchen-clock time. After about three years the patient began having difficulties and sought further help. She explained openly that she was having "psychotic episodes." These "episodes" she "reserved" for the weekend, but they were becoming rather difficult. She wanted to know what she could do about them. She explained further that she did not see how she could put them in the closet with the nude young men. They might become disturbed. She didn't know if these episodes would disturb her in her teaching and in her summer work as a secretary. They might also disturb her employers and other people. She was asked what she thought she ought to do. Her statement was rather simple. "I think I think better and more clearly when you put me in a trance." Accordingly a trance was induced. In the state of somnambulism she said, "The poor thing, she is really having psychotic episodes. They are most distressing. She hasn't really told you the truth. She had to pretend she had a headache and get an excuse from teaching. She has missed more than the allowable number of sick leave days. She really has to do something about it. Last summer she lost two jobs as a secretary. You thought of putting her young men in the closet. Why don't you think of somewhere to put her psychotic episodes?"

The question was asked, "Could she put them in a manila envelope? Let them do whatever they want to do in the envelope and therefore not interfere with her. She could go by the office and leave the envelope for placement in the files." The patient thoughtfully considered this and asked, "Can you tell me [the next time she has a psychotic episode] to go into a hypnotic trance and put the psychotic episode in an envelope and bring it to you?" An agreement to this effect was reached.

The next week the patient appeared most unexpectedly, obviously in a somnambulistic state. "Here's the envelope. Don't open it. It is sealed carefully. The psychotic trance is in there. Put it in your filing cabinet. She will come by later and ask to see it." A few days later the patient appeared in the office and said, "I believe you have something of mine, but I don't know what it is." The sealed manila envelope was taken out of the files. She

said, “So that is where my psychotic episodes went. You know, I think that is a good idea.” For 15 years the writer has been receiving in the mail envelopes containing “psychotic episodes.”

The patient is now living in a city 1,000 miles away. During one disturbing episode she took a sick leave and came to see the writer. She demanded to see the envelopes containing her “psychotic episodes.” They were carefully taken out of the file, one by one, and shown to her. Before this task could be completed, she said, “Now I know I can trust you. Couldn’t completely before. You don’t have to take out the others. Now I can feel comfortable sending them to you.”

At present the patient is gainfully employed and has a civil service position. She will soon be eligible for pension. She has been married eight times and has been self-supporting, but she has never been able to establish a savings account. She was last seen two years ago. She looked at least 15 years younger than her age. She felt free to tell the writer that there was a period of time when she became addicted to alcohol, joined Alcoholics Anonymous, and overcame the problem.

Hypnosis is not a cure. Neither is insulin in diabetes. This writer has used hypnosis on more than one psychotic patient to keep him a productive citizen. The above case history illustrates the value of intercommunication between people to establish good purposes. All of her marriages were brief, psychotic in character. She is not a mental hospital patient. She is a successful civil service worker—not a burden on society. How many more mentally ill patients, hopelessly sick, might be economically rehabilitated if physicians understood hypnosis as a modality of communication of ideas, understandings, and useful unrealized self-knowledge contained in what is popularly called the unconscious?

Only by hypnosis could this patient be approached and contact indefinitely prolonged.

HYPNOSIS TODAY — A TREND

Until very, recently the study of hypnosis had been restricted to its external phenomena. Now it is realized that it is useless to continue to study hypnosis merely for itself alone. It is the association between the psychological aspects and the physical manifestations that now call for investigation. Today’s developments are born of the realization that hypnosis opens the door to a more searching interest of how the person in his body behaves and reacts.

One need only study the mentally ill to note phenomenal changes not understandable by ordinary medical and psychological reasoning. By hypnosis one can so alter a person’s consciousness of his environment that, in his reactions, he can call upon past experiences and learnings to utilize and accomplish equally phenomenal changes. How does a woman have an anesthetic childbirth by the spoken word? How does a man with hemophilia have, bloodless dental extractions without medication? We need to understand the secrets of this sort of thing if we are to understand, psychologically, both health and illness.

The Fourth World Congress of Psychiatry held in September, 1966, in Madrid, disclosed a significant development of scientific interest in hypnosis at the complex physiological level. There was dissension about the ultimate question—why does the unwilling patient heal slowly? And the opposite question—how can this intrinsic force which delays healing be reversed in order to alter the unwilling patient psychologically so that he can heal more rapidly?

Thus today the trends in hypnosis center around a scientific understanding of the functioning of the human body, the forces that influence it, the means by which it can be influenced. Hypnosis can be used to elicit the learnings acquired by the human body, but unrealized by the person. Pain and stress are two of the greatest medicinal problems in their many aspects. These need to be dissected, analyzed, and studied. Mental disease is the breaking down of communication between people. Hypnosis permits a development of communication.

In laboratories of psychology departments, the physiological laboratories, the dental schools, and even in the everyday practice of medicine much is being learned about how to talk to people, to understand them. Any statesman can tell us that most of the world's troubles derive from a lack of intercommunication. So it is with matters of human illness and health. Hypnosis is not a simple matter. It is another important tool in exploring human behavior from a new and different approach a tool that will lead to a definition of the still undefined "personality" and allow us to learn how the human body reacts to stimuli. Stimuli can then be given to take advantage of existing, but unrealized, body learnings.

Hypnotic Approaches to Therapy

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, July, 1977, 20, 1, 20-35

I did bring several typewritten papers with me to read on "Approaches," but I also brought some notes that I think it might be better to talk from.

The first item that I want to mention concerns my demonstration this morning. I requested my subject's permission to say these things. I met her Wednesday—she came over and spoke to me. I've watched her and reached the conclusion that she has a tremendous number of conflicts. She has given me permission to tell you that. When she came up, the remarkable thing was her absolute honesty in telling me that she would resist. Therefore, it became a problem not of trying to force anything upon her but of trying to utilize her resistances and to adapt them in such a fashion that she could accomplish something, so that the members of the conference could obtain information on methods. After induction procedures the subject showed catalepsy of the left arm. In other words, she could yield on one point, but she'd be damned if she'd yield on the other! It was beautifully done on her part, and I think it was a most marvelous thing on her part. Another phenomenon—Dr. Pattie mentioned it to me—was that when she was asked a question, she would nod her head and keep nodding her head long after it was necessary. She didn't know that, but the rest of you knew it. She was not really aware of it. Her answer was that she wasn't really in a trance, but I think some of you realize that she was definitely out of contact with the audience on a number of occasions. She just didn't know you people were here. This was no reflection upon your impressiveness, but just an indication of her ability to forget all about you.

All this is an introduction to one important thing, and I think it is paramount in any approach to hypnotic therapy. That is that one must always protect the subject or the patient. The patient does not come to you just because you are a therapist. The patient comes to be protected or helped in some regard. But the personality is very vital to the person, and he doesn't want you to do too much, he does not want you to do it too suddenly. You've got to do it slowly, you've got to do it gradually, and you've got to do it in the order in which he can assimilate it. A certain number of calories of food per day are necessary, but don't cram them all down at breakfast; if you do, you'll have a stomachache. You spread them out and you don't cram them all down in one mouthful. You take a number of mouthfuls. It's the same way with psychotherapy, as any analytically trained person will tell you. You go into some matters slowly, easily, and gently. In the matter of hypnotic psychotherapy you approach everything as slowly and as rapidly as the patient can endure the material. You don't do it by a drastic, driving technique because that can be rejected. The slow approach enables the patient to recognize there is value in this idea, there is value in that idea, and that's what you want

him to do: to recognize that there is value in this idea and that is value in that idea. Furthermore, you therapists really don't know what the problems are, and it is your job to find out. The patient doesn't consciously know what the problems are, no matter how good a story he tells you, because that's a conscious story. What are the unconscious factors? You want to deal with the unconscious mind, bring about therapy at that level, and then to translate it to the conscious mind.

I think an experiment that I did in antisocial behavior illustrates the need of that approach. I took two secretaries and had them each in a deep trance, and I told them separately an utterly malicious and false story about a third secretary. The third secretary knew that 1 was going to do it and consented to it. I told each of the two girls that utterly malicious, false story, and a couple of days later Secretary A came to me—they both avoided the third girl—and told me she had a very bad headache. In fact, she'd had it since the last hypnotic session with me, and would I please do something about it. I took her in my office, put her in a trance, and she recalled that malicious story. She then gave me her very frank opinion of anybody that would tell such a malicious story about C. She really handed it to me, and it was necessary for me, in self-protection, to call in some of my collaborators and produce the typewritten protocols of the experiment to prove to her that it was an experiment. That was all in a trance state. Then I awakened her, and she promptly recalled a full recollection of the malicious story and she really gave me a nice bawling out—a second one, because my explanation had not yet seeped through. It was necessary again for me to call in my collaborators and bring out the protocols and explain the experiment all over to her conscious mind, so that she knew it at both levels.

Thus, one tries to do hypnotherapy at an unconscious level but to give the patient an opportunity to transfer that understanding and insight to the conscious mind as far as it is needed.

The second girl told me she had had a headache ever since the last time I had hypnotized her, and wouldn't I do something. So I gave her some aspirin and told her it would fix her up. About an hour later she came into the office and told me what sort of a liar I was. It was rather difficult together to consent to see the protocol of the experiment, and she cussed out my collaborators thoroughly too. After I had convinced her in the conscious state, I had to put her in a trance and go through all the whole ordeal with her a second time, because she needed to know it at both a conscious and an unconscious level. It was also necessary to call in the third girl about whom the story had been told to convince both of those girls that it was a put-up job, and she had to tell them both in the conscious state and in the unconscious state.

In therapeutic approaches, how does one protect a subject? I had one extremely bitter experience. I had a nice experimental subject that I was working with and I wanted her to do some hallucinating. I told her to see the loveliest thing she ever saw in her life. I thought that was a safe suggestion, and I gave her a mirror in which to hallucinate the loveliest thing she ever saw in her life. I learned a very drastic lesson. What was the loveliest thing she ever saw in her life. Her mother had been killed in an automobile accident, and she saw the mother's face in repose in the coffin. She burst into tears, and I

lost rapport with her. It took me three weeks to regain that girl's confidence and trust. She was an excellent experimental subject. I learned that when you give suggestions, therapeutically or experimentally, you try to give them in a way that is going to permit the patient or the subject to handle them in a fashion that does not arouse too much difficulty.

In therapeutic approaches one must always take into consideration the actual personality of the individual. One must give thought as to how they express their behavior. Are they overfriendly, hostile, defiant, extroverted, introverted, so on? One must modify his own behavior—that is, the therapist actually must be fairly fluid in his behavior, because if he is rigid he is going to elicit certain types of rigid behavior in the patient. In turn, the patient's rigid behavior is unfamiliar to him, and he is not going to be able to handle him properly. Therefore, the more fluidity in the hypnotherapist, the more easily you can actually approach the patient.

I think perhaps the best way to continue is to give my thoughts as they come to me, and not try to follow a rigid outline.

Who is the important person in a therapeutic situation? Is it the therapist? I really don't think the therapist is important at all. I don't think that the hypnotist is important in the experimental situation. I think he is part of the apparatus, and nothing more. I think the apparatus should be in well-ordered condition, run properly, and so on, but I don't think that any experiment is possible where you have only apparatus. You need a subject in therapy. I don't think the therapist is *the* important person; I think the patient is *the* important person in the situation. I think, too, that the patient should be given the opportunity to dominate in any way, whether it is by complete subservience or by complete dominance of the situation. It is this that the patient comes in for, not to have the therapist take charge, but to give the therapist an opportunity of doing something, and doing something in accord with the needs of the patient, not in accord with the needs of the therapist. I disagree with a lot of therapists who think that they should sit up straight behind a couch, and take notes, and more or less direct this thought and that thought, because that is just their understanding and it is the patient's needs that should be met. Now, this is not intended as a criticism of psychoanalysis, because it is extremely valuable.

Recently I had an experience in experimental therapeutic procedure that I want to cite. It's not published; in fact, all of this material that I am going to give is unpublished. It concerns this problem of amnesia that was mentioned—the John Does. How often are these amnesia victims really amnesic? How often are they neurotics who are having their amnesia serve as a recognizable purpose?

A patient that I know was picked up by the police in Phoenix. They attempted to ascertain her identity and her age. I happened to be one of the psychiatrists called. She gave the year as 1934, and she thought the calendar on the wall was wrong. Moreover, she knew she was not in Phoenix because she knew that was not possible: she had never been in Arizona. The real truth was, of course, that she had been in Arizona for several

years; and certainly it wasn't 1934, it was 1952. She was afraid of everybody, so my wife went with me as a reassuring person. The question was, how would you really handle that amnesia?

All of us have heard about age regression. Obviously, there had been a spontaneous age regression; and a few questions here indicated a definite age regression—a spontaneous one—in which the amnesia was very definite. She took a violent dislike to me because I carried a cane, and she took a violent dislike to me also because I wore a moustache. When the police officer introduced me to her as Dr. Erickson, she took a violent dislike. I asked him to repeat my name until he wondered who was the patient, because I wanted to know what the situation was. I soon found out that it was the first part of my name—not Erickson, but Erickson—to which she objected. So there must have been an Eric somewhere. Where did the cane come in—the fear reactions, the trembling, the perspiration, the involuntary responses she showed to a cane?

I took her to my office and puzzled over this question. What can you do for a genuine amnesia? She was back in 1934, and then I hit upon the very happy idea: why not reverse the process? I pointed to the wall and told her "There's a calendar there, and I think if you look real hard you'll see a calendar that reads 1934." I wanted to put myself into that amnesia pattern, and it wasn't long before I had her seeing a calendar of 1934. Then we watched the leaves of that calendar torn off, the way they do in the movies, one by one, and the years change. And it wasn't April, 1934, it was May, 1934, then June, then July; and then '35, '36, '38. I slowly, gradually, systematically, brought her up to November 1951, and the event of her amnesia.

Some time later she developed another amnesia. It was 1943, and I used the same technique to bring her up to 1952. She became my patient and I learned a great deal about her history. She had had a tremendous number of traumatic experiences in 1934. I know who Eric was. He wore a moustache, had gray hair, and carried a cane. And she had good reason to fear anybody with gray hair who wore a moustache and a cane, and who had those syllables of Eric in his name.

That reversal of regression technique I have tried on experimental subjects many times without realizing its therapeutic situations with patients who suddenly get the needle stuck in a certain year and just can't get away from those events, keep repeating them in an obsessional, compulsive fashion. In such cases you systematically reorient them—a day, a week, a month at a time—until they come to the present age. And what happens? They know something about the control of obsessional, compulsive behavior.

In this same connection there is another exceedingly unpleasant experience that I had therapeutically. This patient came into my office. She had been my patient for some time, and I thought I was making excellent progress with her. That day she was wearing a brand-new dress and she said to me, "Doctor, would you like to have me model my dress for you?" She modeled it very nicely, and then she said, "You know, I'd really like to tell you about a dream I had." So I said, "Go ahead."

She sat down comfortably to tell me the dream, when a look of horror came over her face. She lost all contact with me, and I had to rush to the door to keep her from dashing out and dashing downtown until at least I could understand what was going on. My original diagnosis of her was acute paranoid schizophrenia, and she certainly looked and acted then like a paranoid schizophrenic. I had hypnotized her previously and made use of physical signs—lifting the arms, inducing catalepsy—because usually, with a therapeutic patient, where I use hypnosis I bring about some physical condition so that I can always get in contact. I finally managed to get close enough to her to get hold of her wrist and gently lift it so that she would go into a trance. She was, however, in one of those mute and unresponsive trances.

It took me about four hours, very painful hours, to find out how to handle that apparently deep paranoid episode. I finally hit upon this idea: She didn't like something, she wanted to escape from something. That something had happened at such-and-such an hour—four o'clock, on Tuesday, June 5th, and then of course it wouldn't have happened. And what was it that happened? Well, since it was before June 5th at four o'clock, nothing had happened—in other words, an absolute denial of everything. So I carried her back to May and reestablished relationships with her at the May level. She was friendly, agreeable; then I asked her what she thought about the possibilities of next month. We talked about the possibilities of next month, how she would feel about it, and what possible material might come forth next month. We speculated more and more; and as soon as I tried to approach Tuesday she started getting rigid, her face seemed molded, and so on.

It took four hours, as I have said, before I got her willing to admit the fact that on Tuesday, June 5th, at four o'clock she would come into my office and model a dress for me and then suggest the topic of dreams. The dream happened to be an incestuous dream, and she just couldn't tolerate it. By retiring her to May and then tracing up to June, it was possible to handle it. It was exceedingly slow, painful, and laborious, but the patient needed to get over it and to get an understanding of it.

Another patient was presented to me under rather difficult circumstances. Some people with a psychoanalytically oriented background came to me and said they thought hypnotherapy was without value, and they challenged me to give a demonstration of hypnotherapy. I told them I would be glad to do it and that we probably all would learn something. They said they would select a patient for me. Let's call him Harvey. I took one look at Harvey. He certainly was his mama's dishrag if ever there was one—colorless, coatless, discouraged. I found out that he had been under the treatment of another psychiatrist for a couple of years. He had a pain here—and then he had a pain here—and then he had another pain here.... He was wonderful—as a pathological specimen. But when you talked to Harvey, you wondered if underneath all of that there wasn't a nice guy.

I took Harvey into the seminar room and put him in a trance. He very willingly, very gradually went into a trance. He would do anything to please an authoritative figure. With him you could use the direct, forceful, hypnotic technique. One of the things I found out from his psychiatrist was that Harvey worked in an office doing clerical work far below

his ability. He was usually sick about once a month and lost a day's work, and had a feeling of being unhappy in his work. One of the reasons was this: There was a pile of ashes outside his office, and there was a black man who came to carry away those ashes who was very resentful of white people. He would come into the office, open the window, and he would then shovel the ashes so that, when the wind was right, the ashes blew into the office. Poor Harvey would sit cowering at his desk and wish he could tell off that black man, who was only about 18 inches taller than Harvey and much more muscular.

Even though Harvey worked at a desk, he couldn't write his name legibly. The other psychiatrist had tried to get him to do that over and over again, but Harvey just couldn't write his name legibly. This poses the question as to where one starts in therapy. My feeling was that with Harvey and the sort of situation presented I had an excellent opportunity to demonstrate the importance of the point of departure in therapy. I trained Harvey to be an excellent subject, so that he could hallucinate, both positively and negatively. I avoided the matter of writing. He could describe driving along the street and could bring forth childhood memories which, the other psychiatrist assured me, were not loaded with emotion. Finally, when I thought Harvey was a really good hypnotic subject, I took the opportunity of giving him a pad of paper and asking him, in the trance state, to write his name. His writing in the trance state was just as bad as it was in the waking state. I asked him to write, "This is a beautiful day in June," and it was barely legible.

I then had one of the group who had a beautiful handwriting write his name and "This is a beautiful day in June." When I praised that beautiful writing, Harvey simply cowered in his seat at hearing somebody else getting praised—a painful situation for Harvey. Then I asked Harvey, "How do you suppose Dr. Jones feels about what I said about his handwriting? How do you think he feels about that handwriting? How do you think the pencil feels in his hand? How do you think a pen would feel? How do you think his hand would feel against the pad of paper when he writes so beautifully? How do you think he will feel a year from now when he reads that?"

Harvey really started thinking about it. And then I asked him, "How much would you like to do that sort of thing?" Harvey said, "I'd give anything if I could write legibly, but I can't."

Having laid that foundation (which I have abbreviated very much), I had Harvey hallucinate in crystal balls—they're much cheaper than the kind you can buy in a magic store, and you can distribute them wherever you want all around the room. I asked Harvey to look into a designated crystal ball and to see a little boy, viewed from the rear. "That little boy must be pretty unhappy," I said. "I wonder why. He looks as if he's very, very unhappy. You look at him and tell me where he is."

Harvey said, "Why, that's a little kid about six years old, and he's sitting in his desk at school. The teacher just walked away. She's got a ruler in her hand. She must have been punishing him."

I said, “All right. Now look in that crystal up there [indicating another ball]. I think you’ll see that same little boy at the age of 12. What’s he doing?”

Harvey looked and, sure enough, there was a boy of 12 in it. “He’s walking through the woods with his brother, carrying a gun.”

I asked Harvey how he knew it was the boy’s brother.

“I don’t know. I just think that. The 12-year-old boy does not seem very happy. He doesn’t like that gun, and he looks rather unhappy. I don’t like the looks of that.”

I said, “Why?”

“Well, there are the two boys. One’s about 14 or 15, and the other boy is about 12. They have a dog with them. They are going hunting. But that 12-year-old looks just like that boy over there, and he’s miserable. I wish I could see his face. Now he’s left his brother, he’s wandered off to that tree over there, and he’s very miserable. He’s practically crying.”

“Well,” I said, “what about that crystal up there? Can you see that same boy in that crystal about the age of 20?”

He looked, and he saw him there.

I said, “How does it seem to you that he’s behaving?”

“Well, he’s very, very unhappy. And you know, it’s the same kind of unhappiness. They’re the same boy at different ages, but they all have the same feeling. They’re very unhappy.”

“What about that crystal there? He’s about 30.”

Harvey looked. “The same sort of unhappiness!”

”Well, how does it happen that a six-year-old boy and a 30-year-old boy all have the same kind of unhappiness? At least you describe it as such.”

“They’re really the same boy—but how can that be? I don’t understand. But they *are* the same boy, and it *is* the same kind of unhappiness.”

So I asked him, as a preliminary, “Now, is there anything else in that crystal there ... anything else in that crystal [indicating different crystals]?”

He said, “No, up there ... but up there—and how did it get up there—there’s a place for a doghouse, and it doesn’t make sense. But there’s a place for a doghouse down there too, and that doesn’t make sense.”

We discussed that for a while. The psychoanalyst questioned him about it, but Harvey was very limited in his replies. Then my question was "Now, suppose you look at this crystal and see if you can explain something—why there's dog here, a place for a doghouse there, and a place for a doghouse *there*. Just see something that explains it!"

Harvey looked into the crystal and said, "Why it's that six-year-old boy coming home from school. He's still got some unhappy feelings. I wish I could see his face, but I suppose it isn't important. He's still rubbing his face—at least, looking at him from behind, that's what he seems to be doing. There are some policemen there, and one of them is holding a revolver. The boy rushes in to see what it's all about, and the policeman has just shot his dog." He paused thoughtfully. "But he didn't know about that when he was at school. Then when he was 12 years old, he went hunting with his brother.... Why, there was an accident to his dog! And that boy has never dared to own a dog since then. *That's* why there's a doghouse there in that crystal and a doghouse there."

I said, "Well, maybe that does explain it. But the boy was crying in school, before he found the dog killed. Why was he crying in school?"

"I don't really know, but I've got the most awful feeling in my left hand. And I know just how that boy feels. It feels as if somebody took a ruler and rapped me on the hand for writing with my left hand."

So I quickly shifted the scene, dropped it right there. I awakened Harvey and had a social interview with the psychoanalyst, spending about half an hour chit-chatting about this and that, and then put Harvey into a trance. I wanted those ideas to soak into his unconscious.

When he was in a trance, I told Harvey, "I'm going to give you a piece of paper and a pencil, and I want you to write your name the way that six-year-old boy would have liked to write. But I want you to write with your right hand, just as the other psychiatrist told me he wrote with his right hand—and I mean that he *did write with his right hand*. I want you to have an idea that you can take over Dr. Jones's feeling about his excellent handwriting as you write your name. I don't want you to write it just yet. I'll put the pad of paper there and the pencil there, and after a while I'll have a cigarette and you'll pick up the pencil and you won't notice that you're doing it. You'll take it in your right hand, and you'll write your name and `This is a beautiful day in June' right under Dr. Jones's handwriting. Then I'm going to awaken you, and you'll have no knowledge of having written. Anybody who tells you that you have written anything is nothing but a damned liar—and you tell them so. Make no bones about it. Just tell them they are damned liars."

He wrote his name and "This is a beautiful day in June." I awakened him and we chatted for a while socially. Then someone I had picked out took up the paper, looked at it, and said, "Well, Harvey, you certainly have a good handwriting."

"I have not!"

"Well, here's your name and here's where you wrote 'This is a beautiful day in June'…"

Harvey told him just what kind of a liar he was.

Somebody else told Harvey how good his handwriting was, and was informed as to his status and his veracity. We went through the entire group. Then I said to Harvey, "Well, they may be offensive liars, and cheats, and frauds, and so on, but if you watch that pencil there on the desk—if you just watch it, you're going to see something very interesting, because the hand that wrote your name and 'This is a beautiful day in June' in such good script is going to pick up that pencil. See if you can identify the hand."

"All right," Harvey said, "but nobody's really close enough, and it ought to be easy to identify the person who walks up to the pencil. So I'll watch the pencil . . ." He turned his attention carefully to the pencil. And then, "Why, that's my hand! But I can't write that good. I don't believe it! This writing here—'This is a beautiful day in June'—it's good script!" He paused a moment and then, very deliberately, said, "That *is* my hand and I *did* write it."

I said, "Then we're all agreed, and we're not going to dispute with you. That will be all for this session."

The next day—but it wouldn't have made any difference if it had been a couple of days later—the wind was blowing just right. The black man came in, opened the window, and started shoveling ashes. Harvey went out, stepped up to the black man, and said, "Listen, big boy. If you were working where I am, would you like all those ashes blowing in on you?"

"Well, no, I wouldn't."

"Then why did you open the window?"

"White boy, I think I was just being cussed, and I'm going to close it for you.

The window was closed by the black man. Harvey went home; the next day he went to his boss and said, "Listen, I've been working here for several years, and I haven't had a promotion or an increase in salary. Don't you think it's about time?"

The boss said, "Why, yes."

Harvey went to his psychiatrist and said, "I don't know what you've done to me. You know, I'm 32 years old and I think it's about time I got a girl. Don't you think so?"

The psychiatrist said, "Well, you know, I've got nothing to say about that. You'll have to consult Dr. Erickson."

And Harvey said, “To hell with Dr. Erickson! I’m going to get a girl.”

Harvey’s happily married. He writes legibly.

Now, where did that therapy take place? How much did I need to know about him? I started at the nuclear point—his handwriting. I didn’t know what I would get in those crystal images, but I could see a succession of events there that I could investigate, one by one, and then give him that kinesthetic idea—that kinesthetic sense of a nicely written, right-hand script production—and allow him to vent all aggression by letting him call the members of the group damned liars. He had to call somebody a damned liar. He couldn’t take out aggression against the policeman for shooting the dog: the dog was rabid, and he was just a six-year-old kid at the time. I didn’t know about that either, nor did the other psychiatrist.

Harvey later gave a very nice account of this, when I gave him full recollection of the experience, at a medical group. Harvey is still getting along successfully, and this all took place back in 1945.

I should like to present at this point the use of hypnotherapy in an experimental fashion. I was very much afraid that one of my patients was going to develop schizophrenia. Her very best friend had. She was a very accomplished person, professionally trained, and she worked until 11 at night. As soon as she got off work, she would sneak home, cowering and shivering, because there were some peculiar figures that were following her. Her bedroom was peopled by monsters of some sort. I think you would call her a psychotic, although she had sufficient insight so that you could have some doubts about it. She wasn’t quite certain whether she was having dreams or whether her experiences were real.

“How could I have a dream on the street? I’ve got the feeling, though, that there are monsters back of me in mid-air.”

I asked Mary if it wouldn’t be a very nice thing to see herself in a crystal ball. I produced one, and she described to me the little girl she saw there.

In some surprise she said, “Why, that’s me! And I’m very happy there. I’m playing with my doll. Now I’m going to go over and swing. I certainly was a happy kid. And look at that blue-checked pinafore I’m wearing!”

She really enjoyed looking at herself at the age of six.

So I conjured up another crystal for her. She was several years older. She described herself with a great deal of pleasure.

I said, “Don’t look at that crystal over there yet. Let’s look at the crystal here.”

Slowly, carefully, I carried her through a process of fourteen crystals. The thirteenth crystal was her present state, in which she was walking home from the hospital in fear of those hideous monsters and evils. Were they real or unreal? When she got to the tenth crystal, I told her that she wouldn't know who the girl was in the crystal ball.

She said, "That's a ghastly thing to have me look at."

"Well, you just describe it to me thoroughly, completely, and adequately." We went through the tenth to the twelfth, and they were very, very painful. I said, "Now, I want you to forget the identity of the person in all of these crystals. Just tell me what you think about them—and never mind that crystal over there."

She said, "Well, she was a happy little girl. Then she was a little bit older. There she's going to school—she looks as though she might be in such-and-such a grade. There she's in high school, and there she's going to a Christmas party." And so on. "My heavens! What's happened to that girl? Why should she have such horrible feelings?"

I said, "Well, I don't know—you don't know—but I've got a very pleasant surprise for you. If you'll look in that crystal there, and then look in that crystal over there, you'll discover that they're the same girl. And in that crystal over there, you'll see the picture of a girl who is acting and behaving very real. It isn't really a living picture—it's just a girl in that picture, and she's happy, and she's pleased, and she's going to be doing something that she really wants to do and she's really going to be enjoying it. Now that girl and this girl are the same girl. But the process of growth and development, the changes that occur in life, the accidents in life, and so on ... You know, every story should have a good ending."

She looked and she said, "Well! That six-year-old kid grew up to be a very pretty girl, didn't she? And look at her. She's on a diving board, and she's got on a blue bathing suit with a yellow dragon or something on it, and she's having a wonderful time, she's really enjoying herself. I can hardly believe it. That girl is enjoying herself—she really is!"

I said, "This is only June, but that girl up there is going swimming in August."

Mary went swimming in August. She went swimming in a blue bathing suit with a yellow figure on it—I don't know whether it was a dragon or not. At all events she went swimming. I found out afterward that she had learned to swim and then had developed tremendous fears and anxieties and distresses. She had developed all these other agonies, in spite of the fact that she actually had had professional training, and she had a very difficult time.

She is the head of a professional department at the present time, so I think that experiment was successful. I had a letter from Mary the other day, and she's very happy. She's married—happily married—and getting along very nicely.

What did I do when I started experimental therapy? I let her identify herself in a safe and sure fashion by putting her in a crystal.

There's another item that I want to mention, and that is the idea of time distortion. What do I mean by time distortion? It's been mentioned previously how time can pass very rapidly in the trance state. Lynn Cooper, I think in 1945, published the first article on the subject. Then a couple of years ago Lynn Cooper came to Phoenix, and we worked together on time distortion. Pell reported on that. Lynn Cooper was very much interested in knowing whether you could employ time distortion in therapy, and I agreed that I would try it out. I tried it out with two patients and with very nice results.

How long is time when you're asleep? I can remember the doctor who volunteered for some experimental work at the staff dining room, and I agreed to meet the doctor in the psychology laboratory at one o'clock. She came in. I picked up a book, and we got to discussing psychology and this particular book. I took advantage of that situation to put the doctor into a deep trance. I did the experiment, brought her out of her trance, sat her down, put the book in her hand, and renewed the conversation where I had interrupted it to put her in a trance. We concluded the discussion, and all of a sudden she noticed that it was five o'clock. She expressed her regret that she had allowed her interest in that book to distract me from my experiment.

I said, "Well, it's all right. Tomorrow's another day." She met me again the next day at one o'clock, and I used exactly the same technique, except that I had established a posthypnotic cue for her, saving both time and labor.

After three weeks of that sort of performance the doctor was a little bit irritated with me, and she really castigated me at the staff dining room table.

"Three weeks ago I volunteered to act as a hypnotic subject. All you've done has been to meet me in the psychology laboratory, utter a few inanities about psychological textbooks, and waste my afternoon for three long weeks. I'm sick and tired of that. Either you're going to use me as a subject or you're not. That's all there is to it." (She was downright unpleasant about it.)

Nevertheless, she went up to the psychology laboratory at one o'clock, and I met her there and used the same technique. When the experiment, which required that the subject not know what the experiment was, was completed, I told her that she had been a subject all that time; but I had to tell her in both the trance state and the waking state.

What did time really mean to her? I don't know how many times my patients will tell me, "I've been in here fifteen minutes, five minutes, three minutes." One of my subjects has a neat little trick of checking on a wristwatch, and never allows me to take that wristwatch off. Time perception in hypnosis is one thing; in the conscious state it is another. Cooper has been interested in that for a long, long time. With regard to different kinds of therapy, one of Cooper's subjects, for example, picked some irises, some 150. The actual time spent in that hallucinatory activity was 10 seconds. After the subject was awakened, the

subject was told to remember and was told to demonstrate the rate with which the irises were picked. The rate was essentially the same as if it had been half an hour, which the subject had estimated.

The question came up: How could I use that therapeutically? I had a patient—and I'll give you just one miserable detail of that patient's history, so that you can appreciate why it was difficult to handle the patient. At the age of six a foster uncle decided to take the little girl for a visit. He took her to an isolated cabin, bound her hands and feet to the bed in a spread-eagle fashion, took a jackknife, and really carved up her body in a horrible manner. I've seen the scars.

The physician who referred the patient told me, "I had to fight like a madman to do a physical on this patient. She needs psychiatric care. She isn't an internal medicine case at all. I can't understand those scars. I wasn't able to do a complete physical examination because she fought so fiercely, yet she would apologize and then fight so madly."

It took quite a long time for me to do a physical examination on her. But the scars on her abdomen, and on her thighs, all over her body, were deep and vicious ones. Those of you who have had prison experience in psychiatric treatment know that sort of thing is possible.

I wanted to get from her an account of her past life. She was a good hypnotic subject, and I asked her first to describe a childhood birthday party. I had my stopwatch readily available. The stopwatch was no use. It took her just as long to describe the birthday party that she had hallucinated in a crystal ball as it took for the party to occur. I then tried an auto ride she had experienced when she was a little girl. The time was equivalent. She described things very nicely, very thoroughly, very consistently. If a birthday party took three hours to occur and the psychiatrist didn't know about it, it took three hours of his time to discover the fact. We didn't get very far until fall. It took from July until October to get a history from her. In every instance she gave me only pleasant things, good memories, but in such elaborate detail that they consumed as much time as the original experience.

I therefore carefully explained to her that in a hypnotic state, "just as you are now, time is going to change. Everything is going to speed up with tremendous rapidity, and by the time I drop my pencil you're going to remember everything that happened to you in the first eight years, going to school, things of that sort." I went over and over the idea of speeding up memory. I never got any really traumatic memory except the one relating to the scars that I had discovered. That was the only one. Apart from this I could only obtain from her a dully repetitious, "I got stabbed. I got stabbed. I got stabbed." My knowledge of psychiatry and criminology led me to the conclusion as to what kind of stabbing it was. After I had inculcated the concept of distorted time, rapid time, experimental time, or whatever you want to call it, I told her to look at a crystal ball. I said that I would give her all the time she needed; but in that crystal ball—where she had previously seen a birthday party, an automobile ride, a train ride, some horses, some trees, and things of that sort—she would see everything that had happened to her in a certain period of her

life that covered 16 months. I didn't say 16 months. What I said was "Everything that happened to you from 1930 to 1933, roughly speaking. I don't know, maybe it's the wrong period; but somehow we're going to select the period you should tell me about."

She agreed that she would look in the crystal, and then I explained the Distorted-time idea. I told her that when I said, "Start," she would see in the crystal everything in slow motion so that she could memorize and recall and understand everything so that she could remember and tell it to me. I further indicated that although she would be seeing things in slow motion, it wouldn't take very much time for her to describe what she saw. This was rather a contradictory suggestion, but she understood that. At the proper signal I set my stopwatch; 20 seconds later she had covered 16 months of the most traumatic material imaginable, and did a thorough job of it. The death of her father, the death of her mother, the death of several other people—it was just incredible. It was as if she were held immobile, as if she were fascinated by the terrible procession of events in the crystal. She just couldn't stop, as that chain of slow motions with such extreme rapidity took place.

After 20 seconds' time I noticed that I was fatiguing that poor woman much too much. I put an end to the session, awakened her, and then said to her, "You know, I've never been able to get you to tell me the facts of your life. I've been working through July, August, September, and now it is October. I really don't know very much about you. I do know that you've been stabbed—that's essentially all I know."

She said, "I couldn't stand to tell you."

"Well, we've got the rest of the day. Suppose you tell me."

The rest of the day and a good share of the next day were spent for her to tell the series of events and to bring forth corroborating evidence. I corroborated item after item. 1 had to write to various sections of the country to get proof. For example, did a certain person and the patient, on such-and-such a day, in such-and-such a year, have an automobile accident? You can get such information from vital statistics, police departments, and public records. I wrote to five different states and found she had given me reliable information. It had taken just 20 seconds to secure the impetus of events. The momentum seemed to carry her along with such impelling force that she was unable to stop. I will agree that I had a difficult time with the patient, for she said, "You have no right to know these things." It took quite a long time for her to recognize that I did have the right to know those things. I explained that she had been hospitalized for severe headaches that would last for three weeks at a time, with nausea and vomiting that couldn't be touched by morphine or anything else. There were other details, but I will not relate them here.

Whether 20 seconds, or 10 seconds, periods increased to obtain information about some other aspects of her life. It took me 10 seconds to get a completely repressed memory. She didn't know why, when she came to my office, she didn't like my six-year-old son. I think he's adorable; but he is the most awful, hateful pest—a nuisance—she would shake and tremble at the sight of him. I did everything I could to try to find out why. I gave every association test that I knew. Why did she hate poor little Bobby? He's just an

ordinary kid. What could I do about it? Nothing. She had complete repression. In 10 seconds' time I found out by the same process I had used earlier. I had her look in a crystal, and I said to her, "Somehow or other Bobby's in that crystal over there . . ."

"Oh, no! Bobby isn't in that crystal!"

"Now, why should Bobby be connected with that crystal in any way?"

She told me that what I was saying to her didn't seem to make sense. I said, "No, but it's your job to make sense out of it. So let's put Bobby out of it and put the sense in."

In 10 seconds' time she recalled that in the early 1940s her husband had brought home a girl and announced that this girl was his mistress and that she would have to wait on this girl. There weren't to be any ifs, ands, or buts about it; and he slapped her down. The girl demanded a cup of tea, just to show her power. My patient said, "But the baby's just started crying." (That was the first I knew about that.) Her husband slapped her down again, and she got the cup of tea for the mistress. She then went in to the baby.

The autopsy reported that the baby had strangled to death on a ribbon in his nightie.

Another patient who had been suffering from asthma came to my office and told me she couldn't understand why she had asthma or why she had it only at certain times. I said, "Well, we'll try to diagnose it in this interview."

She said, "You must have a pretty good opinion of yourself."

I said, "All right. It's now two o'clock. At 2:36, by that clock there, you will have an attack of asthma."

She looked at me as though she thought I ought to have my head examined. We chatted on and on very casually about various things, including her childhood. At 2:36 she had an attack of asthma. Why? I guided that conversation very carefully. It seemed to be just an ordinary social conversation, but actually I kept loading it progressively, and at 2:36 I asked her how often her father wrote her letters? As soon as I mentioned her father's letters, she developed an attack of asthma. I had already learned in her previous history that her father never wrote her during the summertime, but always wrote her in the fall, the winter, and the spring. What had her father done to her? Her father had really mistreated her mother in a most outrageous fashion. The mother had left her share of the property to the daughter out of that property. Moreover, the father had written a lot of very disagreeable letters to his daughter every fall, winter, and spring. I was quite safe when I said 2:36, because I knew I could mention her father's letters at 2:36 and that she would get an attack of asthma. I felt sure of this because in her previous history taking I had had her describe when the attacks of asthma came on, where she was sitting, whether by this window or that window, and what she had happened to be doing. The mailman intruded into that situation too many times. Therefore, I wondered about the letters. Yet she had told me about her father not being fair, about his being unjust to her mother and

unjust to her; but that wasn't sufficient knowledge. I had to mention the specific item—the father's letters.

She hasn't had any asthma since we discussed her father's letters, and I helped her compose a few replies to her father. I think that perhaps I may have done some psychiatrist in that state a favor by giving him a patient.

One of the psychosomatic problems that I want to mention now concerns the matter of stuttering that so often constitutes a serious problem. In every psychiatric case you have to take the individual personality into consideration if you're going to handle stuttering. The psychotherapeutic approach and the hypnotic approach, in my experience, are most effective if you recognize one general factor. Stuttering is a form of aggression against society and people in general. You know the old joke about the great big man who asked the small-sized man how he could get to the Union Station in Chicago, and the small-sized man looked at him blankly and didn't answer. The large man went on and asked someone else. Someone went over to the small-sized man and said to him, "Why didn't you tell that chap how to get to the Union Station?" The small-sized man said, "D-d-did you th-i-nk I wanted to get my b-b-bl-o-o-ock knocked off?"

Stuttering is a form of aggression. Why should the patient aggress in a way that is uncomfortable to the patient? I had a patient, a physician, who had stuttered all of his life. When he came to me as a patient, I told him very frankly that his stuttering was an aggression and that I would be very glad to take care of it, if he were willing. I stated also that it would not be a pleasant sort of thing. He asked me if I thought stammering or stuttering were very pleasant things. I put him in a trance and worked quite a while with him on the subject of how he felt about speech and how he felt about people in general. I then built up a negative attitude and aggression toward me, which serves the purpose of allowing the patient to vent his aggression on me individually.

As a result the doctor is in a difficult situation. He speaks clearly and lucidly, has no stammer or stutter. He never fails to send me a Christmas card, but he always writes: "I hate your guts and I'm going to keep right on." Nevertheless, he sends me a Christmas card, and he sends Christmas presents to my children, but he always has a nasty crack for me. When we meet, we laugh and talk and exchange stories. The one I just told about the big man and the little man I've told him, and we've both laughed about it; he thinks it's funny. "But," he has told me, "it seems to me I've got a need for a lifelong hatred of something—I don't know what it is. You're convenient, and you're a nice guy to hate."

I said, "That's right, and it's solved your stammering problem."

Another one of my patients decided that he would get psychoanalyzed. He spent five years in the process to find out what had caused his original stammer. After five years he said, "You know, I've learned a lot about psychoanalysis and the treatment of patients by psychotherapy, but actually, you corrected my stammer. You gave me a certain hatred that was very, very useful, and my psychoanalyst tried to take it away from me.

The hatred I gave him was that trees should not be less than 18 inches from the sidewalk. I thought that was a fairly harmless hatred. He didn't have to do anything about it. He could ignore it, it shouldn't cause him any kind of distress; but at the same time he could really hate it.

"My psychoanalyst," he went on, "tried to take that away from me. He almost succeeded, and then I started to stammer. I decided I was going to keep right on. That hatred was some sort of crutch that I was really using."

He still doesn't stutter. What did I do? I don't know. It was an experimental case, and he came to me on that basis.

There is still another instance that I would like to cite. Chester Garvey came to Worcester, where I was working, and said that he had seen Hull induce hypnosis but didn't quite believe it. Would I please demonstrate hypnosis for him? He was rather antagonistic and hostile toward the idea of hypnosis.

I called in Art and Hulda, who were psychologists working for their Ph.D.s and who were good hypnotic subjects. I explained Dr. Garvey's desire and his disbelief in hypnosis. I asked them if they believed in it. They said they certainly did. I then said, "I've got to go downstairs and do an experiment on the ergograph. So I'm going to hypnotize you, Art, so that hypnosis can really be demonstrated."

Art said, "Okay," and went into a very nice trance, and I promptly left. I wondered what would happen as I left Garvey there with those two Ph.D. candidates. Garvey walked over to Art in the trance state, because Art was in a somnambulistic state, and Art said, "Well, Dr. Erickson has left, and you wanted a demonstration of hypnosis. Both Hulda and I are good subjects. Suppose I put Hulda into a trance." Hulda, assuming that she was going to demonstrate Art, found herself going into a trance! This was a very confusing thing for Garvey. Art put Hulda into a trance and demonstrated a great variety of hypnotic phenomena.

When I came back from the ergograph experiment, I walked into the room and spoke to Art. He said, "I think we're through demonstrating hypnosis." I turned to Hulda to speak to her and realized that she was in a trance state. So I said, "How do you mean?" Art replied, "Well, I put Hulda in a trance to demonstrate to Dr. Garvey what hypnosis is."

I thought that I would add a little more confusion to the situation. I awakened Art. He was still in rapport with Hulda, but I was not in rapport with Hulda. I had him awaken Hulda, and I asked him if she would demonstrate hypnosis to Dr. Garvey. She, not knowing that time had elapsed, proceeded to try with Art in the waking state to demonstrate catalepsy and a few other phenomena. Art kept telling her, "But I'm awake!" Hulda insisted, "No, you're not. I saw Dr. Erickson put you in a trance, and I know you're in a trance."

Of course, that settled it for Garvey. He didn't expect it, I didn't expect it, and it certainly is in contradiction to White's theories of goal-directed behavior, no matter what qualifications you put upon it.

What bearing does that have upon therapeutic approaches? It has a bearing on indirectness of approach. Art was thoroughly appreciative of the fact that Garvey was hostile and antagonistic and resentful. Consequently, he contrived a situation that would overcome it in a way that Garvey could not possibly resist. I use that approach therapeutically quite often. I have an Arizona State College student that I have used a number of times. A patient will come into my office, sit down, and say, "Well, I'm here. What are you going to do about it?" Frankly, I can't do a thing about it because of his attitude. Yet such patients honestly want therapy, but they are antagonistic and resentful. It is very easy to chat with them socially for a while, then bring in a student that they might like to meet and have the student put them in a trance for me. They have no resistance toward the student; it's all channeled and directed toward me. Resistance should be channeled toward the therapist. The student puts them in a trance and then I supplant the student.

Sometimes I have to put the student in a trance first, just to demonstrate that I do know how to produce hypnosis. The patient watches and says, "Well, there's no question about it. You can hypnotize that person." The patient has no resistance against a hypnotized person hypnotizing him. It is a very simple, easy method of overcoming some of the tremendous resistance that psychiatrists meet over and over again.

Yesterday I mentioned a color-blind girl and her reaction to the fact that somehow I had changed her dress on her, and what explanation could I give for that. She was entitled to ask a question like that. I've had that happen more than once, when I've changed a situation. What excuse did I have for taking her out of my office and taking her into her own bedroom? Physically she was still in my office; psychologically she was in her bedroom, and what business did I have there? There is a tremendous need for protecting patients in ordinary psychotherapy. How often is the resistance the result of the therapist's intruding upon intimate memories, intimate ideas? This accounts for a great deal of resistance, and in hypnotherapy one can reach that sort of situation by stating to the patients very definitely your intention to protect them. Patients should understand that, and you should not overlook the possibility that you can unwittingly intrude upon the legitimate privacy of a patient.

There are certain frightened reactions that patients show. I remember getting in trouble with an adult male whose legs I had anesthetized to test for the knee-jerk. He showed an excellent anesthesia; but he decided to shift in his chair, and as every anesthetist knows, with a spinal block you don't move your legs around very much, depending, of course, upon the level of the block. In hypnotic anesthesia, where is the level of the block? In hypnotic anesthesia, you get a motor block also. The patient isn't aware of that. This patient of mine discovered that he couldn't walk, and he was infuriated. I had no business paralyzing him! You'll find, in producing catalepsy in a patient, that he can resent that with tremendous force. Usually, when I find that sort of thing, I use it as a center for

localizing hostility, resentments, antagonism, and aggression. It's a convenient one that the patient has picked out for me, rather than making it necessary for me to produce it.

I was asked yesterday by someone about the problem of phantom limbs. "How do you handle that in hypnotherapy?" A friend of mine who had suffered an amputation had a discussion with me one night. He was also a psychiatrist and psychologist. He had written out his ideas, and he started quizzing me on the subject because he had experienced a great deal of difficulty with his phantom limb. We both had worked out essentially the same method. I suppose you would call it reconditioning.

I will give an illustration. The amputation is here on the arm—the index and second fingers get crossed, you can't straighten them out, and they are painfully tired. How are you going to approach that sort of thing hypnotically? The thing I do is to put the subject in a trance, try to reorient to a time previous to the amputation, which is a very difficult thing. He has only got one arm, and he can't balance his body properly. You reorient, however, certain memories, then you raise this question of crossed fingers. "Now, where do you feel that? Do you feel pressure here, or do you feel it in the joint? Or perhaps your wrist gets tired?" I am speeding up the procedure; but you discuss such matters, and you slowly move up the locus of the feeling to the stump. Get the patients to understand the progressive upward movement, so that they can't be certain it's their fingers, or just exactly where it is.

A patient came to me with very serious neurotic complaints of heart pains. Most medical practitioners will explain to you that you don't get heart pain in the chest wall. But this man knew that he got heart pains in the chest wall, and I became very much interested. Was it on the left side of the sternum, in the middle of the sternum, the right side? Was it between this rib and that rib? I slowly had that pain migrate to his shoulder and migrate down his arm. As it migrated, the pain decreased more and more until it finally vanished.

That isn't the end of the problem, however; because the question is, why does he have heart pains? As long as that chap had heart pains, that is what he talked about. I didn't want to hear about those heart pains; I wanted to hear about some of the reasons why he had heart pain, and I didn't want him wasting his hours describing that pain endlessly, repetitiously, and in tremendous detail. We erased the pain so that we could get down to brass tacks. How did he feel about this person, that person? How did he feel about himself? What was his attitude? The removal of symptoms with which the patient was preoccupied enabled the patient to enter into the causality of the symptoms.

Clinical Note on Indirect Hypnotic Therapy

Milton H. Erickson

From the 1954 *Journal of Clinical and Experimental Hypnosis* (2, 171-174)

A young couple in their early twenties, much in love and married for a year and close friends of several of the writer's medical students at the time, sought psychiatric help. Their problem was one in common—lifelong enuresis. During their 15-month courtship neither had had the courage to tell the other about the habitual enuresis.

Their wedding night had been marked, after consummation of the marriage, by a feeling of horrible dread and then resigned desperation, followed by sleep. The next morning each was silently and profoundly grateful to the other for the unbelievable forbearance shown in making no comment about the wet bed.

This same silent ignoring of the wet bed continued to be manifested each morning for over nine months. The effect was an ever-increasing feeling of love and regard for each other because of the sympathetic silence shown.

Then one morning, neither could remember who made the remark, the comment was made that they really ought to have a baby to sleep with them so that it could be blamed for the wet bed. This led at once to the astonishing discovery for each that the other was enuretic and that each had felt solely responsible. While they were greatly relieved by this discovery, the enuresis persisted.

After a few months discreet inquiry of the medical students by the couple disclosed that the writer was a psychiatrist and a hypnotist and probably knew something about enuresis. Accordingly, they sought an appointment, expressed an unwillingness to be hypnotized and an incapacity to meet the financial obligations of therapy, but earnestly asked if they could be given help.

They were informed that they would be accepted as patients on a purely experimental basis and that their obligation would be either to benefit or to assume full financial responsibility for the time given them. To this they agreed. (This reversal of "cure me or I won't pay" is often most effective in experimental therapy.)

They were then told that the absolute requisite for therapeutic benefits would lie in their unquestioning and unfailing obedience to the instructions given to them. This they promised. The experimental therapeutic procedure was outlined to them, to their amazement and horror, in the following fashion:

You are both very religious, and you have both given me a promise you will keep.

You have a transportation problem that makes it difficult to see me regularly for therapy.

Your financial situation makes it practically impossible for you to see me frequently.

You are to receive experimental therapy, and you are obligated absolutely either to benefit or to pay me whatever fee I deem reasonable. Should you benefit, the success of my therapy will be my return for my effort and your gain. Should you not benefit, all I will receive for my effort is a fee, and that will be a double loss to you but no more than an informative disappointment to me.

This is what you are to do: Each evening you are to take fluids freely. Two hours before you go to bed, lock the bathroom door after drinking a glass of water. At bedtime get into your pajamas and then kneel side by side on the bed, facing your pillows, and deliberately, intentionally, and jointly wet the bed. This may be hard to do, but you must do it. Then lie down and go to sleep, knowing full well that the wetting of the bed is over and done with for the night, that nothing can really make it noticeably wetter.

Do this every night, no matter how much you hate it—you have promised, though you did not know what the promise entailed, but you are obligated. Do it every night for two weeks—that is, until Sunday the seventeenth. On Sunday night you may take a rest from this task. You may that night lie down and go to sleep in a dry bed.

On Monday morning, the eighteenth, you will arise, throw back the covers, and look at the bed. *Only as you see a wet bed, then and only then* will you realize that there will be before you another three weeks of kneeling and wetting the bed.

You have your instructions. There is to be no discussion and no debating between you about this, just silence. There is to be only obedience, and you know *and will know what to do*. I will see you again in five weeks' time. You will then give me a full and amazing account. Goodbye!

Five weeks later they entered the office, amused, chagrined, embarrassed, greatly pleased, but puzzled and uncertain about the writer's possible attitude and intentions.

They had been most obedient. The first night had been one of torture. They had to kneel for over an hour before they could urinate. Succeeding nights were desperately dreaded. Each night they looked forward with an increasing intensity of desire to lie down and sleep in a dry bed on Sunday the seventeenth. On the morning of Monday the eighteenth, they awakened at the alarm and were amazed to find the bed still dry. Both started to speak and immediately remembered the admonition of silence.

That night, in their pajamas, they looked at the bed, at each other, started to speak, but again remembered the instructions about silence. Impulsively they "sneaked" into bed, turned off the reading light, wondering why they had not deliberately wet the bed but at

the same time enjoying the comfort of a dry bed. On Tuesday morning the bed was again dry, and that night and thereafter Monday night's behavior had been repeated.

Having completed their report, they waited uncertainly for the writer's comments. They were immediately reminded that they had been told that they would give an "amazing account" in five weeks' time. Now they knew that they had, and that the writer was tremendously pleased, *and would continue to be pleased*, so what more could be asked?

After some minutes of carefully guided, desultory conversation they were dismissed with the apparently irrelevant statement that the next month was May.

About the middle of May they dropped in "spontaneously" to greet the writer and to report "incidentally" that everything was fine. A year later they introduced the writer to their infant son, amusedly stating that once more they could have a wet bed but only when they wished, and it would be just "a cute little spot." Hesitantly they asked if the writer had employed hypnosis on them. They were answered with the statement that their own honesty and sincerity in doing what was necessary to help themselves entitled them to full credit for what had been accomplished.

COMMENT

To understand this case report it might be well to keep in mind the small child's frequent demonstration of the right to self-determination. For example, the child rebelling against the afternoon nap fights sleep vigorously despite fatigue and will repeatedly get out of the crib. If each time the child is gently placed back in the crib, it will often suddenly demonstrate its rights by climbing out and immediately climbing back and falling asleep comfortably.

Concerning the evasive reply given to the patients about the use of hypnosis, by which they were compelled to assume fully their own responsibilities, the fact remains that the entire procedure was based upon an indirect use of hypnosis. The instructions were so worded as to compel without demanding the intent attention of the unconscious. The calculated vagueness of some of the instructions forced their unconscious minds to assume responsibility for their behavior. Consciously they could only wonder about their inexplicable situations, while they responded to it with corrective, unconscious reactions. Paradoxically speaking, they were compelled by the nature of the instructions and the manner in which these were given to make a "free, spontaneous choice" of behavior and to act upon it in the right way without knowing that they had done so.

Favoring the therapeutic result was the prestige of the writer as a psychiatrist and a hypnotist well spoken of by their friends, the medical students. This undoubtedly rendered them unusually ready to accept indirect, hypnotic suggestion.

The rationale of the therapy may be stated briefly. Both patients had a distressing, lifelong pattern of wetting the bed every night. For nine long months both suffered

intensely from an obvious but unacknowledged guilt. For another three months they found their situation still unchanged.

Under therapy, during a subjectively never-ending two weeks, by their own actions they acquired a lifetime supply of wet beds. Each wet bed compelled them to want desperately to lie down and sleep in a dry bed.

When that opportunity came, they utilized it fully. Then, the next evening, understanding unconsciously but not consciously the instructions given them, they used their bed-wetting guilt to "sneak" into and enjoy a dry bed, a guilty pleasure they continued to enjoy for three weeks.

The uncertainty, doubt, and guilt over their behavior vanished upon discovery at the second interview that they had really been obedient by being able to give the "full and amazing account." Yet, unnoticeably to them, the therapist's influence was vaguely but effectively continued by the seemingly irrelevant mention of the month of May.

Their final step was then to bring into reality a completely satisfactory solution of their own devising, a baby, the solution they had mentioned and which mention had led to an open acknowledgment of enuresis to each other. Then, at a symbolic level, they dismissed the writer as therapist by introducing him to the infant, who in turn represented a happy and controllable solution to their problem. This they almost literally verbalized directly by their amused comment about having a wet bed any time they wished and that it would be only a pleasing thing of adult and parental significance.

The Hypnotic and Hypnotherapeutic Investigation and Determination of Symptom Function

Milton H. Erickson and Harold Rosen

Read in part (a) at the 107th annual meeting of the American Psychiatric Association. Los Angeles, California, May 4-8, 1953; and in part (b) at the Conference of Directors of Mental Hygiene Clinics of the State of New York, Pilgrim State Hospital, Brentwood, Long Island, N.Y., June 2, 1953. Quoted here from the *Journal of Clinical and Experimental Hypnosis*, 1954, 2, 201-219.

With some emotionally sick patients symptom-function can be determined rapidly under hypnosis, in a therapeutic setting.

Symptoms and even syndromes, when emotionally based, may subserve the repetitive enactment of traumatic events; may reproduce, instead, specific life situations; may satisfy repressed erotic and aggressive impulses; or may at one and the same time constitute defenses against, and punishment for, underlying instinctual drives (Weisman, 1952). They may mask schizophrenic reactions or hold suicidal depressions in check (Rosen, 1953). They may serve all these functions concurrently, or none of these, or any specific one or combination of them.

Patients, it should be stressed, see psychiatrists because they have symptoms which cause them trouble. They frequently insist on symptomatic relief. This sometimes is possible: transference cures not infrequently may be effected; environmental manipulation may occasionally be sufficient; defenses may be strengthened; or, with selected patients, symptom site may be transferred (Erickson, 1954), or less incapacitating symptoms substituted for those which otherwise would invalid or hospitalize them. Such symptom substitution, however, can best be achieved if at least a few of the functions served by specific complaint symptoms are known. Once these are determined, the attempt can then be made, with better chance of success, to substitute under hypnosis less incapacitating symptoms which nevertheless serve the same underlying neurotic or even psychotic needs.

However, there are patients with whom this would be impossible. Some may occasionally, nevertheless, be helped—and helped rapidly. They see psychiatrists in the hope, not of ridding themselves of symptoms, but of imbedding them. This is a therapeutic possibility. Symptoms can be narrowed down. A 59-year-old railroad worker [patient of M.H.E.] for example, after a fall one year before he was eligible for pension, developed a hysterical paralysis of one arm. He was willing to accept seven days' hospitalization, but seemed grimly determined to retain his paralysis. The psychiatrist spent the first five of these seven days with another physician, "thoughtlessly" discussing

the hopelessness of his case, examining and reexamining the patient while he was in a trance, and debating whether or not a specific syndrome was present. If so, he would wind up, they agreed, with a hopelessly paralyzed wrist but with free finger, elbow, and shoulder movement. On the sixth day these came back. Internist and psychiatrist both mourned his stiff wrist! The patient had his symptom. He became actually proud of his stiff wrist. He had all the trouble he wanted with it, and all the narcissistic gratification he desired from it, but he was now able to work, and he and his wife received their pension (Erickson, 1954).

Symptom restriction of this type constitutes an exceedingly important adjuvant hypnotherapeutic technique, significant enough to warrant detailed consideration. In this paper, however, we propose to limit ourselves, for the most part, to a discussion of our clinical experience in the investigation and evaluation of symptom-function, with various of the newer and more radical hypnotherapeutic techniques now under investigation. Dissociative states may be induced, for instance, or dream acting-out suggested; attacks may be precipitated and then blocked, either by direct hypnotic suggestion or by regressing patients to a period predating the onset of their disease, so that substitutive motor, vegetative, or other activity is precipitated out in a form accessible to therapeutic investigation; attacks may be precipitated in slow motion, so that individual components can be investigated therapeutically in detail; symptoms may be suggested away, while emotions back of symptoms are concurrently intensified, so that, again, underlying dynamic material will immediately become accessible for therapy; or still other techniques may be utilized (Rosen, 1953).

To illustrate [patients of H.R.] a hypnotically precipitated attack in slow motion, a patient with what for years had been diagnosed as epilepsy began making, as part of her supposed epileptic symptomatology, forced sucking movements with her lips as she acted out the fantasy of trying to suck on—and to bite into—her mother's nipple. In another patient with what was originally diagnosed as psychomotor epilepsy, an attack was hypnotically induced and then deliberately blocked by direct hypnotic suggestion; at this she was intensely aroused sexually, begging her impotent husband, whom she hallucinated as present and whose flaccid penis she was digitally trying to stimulate, to attempt intercourse with her more than once every three weeks. A patient with pruritus insisted that it was her itch, and her itch alone, which was responsible for her tension, her inability to sleep, and her general irritability. Once hypnotized, she was told that, if she really wished it to, her itch could disappear but that whatever it stood for, no matter what, would become so strong, so unbearably strong, that she would be unable to contain it any longer. She began shouting: "Don't let me dig her out! Don't let me dig her out!" And at this, although her itch had disappeared, she began digging her nails into her skin. Early aggressive and traumatic material, with specific reference to her mother, was then spontaneously abreacted. Her pruritus, among the various functions which it served, satisfied hostile and aggressive impulses on one level against her husband and, on another, against her mother. It served also to mask her underlying depression and to hold it in check.

At times a much more indirect approach than this seems indicated. A second patient with pruritus vulvate, [patient of M.H.E.] who had previously been treated by various allergists and dermatologists, was unwilling, so she stated, to be hypnotized if the psychiatrist was curious about her problem: it would, rather, be a question of her conscious strength of character to tell it. It was therefore suggested that she could go into a trance and while in it do something, no matter what, that she would have no hesitation letting the psychiatrist know about. She agreed, hallucinated playing tennis, became "hot and sweaty," and explained that she felt like taking a bath. She was told that, since she was a big girl, the psychiatrist could not let her really take one, but that, if she were a little girl in a big tub, she could. It was added that perhaps a bath by proxy might be even more satisfactory. So she watched and, because the psychiatrist was not wearing his glasses, described seeing a little girl bathing, playing with her genitals, being horribly punished by her mother, and then being forced to scrub the ring off the tub.

During the next session she stated without being hypnotized that she had a silly thing to tell: she had taken a bath the night before and washed the ring off the tub, and she knew that in telling him this the psychiatrist would undoubtedly understand something, although she did not know what it was.

Our approach may at times be, at first, direct and, later, indirect. One patient, [patient of H.R.] for instance, was a rather depressed 28-year-old truck assembler with spasmodic torticollis of almost six months' duration, who finally began drawing unemployment compensation because his wry neck had made it impossible for him to continue paying the close, detailed attention to his work which was demanded of him. Despite long-continued traction his neck would twist immediately to the extreme left once this traction was discontinued.

During the anamnesis some of the defensive aspects of his symptom were hinted at. He had always been shy and embarrassed, had always been afraid of girls, had seldom had a date, and had never had intercourse. But one of his fellow workers had promised to "fix him up" with a girl, once he purchased a car with the $2,000 he had saved. "He said she's a sucker for a guy on a ride," he explained, "And he gave me a rubber. I've still got it. See! And I was just going to buy it [the automobile] when my neck started like this. So I'll have to wait till it's better now. I can't drive this way . . ."

"And for two years" before the torticollis started, "my hands'd shake, and I'd tremble. And sometimes my head would too, just like my hands when I'm nervous. That's because I'm so tight inside. I can't relax at all."

He was hypnotized under the pretext of testing his ability to relax. As long as his head remained twisted to the extreme left, he appeared placid, calm, and even serene. But when, on direct verbal suggestion, his head reverted to the midline, his right hand seized his penis through his clothes, and he began to masturbate. When given permission for his head to revert to the extreme left, he again became the same motionless, placid, and apparently serene individual. At the suggestion, "Your head can remain unturned," his masturbatory activity resumed. "You can, you know," so he was then told, "remain

motionless, if you wish, while your head is unturned." At this, his hands fell to his sides and he again became motionless, but this time all the physiological concomitants of acute anxiety appeared. He began perspiring profusely, seemed drenched in perspiration, and became visibly tremulous.

Since it was not thought that at this point he could tolerate the anxiety attendant upon realizing what at least one of the functions served by his torticollis was, amnesia for this particular part of the hypnotic session was suggested, *provided he would rather not remember it*. Symptom substitution seemed possible. He could, for instance, have been allowed to squeeze a hallucinated rubber balloon and, later, to hallucinate watching someone else doing this. Instead, as a temporary expedient on his new job, he found it possible to hold an oversized pencil rigidly against the steering wheel as he drove a truck.

It should be emphasized that while he hinted during the anamnesis at some of the defensive and perhaps adaptive aspects of his symptom, these did not appear during the hypnotic investigation. Instead, perhaps as a result of the specific hypnotic techniques utilized, one symptom function—that of substitutive satisfaction for autoerotic activity—became obvious. Ferenczi (1950), it will be remembered, believes that tics constitute masturbatory equivalents. This patient's torticollis can under no circumstances be considered a tic, but nevertheless, because of his behavior during the hypnotic investigation, Ferenczi's discussion immediately comes to mind. So does that of Melanie Klein (1948), whose 13-year-old Felix's tic had appeared when homosexual and masturbatory impulses were repressed. However, it should be remembered that with our patient this material came to light specifically as a result of whatever was going on between him and the therapist within, rather than because of, the hypnotic interpersonal relationship. If other hypnotic techniques had been utilized, or if the investigation had proceeded in some other way, the results obtained might in all probability have been different.

One of our patients was a miner's wife [patient of M.R.] in her mid-thirties who was hospitalized for further gynecologic study after having had a hysterectomy three years previously. The abdominal pain of which she still complained and for which she had wished further surgery was thought by her present surgeon to be on an emotional basis. Because of her 20-year history of "nervous spells," a psychiatric consultation was requested.

These "spells" turned out to be, for the most part, anxiety attacks. She would feel as though she were trembling inside; become "horribly frightened" and convinced that she had heart disease; wake screaming from nightmares in which she would see her father in a casket or her husband and son killed; and frequently sigh without knowing why. She was not articulate, gave practically no meaningful details about her developmental history, and characterized herself as a fairly happy, well-adjusted, and socially not incapacitated person, with everything she really wished for. She was able to talk spontaneously only about her "spells," but no additional factual information was elicited about them. X-rays had previously shown a nonfunctioning gallbladder with stones, and a cholecystectomy had been recommended. She knew that the operation was necessary. In

addition, she wished treatment so as not to feel compelled to toss and squirm half the night through, night after night, before falling asleep.

It was suggested that she concentrate on this trembling inside herself of which she complained so much. However, so it was added, with every breath she drew, with every second that passed, she would grow more and more relaxed, more and more relaxed, so relaxed, so completely relaxed that, if she wished, she could fall asleep. "With some patients," the therapist added, "this takes two or three minutes—and with some, much more. Just breathe on, just breathe on, thinking only of this trembling inside you; breathing deeply and gently, deeply and gently, deeply and gently." No other suggestion was made. Lid-paralysis was not suggested. This was repeated over and over again, and the cadence of the hypnotist's statements was timed to her respiratory rhythm. Within four minutes her eyes had closed. She looked as though she were sound asleep.

The therapist began to speak in a low, relaxed tone. "You've had a number of symptoms, Mrs. G," he stated. "You've come here with female trouble, and with what seems to be a bad gall bladder, and with what you think is heart disease. Think only of these symptoms, of nothing but these symptoms. . . . Begin feeling them now. . . . There's something that's common to them all. There's something that's common to them all. Try to feel it. Try to feel it. Feel it, *FEEL IT*, feel it more and more intensely, more and more intensely, until you feel it so strongly that you know it for what it is. This symptom of yours, this main symptom of yours, is getting stronger and stronger now, stronger and stronger, stronger and stronger still. Feel it, FEEL IT, FEEL IT now."

At this she began to tremble. "I'm shaking and I'm trembling" she almost stuttered, but in a low voice, "I don't know why. And that's how I feel all the time." Tears began to flow silently from her eyes. There was no audible sobbing on her part.

"If you'd like to stop trembling now," the therapist stated, "you can. Your symptom will disappear, if you really wish it to, but whatever it stands for, whatever is back of it, whatever it covers up, whatever it's really about, will come to the surface right now. You're strong enough to face it, whatever it is. If you really wish it—it's up to you to decide—your symptom will disappear, but whatever emotion it covers, whatever it's really about, will come to the surface now. You'll know it for what it really is. As I count to three, if you really wish to, if you really wish to know, if you really wish to get treated for it, your symptom will disappear, but whatever it covers up, whatever it stands for, will come to the surface—and we'll see it, we'll see it for what it really is."

At this she was 10 years of age, extremely frightened, nauseated, afraid she was bleeding to death, not realizing that her periods were starting or what they were. A moment later, she was spontaneously abreacting a rape, extremely frightened again, nauseated, and, again, afraid that she was bleeding to death. It was "this same sensation," so she later explained, that she invariably felt not only on intercourse but also whenever her husband seemed to be growing "tender" toward her.

It should be noted that her anxiety manifested itself when it was hypnotically suggested that she concentrate on whatever was common to her cardiac, digestive, and urogenital symptoms. When her underlying emotion of the moment was then hypnotically intensified, it gave rise to the enactment of what emotionally to her was the same repetitive traumatic event. Much more than this was involved, however.

Other factors and other problems will become apparent from even a cursory study of that part of her case protocol which has been abstracted. We feel that in the hypnotic interpersonal relationship, full-blown transference phenomena may develop rapidly, at times within hours or even minutes (Fisher, 1953; Gill, unpublished article; MacAlpine, 1950, Nunberg, 1951). This will be developed in detail in another paper now under consideration. When this patient, however, was told, "Feel it, *feel it*, FEEL IT, more and more intensely," we were obviously on a "fishing expedition," working in the dark, not knowing what was involved, and hoping that something meaningful, no matter what, that could be utilized, would be stirred up. This technique can be exceedingly effective with some patients. Others may be told that, in addition to feeling "it" more and more intensely, they will be interested and curious about knowing what "it" is, but they will not know this until at a time and in a place, no matter when or where, that they wish to and which will be most helpful, therapeutically, to them. One patient, [patient of M.H.E.] for example, stated that she could not tell us, either in the trance state or on a conscious level, what her trouble was. The history which she gave seemed barren of any lead. She was therefore told, while in a trance, that whatever her problem was, she would feel it with increasing intensity, but only at what for her would be both the right time and the right place. This was repeated during half a dozen trance sessions, after which she stated, "I have something utterly silly to tell you. I do my own washing. But my living expenses have been terrible because I never wear a pair of panties more than once. I always take them off in the dark and throw them in the trash can. I never look at them again. The other day I felt the need for a bowel movement, and I felt it very strongly."

"I was in the bathroom at the time. While I was sitting on the toilet, I suddenly realized that I used the bathroom very little. Since childhood I have been soiling my pants and hiding it from myself, and that is silly. Now I can feel it in the right place at the right time, and I wonder what I will do with the three or four dozen pairs of panties I have in stock." It later developed that she took from one to three baths each day. This had always been a nuisance to her. Her bath compulsion has now disappeared.

Even when the psychiatrist goes on such "fishing expeditions" in the dark, if his words be well planned and carefully chosen, his patients will understand and relate their meaning specifically to their own problems. It is not necessary to know what it is that the patient knows. Somewhere in the patient's unconscious there is understanding, just as there is under-standing of—and at the same time resistance to the recognition of—the meaning of even the most anxiety-ridden dream. The therapist's permissive attitude, of being willing to let his patient know but without himself knowing until and unless the patient is ready and wishes him to, serves to make it possible for some patients to place whatever meaning to their symptoms seems to them at the time therapeutically necessary. However, it is of prime importance for the therapist to make it clear, somehow, to the

patient that the right, the correct, the concrete, the specific meaning, applicable at that particular time, be placed on his generalities.

If this be done, the psychiatrist does not fall into the trap, so frequently set—and not only by patients poorly motivated for treatment—of trying to do too much for the patient too quickly. The patient can be relied upon to fit the jigsaw puzzle together and, in point of fact, should have joint responsibility with the therapist for doing so.

Occasionally, when specific investigatory procedures are decided upon, the adaptive aspects of the patient's symptom or symptoms may be emphasized. Or their defensive functions may become apparent. Disguised acting-out frequently takes place. With the unmasking of symptoms, the basic conflict or even personality structure may at times be apparent. This is especially true of those patients whose neurotic symptoms make it possible for them to keep their underlying psychosis in check so that, as a result, they are enabled to continue making, at least at times, a not too inadequate social adjustment.

To illustrate:

One of our patients with torticollis [patient of H.R] could not meaningfully be investigated by any of the techniques so far described. During the consultation session he answered questions almost monosyllabically. He made no spontaneous comments. According to his referring psychiatrist, he had been inaccessible to therapy because of the narcissistic gratification which he gained from his apparent organic disease. Since he had been referred specifically for investigation and, if indicated, for treatment under hypnosis, he was hypnotized by an eye-fixation method. Direct suggestion to the effect that, if he wished, his neck could—it will be noticed that the word "*would*" was not used—revert to the midline, was ineffective. At this he stated that he felt "disappointed, frustrated, hopeless," and with nothing any more that he really wished to do.

"That seems to be your feeling here," the therapist agreed, "frustrated and hopeless. And yet, there must have been a time when there was something you really wished to do—and enjoyed doing. As I count from one to ten, you'll pass back through time, back through time, to that other time when there was something you really wished to do—and enjoyed doing. One—back through time, back through time, to that other time when there was something you wanted to do, something you very much wanted to do—and enjoyed doing. Two—back through time, back through time, to that other time when there was something you very much wanted to do, something you exerted your every energy to do—and enjoyed doing. Three—" etc. The suggestion was reinforced in various ways until the count of ten had been reached.

At this he rose from the chair, strode to the middle of the room, nodded to left and right, smiled, lifted his right hand, and made an impassioned plea for blood donors to the local Red Cross. This, as it developed, was an actual speech which he had made five years previously. It was, in fact, rather good. It lasted about 15 minutes. During this, his head turned at times toward both the right and the left. It frequently was in the midline. After he had finished, he seated himself, smiling, pleased, obviously enjoying the applause. His

head remained in the midline. He was then hypnotically progressed through time (with the one suggestion, however, that his head remain in its present position), at first year by year, then month by month and finally week by week, into the present. His head stayed in the midline, not fixedly but naturally so, without obvious effort on his part.

After he had been hypnotically returned to the present, he remained silent for about five minutes. The therapist remained silent also. He then began whispering, "That c.s. bastard's been telling everybody I'm a c.s. I'd like to kill him. But he's pushed invisible wires into me. So if I do, I'll turn into a c.s. myself. But if *you'll* suck him off, they'll melt away—and I'll be free to kill him. Won't you? *Please*!"

So long as his neck remained in the midline, he was clinically paranoid and psychotic. His productions remained on this level. When, however, on direct hypnotic suggestion his neck again twisted to the extreme left, this paranoid material was no longer evident and he became amnestic for it, even though he was still hypnotized and no suggestion to this effect had been made.

Although his torticollis made it impossible for him to continue practicing his profession, it seemed inadvisable at this particular time to attempt to deprive him of his symptom, since it appeared probable that, if this were done, he would develop in its stead a clinically paranoid psychosis for which institutionalization might be mandatory. This patient, incidentally, after leaving Baltimore saw a surgeon who "cured" his torticollis by operating on him. According to Garnett and Elberlik (1954), who have seen and followed this patient, he did not become psychotic, as we could have expected, although he no longer, at least at first, was able to take recourse in this wry neck of his. The symptom, incidentally, was reprecipitated a few months later. An attempt will be made to get a meaningful follow-up on the type of adjustment which he later on finds it possible to make.

Whether with a patient like this it might, in the last analysis, be most helpful to rob him hypnotically of his defenses so that he could be treated, if he could effectively be so treated, by the type of technique developed by John Rosen (1953), is something about which, without such a follow-up, we at this stage of our research are not qualified even to hazard a guess, nor did we feel it indicated to make the necessary investigation at the time we saw him. The danger to this patient in circumventing symptom-formation by acting-out seemed much too great. What his surgical "cure" involved, and what it had meant to him in fantasy, can only be surmised.

With another type of patient, however, and especially with the patient whose drug addiction is on a schizophrenically depressive, potentially suicidal basis, we think that research in this particular direction may well be warranted, since the symptom of drug addiction may be much worse in its effect than the disease process which it masks and perhaps holds in check, and since with its removal the underlying disease process itself may become accessible to treatment. We feel, at least, that this warrants investigation.

It would seem impossible to overemphasize those dangers which potentially could be involved in the use of investigatory techniques like these. If they are utilized, the patient with a "neurotic schizophrenic" reaction must be given enough concurrent support to abort or, rather, to prevent a clinically psychotic shattering of his ego. And for patients with organic or so-called psychosomatic disease, it seems necessary to proceed at an exceedingly slow and cautious pace: the possibility of precipitating a psychotic episode at times is so pronounced, even if insistence be only on the recall of forgotten memories, that many psychiatrists hesitate or refuse to accept such patients for treatment—and unless an eventuality such as this is anticipated and adequate safeguards taken, such patients can become much more seriously ill emotionally if they are investigated by the hypno-diagnostic techniques described in this article. On the other hand, if the psychiatrist is well-trained and if adequate precautions are taken, these dangers can be circumvented and patients who otherwise would receive no help can be helped—and perhaps helped a great deal.

One of our patients was a veteran in his mid-twenties [patient of H.R.] who had developed a rather severe ulcerative colitis. He was first seen four years ago. We felt that his colitis was serving as a suicidal equivalent, and therefore recommended that he make arrangements for comparatively intensive psychotherapy. Instead, he decided on supportive medical treatment from his gastroenterologist. His colitis went from bad to worse. It ultimately reached the point of necessitating V.A. hospitalization, five months later, for an ileostomy. His gastroenterologist and his surgeon both felt that the operation was mandatory. His colon, they stated, looked like a "red hot" appendix.

The problems involved were discussed with the chief of the medical service and the surgeons, and it was agreed that during the following month our total consultation time at the hospital would be devoted to an attempt to help him desire psychiatric treatment. This was the only psychotherapeutic goal set. Surgery was therefore postponed, although outside consultants were called in to help residents sales-talk, bludgeon, and threaten him to request it. They were unsuccessful.

Within six weeks he reached the point of being ready and willing to accept psychiatric treatment. He was therefore transferred on voluntary commitment, and at his own request, to another V.A. hospital, where for several months he received fairly intensive psychotherapy. He became well enough to leave the hospital, was seen on an outpatient basis for several more months, was not thought to have sufficient motivation for actually intensive psychotherapy, and was therefore carried supportively for some time.

Three and a half years later he requested an emergency appointment. "I am," so he stated, "losing control of my bowels and soiling my underwear almost every day." He explained that since he was a salesman making only $75 a week, he wished just treatment enough to make it unnecessary for him to continue losing bowel control while outdoors. "I don't wish to let it come out!" he emphatically stated.

He was rapidly hypnotized by an eye-fixation method to a trance state deep enough for amnesia to be suggested, and then told that he had the choice of keeping "it" in or not as

he himself wished; but that the choice was his, and his alone, of letting "it" come out or of holding "it" in. So far as possible his exact words were used. It seems obvious that when he used the word "it," he was referring to his bowel movements; but it seemed worth probing in the direction in which probing was being attempted, since otherwise, so far as could be judged, we would be stymied.

Immediately after this suggestion had been made, he began squirming around and, while crying convulsively, shouted at the top of his voice, "I won't! I won't!"

"You don't have to, if you don't wish to," the psychiatrist agreed. "It's entirely up to you." At this he began swallowing rapidly. He then got on his knees in the middle of the office floor, made movements which could be interpreted as pulling down a zipper, went through the motions of taking something in his hand, pulled his mouth over to it, and began sucking rapidly and forcibly. He suddenly again began shouting, "Blow storm! Blow storm!" went over to the couch, lay upon it, kept moving his lips in forced and pronounced sucking movements, laughed and sobbed alternatively, became silent, and then gradually grew relaxed. The session came to an end after he was told that he could remember what had transpired or not, as he himself wished, but that the choice was his and his alone. He became amnestic for this abreaction, and, incidentally, still has no memory of it.

He was seen twice the following week. On both occasions he lay on the couch, was hypnotized by the same eye-fixation method but to a light trance only, and was told that the psychiatrist would remain silent as he stated whatever came into his mind. He was also told that he would remember everything that took place, and everything that he said, during these two sessions. He was able to think only of "Blow storm! Blowstorm!" For months he had had a "terrific desire" for cunnilingus, but had never had courage enough to try it. But that had had nothing to do with his symptoms, or so he stated. What he most wanted out of treatment was to get rid of them, and to be able to lead a normal life with marriage and with children, even though he didn't know any girl he'd like to marry. By now, incidentally, he was no longer soiling his clothes.

He was scheduled to be seen twice the following week, but unfortunately contracted one of the "virus flu's" that were so common at the time. Previously, whenever he had had a cold, so he explained, he would lose complete control of his bowels. For some reason, perhaps related to therapy or perhaps not, he was now able to control them. This was discussed with him in detail two weeks later when he was next seen.

This session was completely on a nonhypnotic level. Immediately after entering the office, he wished to know what the therapist would do himself, if he had his symptoms—I would wish intensive therapy, probably analytic but most certainly analytically oriented (Cushing, 1953). He wished this but could not afford it. He would have to ask his uncle for that much money, and he'd rather die than do that. He could get it, of course, if he really needed it, but he'd rather die. Anyhow, he was no longer that sick! And he had just bought a $3,000 automobile. If it came to a choice between paying a psychiatrist or buying a car, he preferred the car. All that he really wished, and he was exceedingly frank

about it, was to be seen on a twice-a-week basis for the next month, so that he could get his symptoms completely under control. If it became necessary to have treatment every once in a while, in the future as in the past, he would feel satisfied. It was therefore agreed that he would be seen on a twice-a-week basis during the following month.

The next session was an exceedingly dramatic and even melodramatic one. Once hypnotized and in a light trance state, he began panting, gave every overt evidence of pronounced anxiety, and then breathlessly exclaimed, "I'm thinking of a blow storm." He made no further comment about this, however, but stated instead that he was now thinking about a friend's wife, then about the wife of the psychiatrist who had previously treated him, and then about John, an effeminate acquaintance of his whose nose was the same shape as hers. He then began gagging, felt as if he had to rush to the lavatory to keep from vomiting over the office rug, and leaped from the couch in order to do so, only to find that his gagging had ceased. "I came in John's mouth," he explained, "and that's what made me gag." In the discussion which followed it became obvious that he knew he had not been having this particular acquaintance perform fellatio upon him, even though "it seemed real while it happened." This led to a discussion of the fact that when in the street in the course of his daily work he not infrequently experiences exactly the same reaction, but without the conscious homosexual fantasy, although nevertheless "I go through the exact same experience." And, so he continued, "Here's the angle—either I get a cramp or I gag. These are the two forms it takes. In conscious life, if I think I'm coming in John's mouth, I spit—and the moment it's out, I get release."

The session had practically come to an end by this time. He was therefore told that if he wished to remember this material, he could; but that if he did not, he need not. He was then dehypnotized on signal, and the material elicited during the session was briefly discussed with him on the conscious level. He remembered it completely and was able to discuss it in a meaningful way. He had now come into what seemed on the surface a fairly good treatment relationship.

This patient's underlying anger and rage did not come to the fore until later, at least not in a form accessible to therapy. It nevertheless was hinted at during the course of his rather melodramatic sexual acting-out.

This acting-out itself seems worthy of comment. It will be noted that his originally articulated conscious fantasies were those of cunnilingus. Under hypnosis the fantasy which, incidentally, he could remember, was that of fellatio performed upon him. His fantasies on a still deeper level, as evidenced by the acting-out for which he spontaneously became amnestic, were those in which he himself orally and actively engaged in the practice. And all of this, even in the early sessions, he somehow tied in with his colitis symptoms. The orality emphasized by Mary Cushing in her discussion of the psychoanalytic treatment of a patient with ulcerative colitis (1953) immediately comes to mind.

In our experience acting-out of this type frequently concerns itself with suppressed, as well as with repressed, desires. This seems especially true when masturbatory activity

manifests itself. Examples have already appeared in the literature. Apparent epileptic or asthmatic attacks, for instance, can be deliberately precipitated during hypno-diagnostic consultant sessions, and then blocked, after which the inevitably resultant anxiety can be repressed by direct verbal suggestion, so that underlying fantasies may erupt into conscious awareness even to the point of being acted out. As one would expect, attacks investigated up to the present in this way seem to consist of partially repressed erotic or aggressive drives with actual or substitutive motor defenses against their appearance (Rosen, 1953).

One patient, for instance, was a 20-year-old miner's wife [patient of H.R.] with a two-and-a-half year history of what had been diagnosed as "psychic epilepsy." She was referred for intensive neurological and neurosurgical investigation. No studies, however, yielded clear-cut results. A psychiatric evaluation was therefore requested. Because she had been "snowed under" by drugs during electro-encephalography, she was almost an hour late for the appointment. Her nurse at first had been unable to awaken her. Since she was groggy and all but asleep when she reached our office, hypnotic suggestion was utilized to awaken her to the point of making possible a meaningful psychiatric investigation. She then began to explain what her "periods" were like. It was obvious that by this slip of the tongue she was referring to her attacks. They had started, so she stated, "right after I graduated and was looking for a job. I'd feel like I was grinning—just a *silly* grin—and I couldn't control it, but I tried hard. And I always felt somebody was laughing at me, or looking at me. And that made me embarrassed. I always feel embarrassed with these attacks. But if I cough or laugh, I get over them. That's how I stop them. They wake me up, and I start hollering and trying to cry. And they're getting worse, so I get them four or five times a night now."

One of her attacks was then precipitated by the direct hypnotic suggestion that she have it. She opened her mouth, her whole body seemed to quiver, and she moaned. Her right hand went over her mouth, she began to cough, and the "attack" was aborted. She was next told that, at the count of 10, she would have another attack, but that there would be no coughing this time. She moaned; her body quivered, and her legs drew up under her. Both arms became stiff and rigid, and both fists were clenched and held in midair. Her head shook back and forth, as though in negation. Her eyes closed, and she seemed to frown. Her lips were so widely parted that one could see her tight-clenched teeth. After some eight minutes she suddenly went limp, seemed completely relaxed, and showed the "silly" grin she had previously described.

("You seem relaxed. Could you tell me what it is you're feeling?") She had had no feeling at all, either during the attack or after it, or so she said. At this, she was told at the count of five she would have another attack, and that this time she would feel, *really* feel, whatever emotion, whatever feeling, was *really* connected with it. The psychiatrist slowly counted to five. She became rigid, arms bent on elbows, hand and arms jerking rapidly back and forth, head jerking from side to side as though in negation, legs stiff but trembling.

("The attack will cease now as I count to five. It will cease when I count to five. One, two, three, four, five.") She suddenly relaxed, then began to tremble. She seemed fearful.

("As I count to five, your trembling will cease. There's no need to be afraid now. You can face it, whatever it is. One, two, three, four, five.") She seized one hand with the other. Her abdomen began heaving more and more rapidly and more and more violently. She suddenly put her right hand between her legs and for perhaps a minute and a half masturbated herself rapidly through her dress. This was followed by a long drawn-out sigh, after which she lay back on the couch, apparently completely relaxed, and with the same "silly" grin on her face.

After several minutes the psychiatrist asked, "We both know what this is now, don't we?" She nodded. So this meant that every time she had one of these attacks, she was playing with herself. . . . She remembered when she was very small and her brother was putting a snow suit on her. She had asked him if she could play with herself first, if he wouldn't tell her mother. He said he wouldn't. But he did. So her mother told her she would go to hell for it. . . . And now, every time she has one of these attacks, was that what she was doing? ... She was a Catholic, and it was a sin. What should she do? The subsequent discussion centered on her need for psychiatric treatment, and the advisability of her making the necessary arrangements to receive it.

With another patient [patient of M.H.E.] with a "silly grin," such acting-out was neither indicated nor necessary. This patient explained that these silly grinning periods of hers would come on at certain irregular intervals. While she was in a trance state, the psychiatrist discussed the duration of smiling, how it begins slowly and ends slowly, and how the person who smiles is pleased and feels better, as does everybody else. Since it is a very natural thing, so it was stated, it should never be called a grin, nor should it be termed silly, nor a dirty look, but it should be appreciated as one of the normal functions of the expression of the person, whether male or female. Somehow or other, the therapist added, there is an expression that is meaningful.

In her next trance this girl asked the psychiatrist to explain menstruation to her. She was asked if she wanted this on conscious or hypnotic levels. The girl's simple statement was, "I think probably I ought to know in both ways, so tell it to me now, and then awaken me and tell it to me again." Her "silly" grinning periods are now over. Her menstrual pain has disappeared. She no longer stays in bed three days each month with severe cramps. Her statement during her next period, when she walked into the office, was, "Doctor, I am a queen today."

During the past five years one of us has seen masturbatory responses, like the one shown by the first of these two patients with the so-called "silly" grins, in three other nonpsychotic hypnotized patients [patients of H.R.] (Rosen, 1953). He has, in addition, seen on the medical wards during the same period of time three patients whose psychoses had previously not been recognized, and who, during the consultation session, touched or otherwise digitally manipulated their genitals. Needless to say they were not hypnotized. Psychiatric hospitalization was recommended in each case.

It seems of parenthetic interest that patients with borderline schizophrenic reactions are applying more and more frequently for treatment under hypnosis. One patient, [patient of H.R.] for example, stated that she had no symptoms but was applying for psychiatric treatment under hypnosis because she wished to become even better adjusted and even healthier emotionally. Immediately after entering the office, she lay on the couch, bent legs over thighs and thighs over abdomen, and began moaning while making what to all intents and purposes seemed convulsive abdominal movements. She was at no time hypnotized. On questioning, it developed that she was spontaneously abreactin—without any suggestion by the therapist and without being hypnotized—the delivery of a child. When this was further investigated, it developed that she was fantasying going through the birth canal herself and being "reborn." She was showing, as it further developed, a catatonic reaction.

The schizophrenic patient can be said to have ready access to his unconscious. This is amply illustrated by the case material published, for instance, by Frieda Fromm-Reichmann (1950), by John Rosen (1953), and by others. The hypnotized neurotic patient, on the other hand, so we feel, may at times have ready access, not so much to his unconscious as to his preconscious. It is because of this that with selected patients symptoms and syndromes can readily be investigated by hypnotic techniques of the type described. Symptom origin occasionally may be rapidly correlated with life situations or traumatic events. Their symbolic significance, especially when homosexual, masturbatory, aggressive, or homicidal impulses are repressed, may become apparent (Seitz, 1953). Isolated affects, thoughts, or emotions, especially if phobic material is being dealt with, can be appropriately fused even in the conscious acting-out of a previously traumatic event. Or specific fantasies, likewise, may be acted out.

One patient, [patients of H.R.] for instance, with pseudocyesis was seen in emergency consultation after having wired mother and mother-in-law, both of whom lived in other states, to come immediately, since labor had started two weeks earlier than she had expected, and since she was now leaving for the hospital.

She came to the office under protest, walked over to the couch, and lay upon it, drawing both legs up under her. Because of her abdominal protuberance, she could easily have been taken for a pregnant patient.

The therapist remained silent. After three or four minutes she spontaneously began sobbing: "I don't want to kill myself! I'm not too unhappy at not having a child. But I don't think that I can live without one....

"I thought I was pregnant. I felt those movements, and I was so happy. I'd throw up my food and laugh about it. I went to a doctor—almost nine months ago—and he told me I was [pregnant]. Then I started spotting. So I went to Dr. A. He said, `If you are, it's too soon to tell!' I wondered why he didn't tell me, so I went to Dr. B. He said I was. Then, two months later, he gave me a test and said I wasn't. But I knew I was. So I watched my

diet and took care of myself. I feel life. I'm pregnant. I know I am!" And at this, she began sobbing convulsively.

As it developed, she had told her neighbors, her friends, and her relatives that she was pregnant. She had even told everybody the date on which she expected to enter the hospital for delivery. "I feel life inside me now," she insisted, "I'm about to have the baby. It won't be long now."

"And yet, every physician has told you you're not pregnant. Why do you think they've said this?"

She was silent about five minutes and then, very slowly, began to speak: "These past months I've been living in a dream world. I've planned and I've talked. I wish I were dead now. I couldn't do anything to myself—I'm Catholic—but I keep thinking of stepping in front of a car ... It's been four years ago last May, when my father died, and that's when I cried too much. And ever since *I've kept everything inside*. I didn't want to worry my Dad. We didn't have no mother. It's never bothered me, being so bottled up all my life, but I never really cried because my Dad would worry—except when the doctor said he had only 30 days to live. And he was buried on my first wedding anniversary." She was now sobbing convulsively. She then began to scream, "I'm going to have my baby! I'm going to have my baby!" And at this, she ceased speaking.

She was hypnotized at this point. Her legs spread apart on the couch; her knees bent; her thighs drew up over her abdomen; she began moaning and groaning; and then, during the next ten minutes, her buttocks and abdomen heaved up and down, back and forth, almost rhythmically. When asked what she was doing, she answered, "Having my child." The psychiatrist repeated, "Your—child? Are you sure?" Her body movements stopped at this point, she ceased groaning and moaning, and in an almost inaudible voice exclaimed, "No—not my child. It's my father I'm giving birth to—I need him so much." And at this, she became completely silent and motionless.

She then spontaneously added, while still hypnotized, that she knew intellectually she was not actually pregnant, but she felt she was. . . . However, she had now delivered—so she was no longer really pregnant!

Before the hypnotic session was terminated, this patient was told that she could remember everything that had taken place and everything she had said, provided she really wished to; but if she wished to, she could forget anything she had said or done while she was hypnotized, either in whole or in part. The hypnotic session was then terminated.

Actual acting-out of this type can not infrequently be circumvented by having the patient dream, while in a trance, whatever it is she really wishes, dreaming it very freely, very vividly, without need for inhibition, so that it becomes real to her. This dream method of acting things out can also be exceedingly effective. Because of the length of this article, and the simplicity of this technique, examples will not be given here.

DISCUSSION

In this paper we have stressed and illustrated various of the hypnotic techniques whereby symptom-function in both neurotic and psychotic patients can be evaluated. Parts of hypno-diagnostic sessions were quoted almost verbatim. Basic conflicts and even personality structure at times became apparent. No attempt has been made, however, to describe the course taken later in therapy by these patients. This will probably be done in a number of clinical papers dealing specifically with the individual patients involved. In this paper we have attempted to limit ourselves to a discussion of hypnotic and hypnotherapeutic investigatory techniques in the determining of symptom function.

With some patients functions served by neurotic symptoms seem almost conscious. They become obvious almost immediately on trance induction. No specific specialized hypnotic techniques seem necessary. One patient [patient of H.R.]with severe pruritus, for instance, who stated that she wanted nothing so much as the intercourse which nevertheless caused her intravaginal itch to become unbearable, was convinced that her only "cure" lay in obtaining a divorce. With other patients, on the other hand, this material is, of course, preconscious. This nevertheless may be elicited or acted out, again, merely on hypnotic induction. Our patient with pseudocyesis is a case in point. But with some patients, like the one with ulcerative colitis, specific key words must be seized upon and repeated before dynamics or function become experimentally clear. And with still other patients specialized hypnotic techniques must be utilized. These have been illustrated in detail during the preceding discussion.

When these techniques are utilized, however, a word of caution seems necessary. Regression, as Kris has stated, under certain circumstances can be in the service of the ego. However, the inept use of these techniques by diffidently trained or untrained psychiatrists, psychologists, or even self-ordained family counselors, who neither know nor realize what they are dealing with, can result in pronounced harm to the patient. Fantasy formation may be encouraged with psychotic patients, or the patient may, either by direct suggestion or by the mishandling of dynamic material, be enabled and pressed to consolidate defenses when such consolidation would be contraindicated. This does not constitute an objection per se to the use of radical hypnotic investigatory techniques. We do object, however, to the unlicensed and uncontrolled use of hypnosis by inept and untrained individuals who consider it a parlor trick and who utilize it either as a cloak for their own lack of adequate training in dynamic psychiatry or as a means of obtaining substitutive gratification for some of their own unresolved personality problems (Rosen, 1953).

It can readily be seen, for instance, that if specific precautions were not taken, some of our schizophrenic (preschizophrenic or psychoneurotic schizophrenic) patients who were making a fairly well-compensated social adjustment could utilize such techniques for the precipitation even of a catatonic state. Reality testing, with preservation and strengthening of the ego, rather than merely the abreactive induction of aggressive

phenomena, must always be the desideratum. On the other hand, with some psychotic patients this may, paradoxically enough, be of value.

To illustrate: the husband of one of our patients [patient of H.E.] thought, so he stated, that his wife was catatonic. He turned out to be a petty criminal, a voyeur, and a sexual exhibitionist. Shortly after he was arrested and sentenced, she asked why we kept roses floating up in the office. She knew that the psychiatrist was a hypnotist and, on entering the office, she had gone into a trance. She was told to let the roses float into a vase. They were then made, first to change color, then to change into a rosebush, but a rose bush which the psychiatrist had never seen. As a result of this, our patient described a little girl watching her father cut roses. After some months of treatment she would exclaim spontaneously, "Let me sit over there, and I will tell you what to do with those roses and with that little girl who is growing up." The roses dropped out. Her varied ways of spelling her name at different age levels came up. She would often discuss that hallucinated figure of hers, which bore different names, wore different clothes and was in different places according to the particular event described. High school adjustments ultimately came into play, and then college adjustments followed. She is no longer clinically psychotic, and is now able to hold a responsible position.

In a field as complex as that of human behavior it usually is extremely difficult and sometimes impossible to set up satisfactory experimental conditions for the investigation even of what may be assumed to be relatively simple phenomena (Wolberg, 1945). When behavioral patterns come under investigation, hypotheses can frequently be advanced but seldom validated (Brennan, 1949). Determination of symptom-function, unless the patient is under long-term therapy, is usually impossible. Nevertheless, with selected patients hypnotic techniques have already been utilized as potent therapeutic and experimental tools in the validating of previously described dynamic concepts. The most significant of these, in all probability, are Erickson's hypnotic experiments on the psychopathology of everyday life (1939), Erickson and Kubie's translations of the cryptic automatic writing of one hypnotic subject by another when in a trancelike, dissociated state (1940), Farber and Fisher's investigation of the interpretation of dreams not their own by hypnotized college students (1943), Wolberg's direct suggestions for material to be incorporated symbolically into dreams by his hypnotized patient (1945), and Rosen's studies of hypnotic fantasy-evocation and dramatization techniques, especially in a patient with severe pruritus vulvae (1953). Seitz' experiments, in addition, warrant careful study (1953).

It will be noted that a number of our patients abreacted spontaneously, occasionally in the present but at times by regressing to earlier life situations and behavioral patterns. In most of the illustrative cases this seemed to be on a compulsive basis.

While we feel that abreaction of this type may serve to make evident at least some of the functions which symptoms and symptom-complexes serve, nevertheless even here a word of caution seems necessary. These patients may somehow, perhaps not too rarely, find it possible to seize on the hypnotic relationship to rationalize to themselves their acting-out of suppressed or repressed desires. With a number of patients, this in all probability

constitutes a sexual advance toward the therapist, and must be considered as both an attempt at seducing him and an expression of unconscious sexual impulses which nevertheless are being utilized to mask, but without effectively disguising, pronounced underlying hostility and aggression-on one level against him, and on deeper levels against key figures in early childhood and infantile environments (Rosen, 1953; Wolberg, 1945).

Such acting-out, although for the moment serving to release tension and thereby provide emotional relief, solves no personality problems and as a result cannot be considered curative. It does to some extent, however, involve dynamic participation on the part of the patient, and may make—or help make—possible his active participation in the setting of the therapeutic goals to be attained, as well as his active collaboration later during the treatment process itself. A discussion of this, nevertheless, would be beyond the scope of this paper.

SUMMARY

1. Symptoms and even syndromes may subserve the repetitive enactment of traumatic events; may reproduce, instead, specific life situations; may satisfy repressed erotic and aggressive impulses; or may at one and the same time constitute defenses against, and punishment for, underlying instinctual drives. They may mask underlying schizophrenic reactions or hold suicidal depressions in check. They may serve these and other functions concurrently, or none, or any specific one or combination of them.

2. With selected patients under hypnosis symptom-function may be determined rapidly and in a therapeutic setting. Various techniques can be utilized. Attacks may be precipitated and then blocked, either by direct hypnotic suggestion or by regressing the patient to a period predating the onset of his disease, so that substitutive motor or other activity will be precipitated in a form accessible to the therapeutic investigation; attacks may be precipitated in slow motion, so that individual components can be therapeutically investigated in detail; dissociated states may be induced; dream acting-out may be suggested; or symptoms may be suggested away while emotions back of symptoms are concurrently intensified, so that, again, underlying dynamic material will immediately become accessible for therapy. Still other techniques may be utilized.

3. If treatment, as well as evaluation, is through these techniques, and if treatment is successful, it may be that the analogy of a log jam will be of value. The jam can usually be broken by pulling out one or two key logs. The rest then start falling into place—and the whole log jam disappears. This may be what happens, although to a limited extent, during therapy of this type.

4. Various of these techniques have been illustrated throughout this paper. Case histories however, have at times been distorted in order to maintain the anonymity of the patients involved.

Experimental Hypnotherapy in Tourette's Disease

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, April, 1965, 7, 325-331.

Two patients, both in their mid-thirties, one a married woman with three children, the other a married man without children, much to his regret, presented themselves for treatment for Tourette's Disease. Both had a history of a sudden acute onset, and both required therapy over a two-year period, the therapeutic sessions becoming progressively more infrequent as therapy continued. Both insistently demanded hypno-therapy and were convinced that it would be their salvation. For both the onset of the condition was acute and circumscribed and remarkably similar.

FIRST PATIENT

During the course of listening to a sermon one Sunday, this patient, the woman, had become horribly distressed to find herself unaccountably impelled to utter a variety of obscenities, particularly vulgarisms concerning body functions and sexual activity, all being ascribed to Jesus. She fought the overpowering vocal impulses desperately along with compelling desires to grimace, to gesticulate, and to posture. Her husband, noticing her distress, tried to make whispered inquiries, and this intensified her symptoms. She finally resorted to the measure of covering her mouth with handkerchiefs and shoving her fingers as far as she could into her throat. This resulted in retching, and she hastened to the ladies' lounge, shouting "Get out" to those who sympathetically came to her assistance. By turning on a faucet and a continuous flushing of the commode, she managed to cover-up a half-hour's exhaustive repetitious vulgar vocalizations. Fortunately, since she had the keys to the family automobile in her handbag, she managed to get to the car and then to drive a mile to reach home, racing the car engine in first gear to cover-up her continuous vocalizations. She locked herself in the bedroom and spent an exhausting afternoon in vocalizations, grimacing, and posturing, interrupting herself only enough to yell at her husband that she was all right, that she wanted solitude, to let her alone, that she would see him on the morrow. That evening, without having eaten lunch or dinner, she took a heavy dose of sedatives and managed to sleep.

The next morning she awakened in acute fright, wondering if she had developed a sudden psychosis. The compulsive vocalization was still present as well as the need to grimace, to gesticulate, and to posture. She yielded to these and desperately reviewed mentally possible measures of concealing, distorting into more acceptable forms, and passively yielding to the impulses so that she could pattern her symptomatic behavior into some less distressing form. Since she had met the author socially on a previous occasion, she made use of her bedroom telephone extension to solicit his aid. The content of her telephone call was practically diagnostic in its character.

A house call was made, and the husband was reassured after a fashion to permit some reasonable provisions to meet his wife's condition. He was distressed by the secrecy being maintained but yielded to the extreme violence of her demands issued through the bedroom door in halting phrases because of interspersed whispered obscenities.

She demanded hypnotherapy, about which she had read various glowing lay accounts. Despite the adverse nature of the situation the author agreed, but emphatically demanded that she yield completely in utter submission to his choice of procedure. Approximately two hours were spent because of her involuntary interruptions of the author in making certain that she agreed without any reservation to any therapeutic procedure the author had in mind. Innumerable seemingly outrageous possibilities were outlined to her to make certain that she understood that the psychotherapy in mind was by no means even remotely orthodox. As soon as she understood this fully, hypnotic induction was undertaken. All appropriate and fitting hypnotic suggestions were offered in the proper sequence and progression that the author's experience had disclosed to be most reasonably effective. However, those suggestions were embellished, interlarded, couched, and elaborated with obscenities, vulgarities, and profanities that far exceeded the worst she had uttered.

She was utterly appalled, horrified, and what was most important, completely silenced with a rigid fixation of her attention upon the author and the hypnotic suggestions being offered to her in such a peculiar emphatic fashion. (The fact that she knew the author well socially undoubtedly constituted a highly significant but not measurable factor in the total situation.) At all events, within 10 minutes she developed a profound somnambulistic hypnotic trance in which silence, passivity, and abject obedience were demanded and received. With urgency and calculated haste she was disoriented for time and place, suggestions of a state of fright, of complete obedience to, and of utter dependence upon, the author as the representation of all that was good, reliable, comforting, and helpful were emphatically given to her. Thereupon she was reoriented with extreme care to avoid any possible traumatic event to a time two years in the past with emphatic instruction to remain so oriented or regressed after awakening from the trance despite all disturbing and wonder-provoking stimuli of her surroundings.

As soon as the author felt relatively secure in his control of the situation, the husband was summoned. Fortunately, he was a college graduate with a considerable background in psychology. Rapport with his wife was established for him.

The first measure with him was to inform him extensively concerning the syndrome of Gilles de la Tourette's Disease and to assure him that he would be furnished with references in the literature so that he could understand the peculiarity of his wife's affliction. This was done in his wife's presence in her regressed state, and she was informed of the possibility that sometime in the remote future she might develop such a condition. While she was thinking this over in the trance state, her husband was separately informed of the true state of affairs and of the regressed trance state of his wife as a temporary measure of controlling her problem. In his distress he agreed to let the

author attempt experimental therapy, since the author could not inform him of any adequate therapeutic procedure.

The therapy worked out then and instituted was:

1. Informing the patient in the trance state that "in the future" she would be so afflicted.
2. Informing the patient that she was in a somnambulistic regressed trance state and that this was serving to control her problem, which was an actuality in her ordinary waking state.
3. Seeking the patient's cooperation in devising some measure of control of the symptoms.
4. Emphasizing that, since hypnotic regression had effected a temporary relief, hypnotic suggestion could and would undoubtedly be efficacious.
5. Suggesting that the patient be content with minor progress in control and improvement rather than demanding a miraculous cure.
6. Securing her absolute promise to abide by both her condition and the modifications of it that would be suggested.
7. A long discussion concerning the type of motor components that she would willingly permit and the nature of the utterances in regard to both content and volume.
8. The absolute need for her to remain an excellent hypnotic subject for either the author or any other therapist who might take responsibility for her.
9. The absolute need for her absolute obedience—instant, complete, and without question—upon the slightest request, whether she was awake or in the trance state, and that this obedience would be expected even when she personally objected to instruction.
10. The teaching of the patient of a series of 10 posthypnotic cues by which to develop a trance state and a regression state. (The author did not want to rely upon one or two such cues.)

As this instruction of the patient progressed, it became increasingly difficult to maintain the trance state as well as the state of regression. The patient became increasingly distressed about the author's description of her condition; she obviously did not want to believe his statements, yet the demeanor of her husband, with whom she had been given needed rapport, as well as the emphasis with which she was being given instructions, were most compelling of her belief and acceptance. However, it was apparent that this trance state could not be maintained much longer, and a compromise was offered to the effect that she would arouse from the trance state to remain in the waking state of awareness for whatever time she wished, not to exceed an hour, and that she would then develop a profound somnambulistic regressed trance state. To this she agreed.

She awakened only to burst into a torrent of characteristic utterances accompanied by posturing and gesticulations.

After about 20 minutes of this she managed to express a wish that the author would or could in some way take charge of her situation. This was followed by further uncontrollable behavior and then a brief pause, during which another trance state was induced with explicit and emphatic instructions that henceforth at the first sense of uncontrollable behavior on her part she would immediately regress in age to a period of two years in the past. She accepted this instruction with a facial expression of hope.

After a second brief orientation of her husband concerning her condition, during which the patient listened attentively, attention was given to the task of outlining further the course of therapy for her. This was to include: (1) periodic visits to the author's office; (2) the systematic learning of a pattern of behavior that would meet the compulsions of her illness and yet enable reasonable daily life adjustments. Blind and complete acceptance of these two requirements was demanded and finally agreed to in a most binding fashion.

It was then explained that:

1. She was to continue her symptomatic behavior in a "satisfying" but "better" manner. That is, since her manifestations would occur in either the presence or absence of others, her symptomatology could be entirely adequate if she alone knew of it. Thus, her utterances need not be so loud, since she could hear even the softest of whispers as well as the loudest of shouts. Additionally, the posturing could also be minimal, since she could be aware of it and any associated thoughts, however minimal the postural movements were. There was added the explanation that her illness, however severe, must necessarily be inconstant in manifestation, since she would have to eat, to drink, and to sleep, and that each of these activities would constitute temporary barriers to symptom manifestation. Hence, thoughtful and careful consideration of these facts would permit realization that there could be other periods of symptom-freedom and hence that extensive therapeutic procedures could be instituted. Much repetition and explanation of these ideas had to be given together with emphatic instruction that all understandings presented were to become an integral part of her waking state regardless of symptom-distress.

2. Systematic instruction was then given and practice insisted upon in uttering in low tones and whispers both her own utterances and some of those the author had voiced. This was demanded most cautiously, with full instruction that a regressed state would develop instantaneously if the author anticipated difficulty for her. This anticipated difficulty, not explained to her, was the possibility of her arousal from the trance and loss of control of the situation. Perhaps unnecessarily, the author did elicit the regressed state several times as a precautionary measure. Also, she was to develop new gesticulations more awkward and less meaningful to the observer than were the "grinds and bumps" which constituted a part of her motor manifestations. Coughing, gasping, choking, yawning, if necessary learning how to belch voluntarily, crossing her legs violently, or whatever else she felt

could be bearable were suggested, and she was made to demonstrate the suggested acts.

The patient became most meditative and subdued, and when a regressed state was induced, she was asked to view herself in the future in a thoughtful situation with the author's right hand on her left shoulder and holding her left hand with his left hand. In this way it was possible to pseudo-orient her to the future while in the regressed state with physical contact constituting a part of the conditioning process. Thus, the composure of her regressed state allowed her comfortably to speculate upon her "future needs" as seem indicated by her visual hallucination of herself in suggested special settings, including her actual present condition.

In elaborate detail many ideas about her general and symptomatic behavior were worked out in relation to her home, her family, and her various obligations. Provision was made for her family to leave immediately on a vacation for two weeks with a complete cancellation of all social obligations and all incoming telephone calls. Thus the patient was ensured privacy and opportunity to practice new patterns of behavior.

She made regular visits to the author, but instead of racing the engine, she turned on the car radio to high volume and yielded completely to her vocalizations. Thus, she "got it out of my system" to permit therapeutic interviews with the author. These were barren so far as understandings or information were concerned, but they were most useful in augmenting her ability to modify, control, and direct her symptomatology.

One significant oversight in the proposed therapy was disclosed by the events of one night about a month later. She awakened suddenly and disturbed the whole household by a violent manifestation of her symptoms. When interviewed in both waking and trance states the next day, the explanation was that she had to have "escape valves" as a "safety measure." This led to the provision that weekly, biweekly, or even less frequently she would go into the garage, close it, turn on the car radio full volume, and "let loose with everything."

At first this occurred weekly, but slowly came to be more and more infrequent until the practice was discontinued.

Therapy was continued for two years, first at weekly intervals, then finally at monthly intervals. That the last year of therapy was necessary was questionable in the author's mind. The patient, however, felt that she would feel more comfortable if therapy were continued, even though it was slowly transformed into essentially little more than social visits.

More than five years have elapsed since therapy was discontinued. The patient is free of her symptoms, and has been wholly so since the completion of the first year of therapy. A year ago (1963) she sought an interview with the author on other matters, reminisced with amusement about her previous condition, and declared, "I can say all those things and make all of those movements voluntarily without any distress. Let me show you."

She did most comprehensively and then with a laugh remarked, “I am not sure whether some of the things I just said were mine or some of the embellishments with which you horrified me so terribly. Have you or any other psychiatrists any understanding of what an awful mental state descended upon me that time? It makes me shudder to look back upon it, but I remember you telling me that other people got it too. It’s really too awful to think about, but I wanted you to be sure I’m over it.” (At this writing, she still is.)

Questioning of her during therapy and subsequently of why therapy seemed effective elicited no information. The only conclusion was that it was a blind effort that fortunately succeeded with her.

SECOND PATIENT

A year after therapy with this patient was discontinued, a second, much less severe patient presented himself. His statement was that he was on his way to church one Sunday when, as he caught sight of the church building, he found himself involuntarily bursting into incredible obscenities and profanities with grinding of his teeth and much shaking of his fists. Little description was needed of his symptomatology, since he punctuated the narration of his history with it.

At first only the sight of his own church led to symptom manifestation, then other churches, then the sight of anyone in religious garb. By occupation he was a bartender in an exclusive bar; but as his symptoms continued he discovered that the utterance of a single word of profanity would precipitate an uncontrollable explosion of a minute or two duration from him. At first he avoided going to church, then to streets where there were churches. Finally he had to resign his lucrative position and secure employment in a rough-and-tumble tavern where he soon became favorably known as “The Cussing Bartender” and where his language and behavior attracted a certain clientele, since his episodes were brief though repetitious. In fact, it became a challenge for the tavern’s clientele to think up new precipitating phrases which the patient found himself unable to keep from incorporating in his own vocalizations.

His wife resented his reduced income, swore at him in her anger, and became suddenly and painfully aware of her husband’s affliction, which he had kept secret from her, enabled to do so by his working hours and careful avoidance of her. She insisted upon psychiatric therapy without delay.

As the patient related his problem, the other patient was called to mind. He differed in that his manifestations seemed to require a “triggering” by sight of something pertaining to religion, religious thinking, or hearing profane and obscene utterances by others.

The patient was then questioned about his willingness to undertake hypnotherapy, and he declared that that was his purpose in seeking the author’s assistance.

A satisfactory deep trance was elicited with not too much time or effort being required, and an explanation was given to him in the trance state that before treatment of his

problem, there would be undertaken an extensive educational project that would enable more rapid therapy once it was begun. He was reluctant about this since he desired therapy at once, but finally he yielded to the author's persuasions.

Thereupon, a systematic program was instituted to train this patient in selective sensory exclusion of stimuli, visual and auditory, and to establish psychological blocks to render various words "nonsense syllables." This was carefully explained to his wife, And her cooperation was won; the patient's own high intelligence and psychological sophistication were of significant value in promoting therapeutic intentions.

Extensive inquiry elicited a satisfactory list of evocative stimuli, and slowly the patient learned a selective blindness that allowed him to see a church as, for example, a "white building," a nun as "a woman dressed in a ridiculous-looking black dress," to listen to oaths and obscenities as "meaningless nonsense syllables," to regard Sunday as his day off duty, and to look upon his wife's church attendance as a special feminine social activity. A thoughtless asking of grace at an evening meal he regarded with confusion and bewilderment, developed a headache, and went to bed without eating. That incident terminated that mealtime practice. Fortunately, there were no children, and the social activities of the man and his wife together were extremely limited.

As for religious thoughts of his own, the patient was extensively instructed in the matter of nonsense syllable experimentation and given to understand that he, too, could devise nonsense syllables. In this way any religious thoughts coming to his mind became transformed into nonsense syllables.

He was seen regularly in the office biweekly for about three months. During this time he was instructed in the trance state to put into force his hypnotically acquired learnings, not constantly, but at first infrequently and then with increasing frequency, so that his symptoms would occur with decreasing frequency. The patient was most cooperative, and by the end of three months he had lost his job as "The Cussing Bartender." However, he secured reemployment on probation in his original position.

After the three months he was seen with decreasing frequency, until he reported not oftener than once a month at the end of two and one-half years of therapy. During the last nine months of therapy much time was given to "There are lost memories coming back to me. I lost them some way, but now they are coming back and I like them." Cautious questioning disclosed that the word service had a "special, very special, really wonderful meaning, but just what I don't know. It has something to do with what I want to call `sacred,' whatever that means." Bit by bit, during the last nine months, he was allowed to recover from his sensory inhibitions and induced aphasia but was cautioned repeatedly in the trance state to do this "comfortably, happily."

A year after discontinuance of therapy he entered the office to request that he be informed why he had ever undertaken psychiatric therapy, why his regular visits were such a blank in his memory, and why his wife would not discuss the matter with him despite the fact that her manner suggested full knowledge on her part.

He consented to go into a trance, and in the trance he was asked the advisability of giving him full conscious information. He assured the author earnestly that all would be well, but he agreed to redevelop a trance state upon the occurrence of any emotional distress.

Aroused, he listened most attentively, demonstrated a slow spontaneous recollection of his original problem, developed a sudden trance in which he explained that his memories horrified him but that he was no longer a victim of that disorder, that he would not be more than distressed by his memories if awakened, that there would be no recurrence. He was awakened, showed reluctance about further discussion, but did assert that he remembered fully and was certain he would not again be so afflicted.

A year later he reported that, shortly after the previous visit, he had begun to go to church without difficulty and that he had had no further symptomatology. He, too, inquired into the author's understandings of his illness and expressed regret that the author knew so little about the condition.

OTHER EXPERIENCE

The author has seen professionally two other cases. One was a 13-year-old boy and the other was a 16-year-old girl. Both had fairly acute onsets but not as sudden as the two patients reported above. In both instances efforts made to treat the patients were utter failures. In all, for each there were no more than four interviews, and no rapport of any sort could be established despite the fact that both patients were of good intelligence. Their parents were demanding, frightened, bewildered, and embarrassed, and even they could not be handled satisfactorily. They wanted immediate results, a prescription preferably, and were not interested in any systematic attempt at therapy. They sought aid elsewhere, completely dissatisfied with the author. The eventual outcome is not known for either of these patients.

SUMMARY

A report is given of the experimental hypnotherapeutic treatment of Gilles de la Tourette's Disease or Syndrome. The experimental therapy consisted of using simple hypnotic trances and hypnotic regression to permit a reeducation of the two patients in a progressively greater control of their condition and with a progressive alteration of symptomatology to render it less severe. Both patients made a recovery in approximately a two-year period. No understanding of the causation of the onset of the condition was discovered in either instance. For further references, see Chapel et al., (Chapel, J., Brown, N., & Jenkins, R., 1964, Tourette's disease: Symptomatic relief with haloperidol. *American Journal of Psychiatry*, *121,* 60-70.), and Eisendberg et al., (Eisenberg, L., Ascher, E., & Kanner, L., 1959, A clinical study of Gilles de la Tourette's disease (maladie des tics) in children. *American Journal of Psychiatry*, *115,* 715-723.).

Hypnotherapy: The Patients Right to Both Success and Failure

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, January, 1965, 7, 254-257.

Many times the author has been asked to publish an account of a failure in hypnotherapy when success was fully anticipated. To date the author has hesitated to do so, since there was no understanding of why the failures occurred (and there have been failures, as one should expect). Why this is so seems best explained in terms of either the therapist's lack of understandings or the patient's own purposes.

The following case history is cited as an excellent example of a failure despite a partial success that still persists but which derived from neither hypnotherapy nor psychotherapy but from an unconventional procedure which changed a serious symptom into a primary nuisance to the patient with its subsequent abolishment. Such could scarcely be considered therapy; it was no more than a symptom removal that enabled him to function adequately within his own restricted limits.

He was an excellent hypnotic subject, but he was passive. He "never got around to it" in carrying out posthypnotic suggestions. Questioning him in the trance state for his history was as futile as in the waking state. He liked to "rest" in the trance state. No measure seemed to stir him into even responsive replies to simple questions. Thus, when asked if he had siblings, he replied "yet." When asked, "How many?" the reply was, "Dottie." In the waking state he gave as his siblings, "Joe."

All he wanted was a symptom correction, nothing more, and while much effort was made by this author and several other psychiatrists, no adequate history was ever obtained from him, although an adequate history was obtained by several psychiatrists from his sister "Dottie."

When first seen by this author, the patient had been shopping around, seeing various psychiatrists, all of whom were requested to undertake the removal of a single symptom and all of whom agreed that he needed intensive psychotherapy for his obviously schizoid condition. Only the author agreed finally to give the therapy requested, believing that it might lead the patient into accepting further treatment. Even so, he continued to shop around to inquire of others if he should have his symptom removed. Several told him to go ahead and that he might want to enter therapy. Accordingly, he returned to the author and made his firm restricted demand for the removal of a single annoying symptom, and he was accepted as such a patient.

Neither direct nor indirect hypnotic suggestion was of any avail. The patient remained passive in relation to all hypnotherapy. A nonhypnotic psychotherapeutic approach was equally ineffectual. Thereupon, the author devised the following procedure, which was then presented to him in much the same way as one would present a prescription saying, "Take this to the druggist and get it filled."

This patient's demand of the author was a symptomatic cure of what he called a phobia. Every effort was made to induce the patient to recognize that, though his "phobia" needed correction, he was a decidedly maladjusted person who came from a large family of children, all of whom were, with one exception, neurotic or schizophrenic, and that two of his siblings had committed suicide in state mental hospitals. The patient, a first-semester college student, declared that, while he had a schizoid personality and that he felt personally inferior, he wanted and would accept therapy for only one thing, his "phobia." This "phobia" was that he could drive a car on only certain streets in Phoenix and Tempe, and that he could reach Tempe (11 miles away) only by following one particular highway. There was one other highway by which he had often tried to leave Phoenix, but he could go no farther than the city limits. If his car passed beyond the city limits sign, he would become dizzy and nauseated; after either vomiting or retching, he would then faint and sometimes remain in that state 10 or 15 minutes.

His brother, his brother-in-law, and various friends had many times gone with him on that highway, but whether he was driving or they were made no difference. If they were driving and kept on going until he recovered from his faint, he would again faint and continue to repeat his fainting if they continued to drive on. The same thing occurred within the city limits of both Tempe and Phoenix, and he often had to park his car on a main street and walk a few blocks to reach certain destinations. On all the main highways except one leading out of Phoenix, he could not even walk beyond the city limits sign without fainting, even though he might be in the company of relatives or friends. For this problem and this problem alone he demanded therapy. Other psychiatrists had refused to accept him on his terms, declaring that they could not help him when he placed restrictions on therapy.

This author told him that he would be accepted as a patient, his terms abided by, but that if he benefited, it was hoped that he would accept further therapy. Since the patient was obdurate and demanding in his attitude, he was given a solemn promise that the author would not make any attempt other than to free him of his car driving problem. Several hours were spent with him in letting him convince himself that the author meant exactly what he said, and in securing from the author an absolute promise that he would do exactly as the patient instructed him.

This promise had been given without any details of procedure being disclosed to the patient. When the promise was finally accepted by the patient, he was handed an envelope bearing in large plain letters, "Anybody curious about me, please read the contents of this envelope." Inside, on the author's letterhead stationery, was the simple statement: "This man is my patient and he is obeying medical orders. If you find that he

is unconscious, wait at least 15 minutes. He will then recover and will answer your questions to your satisfaction." There followed my signature.

The patient was then instructed that the next morning at 3:00 a.m., since it was a weekend, he was to take the highway leading to Flagstaff, 150 miles away. Wearing his very best clothes, he was to pin the envelope to the front of his jacket with the notation on the envelope uppermost and to drive to the city limits on that highway. Just before he reached that point, he was to turn off onto the wide shoulder of that highway. (The author was well acquainted with that long, level, wide-shouldered stretch of highway with a sandy, shallow ditch running alongside of the wide shoulders.) As he reached the sign, he was to shift into neutral, turn off the ignition, coast to a stop or brake the car to a stop just beyond the sign, leap out of the car, rush over to the shallow ditch, and lie down on his back, face up, and stay there at least 15 minutes. Then he was to get up, dust the sand from his clothes, get back into the car, start it, shift into first gear, drive one or two car lengths and stop the car, turn off the ignition, put on the brake, and again lie in the ditch as before for another 15 minutes.

This process was to be repeated again and again until he could drive from one telephone pole to the next, and then past the second pole on toward the third, stopping at the first evidence of any symptoms and spending 15 minutes on his back in the ditch each time. It was further explained that traffic on that highway was decidedly slight at that hour in the morning, that if a Highway Patrol car came along the officers would undoubtedly call the author for information, that the only real problem was to be at the city limits at 3:00 a.m.

The patient's reply to all this was, "But that's plain crazy." The author replied, "Agreed, but you want a symptomatic cure, and that is what you are going to get. You made me promise and I made you promise. So, that's it." The patient protested further, "But what if I start to faint when I get up out of the ditch?" "Lie down for another 15 minutes, look at the sky and get mad at me. Then move on in the car to the next spot to lie in the ditch. That's what you want, a symptomatic cure, and you're going to get it."

At about 9:00 p.m. he entered the author's home and stated, "After about the tenth time lying in the ditch I began feeling like a damn fool. I got back in the car and started driving from one telephone pole to the next and then to the curve I could see ahead in the road, and then I got interested in the scenery. I drove to Flagstaff through Oak Creek Canyon and managed the mountain road O.K. I drove around Flagstaff, came back to Phoenix, and I've been driving all over Phoenix and Tempe. I sure as hell was afraid when I started out at 2:30 a.m., and I was scared the first time I laid down in the ditch. Then when I brushed the sand off my clothes I didn't like it. I thought it was a damn fool thing for you to make me promise, and the more I did it, the madder I got, and so I just quit and began enjoying driving."

Thirteen years have elapsed. He graduated creditably from the university in the normal period of time, but he is still very definitely a severe schizoid personality. He has seen a number of psychiatrists but has never remained with any one of them sufficiently long to enter into therapy.

He works irregularly, and although he completed four years of college successfully, he lives at a substandard level. Parental funds keep him from being penniless much of the time, and he has driven his car all over the United States on vacation trips and "job hunting."

When he does work, it is exceedingly well done, and he has been known twice to agree to a year's contract which called for a generous bonus at the expiration of the contract. He broke the contracts a week ahead of time and lost both bonuses. Each position was at a managerial level.

His parents, his normal brother, his neurotic sister, and two normal Brothers-in-law have made many ineffectual efforts to get him to stay with some psychiatrist. He is known to have visited at least half a dozen.

His status at the present time is that of one who, in a depressed mood, continued fruitless futile driving about, securing a job, working briefly and then quitting, living at a substandard level and always defeating himself. A typical example of his self-defeating activity was driving 255 miles to see the Grand Canyon, arriving late at night, and then leaving at about 4:00 a.m. the next morning to return to Phoenix without having even looked at the Grand Canyon. His explanation was, "Well, the motel bed wasn't so good."

COMMENT

That the patient wanted and accepted therapy for a troublesome symptom is apparent. That he was definitely an intelligent young man is attested by his good college record and his two managerial positions, each done competently with the exception of breaking the contract at the last week and losing his bonus both times. This, however, did not cause his employers any loss; rather, they profited from his act.

This patient demonstrated a capacity to benefit rather easily and well from the intervention by someone who could create a therapeutic situation but which the patient would accept for one purpose only. The man is not satisfied with his total situation; periodically he seeks but does not accept help from the author and other psychiatrists but that is as far as he will permit matters to go. There seems to be no possible way to motivate him despite his own clear statement, "It looks like I will finally end up in the state mental hospital like my sister, and I sure don't like that idea." He did accept the suggestion that to force mental hospitalization upon himself, he might wander about the streets in a confused way until the police picked him up, but when this occurred (on two occasions) he succeeded in convincing the police that he was just "absent-minded." Thus, twice he competently averted a sanity hearing.

In brief, this man needs help, has a poor prognosis, and, to this author and a number of other psychiatrists, is therapeutically inaccessible, despite the fact that he is a good though completely passive hypnotic subject.

Successful Hypnotherapy that Failed

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, 1966, 9, 62-65.

The following brief case history is reported for the significant values it has in demonstrating the fallibility of success in hypnotherapy.

At a lecture on, and demonstration of, hypnosis before a dental society, the author was asked to "cure" a "gagging" patient. Upon the author's agreement to make such an attempt, the patient, a 45-year-old man, came forward. He gave his own history readily and informatively, and he was aided in this by his family dentist, who was present in the audience and who came forward with his records to offer special items of information. In summary, the history was that following a toothache and a tooth extraction at the age of 10 years, the patient's mouth had healed satisfactorily. About a month later, when brushing his teeth, the patient noted a slight gagging, but merely wondered at the cause. This slight gagging increased until, at the expiration of another month, the gagging had become so severe that he could not brush his teeth. His family dentist was consulted but could find no cause for this peculiar gagging. The family numbered a psychiatrist and a psychologist among their friends, and both saw the patient separately and together. No explanation of the patient's complaint was found by them despite a searching study. The dentist prescribed mouthwashes and a program of slow, systematic reconditioning of the patient to the use of a toothbrush. This was begun by having the patient close his mouth and touch his lips with the brush, with the intention of slowly introducing the toothbrush into the mouth, and then beginning to initiate the tooth-brushing very gently. The psychiatrist and the psychologist worked with the dentist to devise this plan of reconditioning the patient, who was most cooperative.

Unfortunately, the results were worse than the original gagging. The patient shortly began gagging when he merely picked up the toothbrush. Further psychological and psychiatric studies were made with no significant discoveries. The gagging continued to grow worse until eating became a problem. He finally extended the gagging to include the use of a fork or a spoon, and he had to resort to the use of his fingers in eating.

At the age of 22 he fell in love, became engaged to marry, but discovered to his horror that any attempt to kiss mouth-to-mouth resulted in gagging and retching. However, he could give and receive kisses elsewhere than on the mouth.

At the age of 23 he was forced to seek dental care. An examination could be done only under general anesthesia. The dental pathology was so extensive that two dental consultants were called upon for their opinions. All three recommended total extractions of upper and lower teeth. The patient agreed relievedly, since he had had many serious

toothaches which he had been forced to endure without dental care except general medication.

General anesthesia was required for the extraction and the preparation of the dentures, and these were fitted in place while the patient was under general anesthesia. To help him become adjusted to the dentures he was heavily drugged first with morphine and then barbiturates.

With the lightening of his narcosis, he began gagging and retching.

After his mouth had healed completely, a new set of dentures was made and fitted in place by means of a general anesthesia. They led only to gagging and retching despite every measure employed to help the patient.

During World War II he managed to enlist for "limited duty" but shortly received a medical discharge because he could not use dentures or eating implements. In civilian life he made an excellent marital, social, and economic adjustment. Repeatedly he was offered promotions that involved meeting people as a salesman if he would wear dentures. Altogether, 10 sets of dentures were made for him with no helpful results. His employer gladly retained him in the lesser occupational position.

In preparation for the dental meeting at which the author was to lecture, his dentist prepared a new set of dentures for him, using, as was customary, general anesthesia. The patient was carrying them in a box in his pocket. He was asked if he wished to be hypnotized and instructed to wear the dentures. He affirmed this to be his desire, but he explained, "First I want you to see this." Thereupon he opened the box, took out the dentures, and slowly moved them toward his mouth. When they were within two inches of his mouth, he began gagging and retching. Moving them away he stated, "That's why I didn't eat breakfast this morning."

With great insistence he was urged to put the dentures in his mouth long enough for the author to see them in place. He agreed to this, but it was noted that he suddenly began perspiring freely. Slowly, with rigid carefulness, he opened his mouth, inserted the dentures, breathing deeply and then holding his breath as his dentist had taught him. He was able to retain the dentures about eight seconds, by which time streams of perspiration were rolling down his face and the front of his shirt was wet with perspiration.

He was asked to put the dentures back in the box, and a simple technique of trance suggestion was employed. The patient developed a somnambulistic trance state within a few minutes. Various phenomena of the somnambulistic trance were demonstrated for the benefit of the audience and to deepen the patient's state of hypnosis. No attempt was made to have him wear the dentures in the hypnotic state. Such an attempt, it was thought, might jeopardize the possibility of success. Hence he was used to demonstrate the phenomena of deep hypnosis as a measure of ensuring extensive learning. Finally, contrary to the author's wishes, he abided by the audience's insistent demand for a test of denture wearing in hypnosis. The patient readily allowed his dentist to insert the dentures.

No evidences of discomfort were noted. The patient was then given carefully worded posthypnotic suggestions that he would not notice that he was wearing his dentures when he aroused from the trance state until he was asked to look into a mirror and to smile. He agreed to this readily and aroused upon appropriate suggestions. He had an amnesia for being in the trance and reiterated his statement that he was willing to be hypnotized. He was asked if his dentures were in the box in his pocket. He asserted that they were but that he hoped they would be in his mouth after he had been hypnotized. He was handed a mirror and asked to look at his smile. In a puzzled manner he took the mirror, but as he looked into it, he was obviously most startled. He immediately took the box out of his pocket and found it to be empty. His bewildered behavior was delightful to observe. A member of the audience asked if he would like a steak for luncheon. He stated he would.

The rest of the story is simple. He ate a steak for luncheon in the company of a large group of dentists. He had a second steak for dinner and a third just before midnight, still surrounded by interested dentists. He went home the next morning in the company of his dentist.

All this occurred in the early part of March. Upon arriving at home, his employer gave him a promotion to begin on Monday of the next week. His dentist, whose office was located next to the building where the man was employed, checked daily on the patient's wearing of his dentures. The patient kissed his wife on the mouth for the first time in their 20 years of marriage, and he also kissed his children.

For two months the author received weekly reports from the dentist, whose inquiries had disclosed that the patient was unwilling at first to take his dentures out even to wash them. Then in June letters were received from both the dentist and the patient to the effect that all was well. Another such letter from the dentist was received in July. In August the patient and the dentist went on a fishing trip. All went well. During this fishing trip the patient expressed much appreciation for what had been done for him.

Then on the morning of September 23 the patient awakened, chatted briefly with his wife, and then remarked casually that he was leaving his dentures at home that day. His wife protested, but unemotionally he remarked that it just "seemed to be a good idea." His employer was out of town, and the dentist did not see him that day. In the evening his wife asked him to wear his dentures for dinner. He refused to do so, and she was too bewildered to ask for an explanation.

The patient sat down to dinner, but as the first forkful of food approached his mouth, he gagged. His wife leaped up, secured the dentures, and handed them to him, telling him to put them in his mouth. As he started to do so, he gagged.

He ate the evening meal with his fingers. His wife accompanied him to the dentist the next morning, taking the dentures with her. The dentist induced a deep trance but elicited only the explanation that he did not want to wear the dentures. No additional explanation could be elicited. He manifested no emotional disturbance. His unwillingness to wear his

dentures seemed to be no more than a simple statement expressive only of a matter-of-fact attitude.

A long distance telephone call to the author by the dentist led to the advice to refrain from making any issue of the matter. Accordingly, the dentist so instructed the patient's wife, and she accepted the advice.

Two weeks later the patient wrote a simple straightforward account of what had happened, of his intention of not wearing his dentures, of his willingness to be demoted by his employer to his original position, and of his wife's statement that all had gone reasonably well previously and probably would again. He stated further that he knew of no reason for abandoning his dentures, that he regretted disappointing everybody, but that life seemed to be as satisfying one way as another.

A year later the dentist wrote that the patient was contentedly adjusting without his dentures, that the topic of denture-wearing had long been closed, and that the patient and his family were doing well despite the return to the previous lower income.

Another year later the situation was unchanged. The patient, in reply to questions, stated that the only possible explanation that had occurred to him was that the long years without dentures had fully accustomed him to their absence, that he was not sure of this as an adequate explanation, but that he could think of no other explanation. Moreover, he did not mind the requisite adjustment to their absence nor did he feel any loss in not using them nor any desire to return to their use. To a specific question he replied that he now could not understand why he had formerly wanted to wear dentures.

The author has no understanding of the course of events with this patient. Successful therapy was apparently achieved, enjoyed for months by the patient, and then apparently abandoned for no known reason and without regret. The man adjusted well before the extraction of his teeth, and except for his medical discharge from military service, he adjusted well in the edentulous state. He adjusted well during the months of wearing the dentures, and he adjusted well after discarding them. The family dentist and the psychiatrist and the psychologist friends all found nothing of note in their association with the man and his family that would be considered as offering even a semblance of an explanation of the patient's behavior.

13. Visual Hallucination as a Rehearsal for Symptom Resolution

Milton H. Erickson and Ernest L. Rossi

"A doctor and his wife wanted me to cure their 10 year-old son of bed-wetting. It was to be a one-shot effort. I knew the parents well. I had trained the father in hypnosis, and the boy had heard his mother and father speak of me very highly. The boy wanted a dog, but his parents said he could not have one because he wet his bed. I told the parents that the boy could visit me, but they were not to tell the boy that I was supposed to cure his bed-wetting.

TRANCE INDUCTION VIA EXPECTANCY

"The boy came and was intelligent and curious about hypnosis. I told him he could go into a trance and he could have something he wanted very much. He said, 'What?' I repeated that it would be something 'you would want to do very much.' Now when he understood that, he was willing to go into a trance.

"He went into a very nice trance, and I continued, 'Now we will get to find something you would like very much.' His eyes opened, though he remained in trance. 'We will take a walk down the street, maybe we will see something.' I then turned my head to indicate looking into the distance and exclaimed, 'Oh, there is that mother dog; she has got two puppies! [Pause] I think I like the black-and-white one best. Which one do you like best?' The boy looked in the indicated direction and softly said, 'I like the brown-and-white puppy.' I said, 'Would you like to pet it?' The boy reached over the side of his chair and petted the hallucinated puppy. I reached over and petted my puppy and said 'You are going to get a puppy and you can set the date when you are to get the puppy. *I know that! I know you can get a puppy!* Give yourself time, maybe you had better wait for two weeks. And on that day when you come to the breakfast table you will all of a sudden have a bright new idea two weeks from today. You will

---

The first four paragraphs of this paper are an edited version of a taped interview with MHE by the editor who then contributed the analysis that follows.

walk to the table for breakfast, and say to your father and mother, 'Today is the day you are going to bring me a puppy.'

"He did just that, and when they asked him what kind of a puppy, he just said, 'You'll bring the right one, I just know.' I had told his parents it was to be a brown-and-white puppy. But the idea just occurred to him consciously that morning two weeks after his visit with me."

What are the factors involved in this successful hallucinatory experience that lead to a cure of bed-wetting?

1. The parents spoke well of Erickson, so the boy looked up to him.
2. Erickson told the parents not to tell the boy that Erickson was to cure the bed-wetting because that might set up the situation as a challenge, which the boy might feel he had to resist even if he wanted to cooperate on a conscious level.
3. Trance was presented to the boy as an experience where he "could have something he wanted very much." This immediately mobilized his positive expectations and, in particular, probably activated his wish for a dog on either a conscious or unconscious level because, in fact, he did want a dog.
4. These activated associations had an immediate outlet when Erickson mentioned the two puppies.
5. The parents had told him that he could not have a dog until he stopped bed-wetting. Erickson knew this was a frustrating contingency within the boy's mind. It was frustrating because his ego could not control the bed-wetting, and therefore he could not get a dog. Erickson did not have to crudely say or suggest anything further about that painful contingency: *If* you stop bed-wetting, *then* you can have a dog. Erickson simply utilized this already existing contingency and added a few things that would help the boy achieve it:
   a) Erickson gave the boyan intense hallucinatory experience of the dog he wanted. This strengthened the boy's inner image, and his goal became more real by being rehearsed in the trance situation.
   b) Erickson perhaps delivered a strong, secret message to the boy by emphasizing, "I know that! I know you can get a puppy!" The boy knew that Erickson had a lot of prestige with the boy's parents. If Erickson said something, it must carry strong weight with the parents. The boy now had a secret ally in Erickson, so the problem of getting a dog seemed less hopeless.
   c) Erickson gave the boy time: two weeks to learn how to control his bed-wetting with his now vastly strengthened inner resources. Erickson did not have to directly say, "You can have two weeks to learn to control your bed-wetting." Such a crude suggestion was not needed because it was already *implied* when Erickson

said he knew the boy could get a puppy. The parents' contingency plus Erickson's conviction formed a classical logical argument: modus tolons.

Parent's Contingencies	Symbolic logic
"*If* you stop bed-wetting,	S
then you can have a dog."	D
or S> D where > = If ... then implication	
Erickson's Convincing Addition	
"I know you can get a puppy."	D

Together these two statements lead to the logical conclusion, S, that bed-wetting will stop. Thus via modus tolons–

S > D
D
. ·. S

6. Erickson utilized another of his favorite hypnotic forms when he made his posthypnotic suggestion contingent on an inevitable piece of future behavior:

Posthypnotic Suggestion	*Commentary*
"When you come to the breakfast table	The time-binding introduction of an implied directive.
you will all of a sudden have a bright new idea two weeks from today.	If it is to be "new," it implies that he will be amnesic for the idea until two weeks pass.
You will walk to the table for breakfast	An inevitable piece of behavior onto which
and say to your father and mother, 'Today is the day you are going to bring me a puppy.'"	this suggestion can be hitchhiked.

The boy's triumphant conviction, "You will bring the right one, I just know," in answer to his parents' question two weeks later about the kind of dog he wanted, is an amusing incidental validation of the connection between Erickson's suggestions and the correct implications the boy drew from them.

Special Techniques of Brief Hypnotherapy

Milton H. Erickson

Quoted from the *Journal of Clinical and Experimental Hypnosis*, 1954, 2, 109-129,

The development of neurotic symptoms constitutes behavior of a defensive, protective character. Because it is an unconscious process, and thus excluded from conscious understandings, it is blind and groping in nature and does not serve personality purposes usefully. Rather it tends to be handicapping and disabling in its effects. Therapy of such distorted behavior ordinarily presupposes that there must be a correction of the underlying causation. However, such correction, in turn, presupposes not only a fundamental willingness on the part of the patient for adequate therapy but also an actual opportunity and situation conducive to treatment. In the absence of one or both of these requisites, psycho-therapeutic goals and methods must be reordered to meet as adequately as possible the total reality situation.

In attempting such modified psychotherapy the difficult problem arises of what can really be done about neurotic symptomatology where the realities of the patient and his life situation constitute a barrier to comprehensive treatment. Efforts at symptom removal by hypnosis, persuasion, reconditioning, etc. are usually futile. Almost invariably there is a return to the symptomatology in either the same form or another guise, with increased resistance to therapy.

Equally futile, under such limiting circumstances, is any effort to center treatment around idealistic concepts of comprehensiveness, or, as is unfortunately too often the case, around the therapist's conception of what is needed, proper, and desirable. Instead, it is imperative that recognition be given to the fact that comprehensive therapy is unacceptable to some patients. Their total pattern of adjustment is based upon the continuance of certain maladjustments which derive from actual frailties. Hence, any correction of those maladjustments would be undesirable if not actually impossible. Similarly, the realities of time and situational restrictions can render comprehensive therapy impossible and hence frustrating, unacceptable, and actually intolerable to the patient.

Therefore, a proper therapeutic goal is one that aids patients to function as adequately and as constructively as possible under those handicaps, internal and external, that constitute a part of their life situations and needs.

Consequently, the therapeutic task becomes a problem of intentionally utilizing neurotic symptomatology to meet the unique needs of each patient. Such utilization must satisfy the compelling desire for neurotic handicaps, the limitations imposed upon therapy by external forces, and, above all, provide adequately for constructive adjustments aided

rather than handicapped by the continuance of neuroticisms. Such utilization is illustrated in the following case reports by special hypnotherapeutic techniques of symptom substitution, transformation, amelioration, and the induction of corrective emotional response.

SYMPTOM SUBSTITUTION

In the two following case histories neither a willingness for adequate therapy nor a favorable reality situation existed. Hence therapy was based upon a process of symptom substitution, a vastly different method from *symptom removal*. There resulted a satisfaction of the patient's needs for defensive neurotic manifestations and an achievement of satisfactory adjustments, aided by continued neurotic behavior.

Patient A

A 59-year-old uneducated manual laborer, who had worked at the same job for 34 years with the expectation of a pension at the end of 35 years, fell and injured himself slightly. He reacted with a hysterical paralysis of the right arm. The company physician agreed to one week's hospitalization. Then, if the patient had not recovered from his "nonsense" at the expiration of that time, he was to be discharged as mentally ill with forfeiture of his pension.

Examination of the man disclosed his arm flexed at the elbow and held rigidly across the chest, with the hand tightly closed. During sleep the arm was relaxed, and the original diagnosis of a hysterical disability was confirmed.

No history other than the above was obtained since the patient was uncommunicative and spent his waking time groaning and complaining about severe pain.

After enlisting the aid of two other physicians, an elaborate physical examination was performed. The findings were discussed with much pessimism and foreboding about his recovery. This was done in low tones, barely but sufficiently audible to the patient. Everybody agreed that it was an "inertia syndrome," but that hypnosis would have to be performed in order to confirm that diagnosis. The prognosis was solemnly discussed and everyone agreed that, if it were the serious condition suspected, its course would be rapid and characteristic. This progression of the disease would be characterized by a relaxation of the shoulder joint, permitting arm movement within the next two days. Unfortunately, this would be accompanied by a "warm, hard feeling" in the right wrist. Then the elbow would lose its stiffness, but this would settle in the wrist. Finally, within the week's time, the fingers would relax and their stiffness would also settle in the wrist. This wrist stiffness would lead to a sense of fatigue in the wrist, but only upon use of the right arm. During rest and idleness there would be no symptomatology. Impressive medical terminology was freely employed during this discussion, but every care was taken to ensure the desired understanding of it by the patient. The patient was approached about hypnosis and readily agreed. He developed a good trance, but retained his symptoms in the trance state.

A physical reexamination was enthusiastically performed, and the same discussion was repeated, this time in a manner expressive of absolute conviction. With definite excitement, one of the physicians discovered signs of relaxation of the shoulder muscles. The others confirmed his discovery. Then "tests" applied disclosed . "early changes in the first, fourth, and fifth nerves" of the elbow. All agreed, after solemn debate, that the second and third nerve changes should be slower, and that the general pattern left no doubt whatsoever about the diagnosis of "inertia syndrome," and its eventual and rapid culmination in a permanent wrist impairment. All agreed that there would be free use of the arm and that the wrist fatigue would be apparent but endurable during work. Everyone was pleased that it was a physical problem that could be surmounted and not a mental condition.

The patient's progress was exactly as described to him. Each day the physicians solemnly visited him and expressed their gratification over their diagnostic acumen.

He was discharged at the end of the week with his stiff wrist. He returned to work, completed the year, and was retired on a pension. The wrist had troubled him with its fatigability but had not interfered with his work. Upon retiring all symptomatology vanished.

However farcical the above procedure may seem in itself, it possessed the remarkable and rare virtue of being satisfying to the patient as a person and meeting his symptomatic needs adequately.

Patient B

A factory laborer, following a minor injury at work, developed a hysterical paralysis of the right arm which invalided him. A settlement had been made which would be exhausted in less than another year. At the insistence of the company physician he was sent to the writer for hypnotic therapy. The patient was antagonistic toward treatment, felt that the company was victimizing him, and stated that he would agree to only three sessions.

On taking his history it was learned that, several years previously, he had had removed by hypnotic suggestion a paralysis of the left leg. However, shortly after his "recovery," his left arm became paralyzed. Again hypnotic suggestion had effected a cure, followed shortly by a right leg paralysis. This, too, had been cured by hypnotic suggestion, and now he had a right arm paralysis.

This background suggested both the inadvisability of direct hypnosis and a need by the patient for some neurotic handicap.

Accordingly, the company physician was immediately consulted and therapeutic plans outlined. He agreed to them and promised full cooperation on the part of the company for a work placement for the patient.

A therapeutic approach was made by bringing out medical atlases and discussing endlessly and monotonously, in pseudo-erudite fashion, muscles, nerves, blood vessels, and lymphatic channels. This discussion was increasingly interspersed with trance suggestions until the patient developed a somnambulistic trance state.

The whole discussion was then repeated, and to it was added the reading from textbooks of carefully chosen sentences describing the fleeting, evanescent, and changing symptoms of multiple sclerosis and other conditions, interspersed with illustrative, fabricated case histories. The possibility of a comparable changing symptomatology for him and its possible and probable establishment in a permanent fashion was insidiously and repetitiously hinted.

The next two sessions were of a comparable character, except for the fact that numerous pseudo-tests were made of the nerves in his arms. These tests were interpreted conclusively to signify that a certain final, permanent disability would be an inevitable development. This would be the loss of the functioning of his right little finger but with full use otherwise of the whole arm.

The third session was completed by a review of the pseudo-test findings and a consultation of the medical atlases, with numerous references to textbooks. All this led to the inevitable conclusion that within another month there would be a numbness and stiffness of his little finger, which would always be slightly unpleasant but which would not interfere with his employment.

Approximately a month later the patient volunteered to relinquish half of the remaining weekly disability for a lump sum settlement and reinstatement at work. This was granted, and he applied the money to the mortgage on his home. The company physician secured a placement where a disabled right little finger did not constitute a problem.

Three years later the man was still steadily and productively employed. However, he had informed the company physician that the writer was mistaken in one regard. This was that his finger was not constantly crippled but that the condition waxed and waned from time to time, never really causing difficulty but merely making itself apparent.

Comment

Little discussion of these two case histories is necessary. Apparently both patients desperately needed a neurotic disability in order to face their life situations. No possibility existed for the correction of causative underlying maladjustments. Therefore, as therapy, there was substituted for the existing neurotic disability another, comparable in kind, non-incapacitating in character, and symptomatically satisfying to them as constructively functioning personalities. As a result both received that aid and impetus that permitted them to make a good reality adjustment.

Although more in the way of understanding the total problem could be desired, the essential fact remains that the patients' needs were met sufficiently well to afford them the achievement of a satisfying, constructive personal success.

SYMPTOM TRANSFORMATION

In the next two case histories the therapeutically restricting factors were the limitations imposed by time and situational realities. Accordingly, therapy was based upon a technique of *symptom transformation*. While seemingly similar to symptom substitution, it differs significantly in that there is a utilization of neurotic behavior by a transformation of the personality purposes served without an attack upon the symptomatology itself.

In understanding this technique it may be well to keep in mind the patter of the magician, which is not intended to inform but to distract so that his purposes may be accomplished.

Patient C

During the psychiatric examination, a selectee, otherwise normal in his adjustment, disclosed a history of persistent enuresis since the age of puberty. Though much distressed by this, he had otherwise made a good social, personal, and economic adjustment. However, because of his enuresis, he had never dared to be away from home overnight, although he had often wished to visit his grandparents and other relatives who lived at a considerable distance. Particularly did he wish to visit them because of impending military service. He was much distressed to learn that enuresis would exclude him from service, and he asked urgently if something could be done to cure him. He explained that he had taken barrels of medicine, had been cystoscoped, and numerous other procedures had been employed upon him—all to no avail.

He was told that he could probably get some effective aid if he were willing to be hypnotized. To this he agreed readily, and he developed a profound trance quickly. In this trance state he was assured most emphatically that his bed-wetting was psychological in origin and that he would have no real difficulty of any sort in overcoming it if he obeyed instructions completely.

In the form of posthypnotic suggestions he was told that, upon returning home, he was to go to the neighboring city and engage a hotel room. He was to have his meals sent up to him, and he was to remain continuously in that room until three nights had elapsed. [The rationale of three nights was simply this: If the plan were effective, the first night would be one of doubt and uncertainty, the second would be one of certainty, and the third would bridge a transition from bed-wetting anxiety to another anxiety situation.] Upon entering the room he was to make himself comfortable, and he was to begin to think about how frightened and distressed he would be when the maid, as his mother always did, discovered a wet bed the next morning. He was to go over and over these thoughts, speculating unhappily upon his inevitable humiliated, anxious, and fearful reactions.

Suddenly the idea would cross his mind about what an amazing but bitter joke it would be on him if, after all this agonized thinking, the maid were surprised by a dry bed.

This idea would make no sense to him, and he would become so confused and bewildered by it that he would be unable to straighten out his mind. Instead, the idea would run through his mind constantly, and soon he would find himself miserably, helplessly, and confusedly speculating about his shame, anxiety, and embarrassment when the maid discovered the dry bed instead of the wet bed he had planned. This thinking would so trouble him that finally, in desperation, he would become so sleepy that he would welcome going to bed, because, try as he might, he would not be able to think clearly.

Then the next morning his first reaction would be one of abject fear of remaining in the room while the maid discovered the dry bed. He would search in his mind frantically for some excuse to leave, would fail, and have to stare wretchedly out of the window so that she would not see his distress.

The next day, beginning in the afternoon, the same bewildered, confused thinking would recur with the same results, and the third day would be another repetition of the same.

He was told further that, upon checking out of the hotel after the third night, he would find himself greatly torn by a conflict about visiting his grandparents. The problem of whether he should visit the maternal or the paternal set of grandparents first would be an agonizing, obsessional thought. This he would finally resolve by making the visit to the first set one day shorter than that to the second. Once arrived at his destination, he would be most comfortable and would look forward happily to visiting all of his relatives. Nevertheless, he would be obsessed with doubts about which to visit next, but always he would enjoy a stay of several days.

All of these suggestions were repetitiously reiterated in an effort to ensure the implantation of these pseudo-problems and to effect a redirection of his enuretic fears and anxieties and a transformation of them into anxieties about visits with relatives, and not anxiety about a wet bed for his closest relative, his mother.

Finally he was dismissed after approximately two hours' work with a posthypnotic suggestion for a comprehensive amnesia. Upon awakening he was told briefly that he would be recalled in about three months and that he would undoubtedly be accepted for military service then.

About 10 weeks later he was seen again by the writer as the consultant for the local draft board. He reported in detail his "amazing experience" at the hotel with no apparent conscious awareness of what had occasioned it. He explained that he "almost went crazy in that hotel trying to wet that bed, but I couldn't do it. I even drank water to be sure, but it didn't work. Then I got so scared I pulled out and started to visit all my relatives. That made me feel all right, except for being scared to death about which one to see first, and now I'm here."

He was reminded of his original complaints. With startled surprise he replied, “I haven’t done that since I went crazy in the hotel. What happened?”

Reply was made simply that what had happened was that he had stopped wetting the bed and now could enjoy a dry bed.

Two weeks later he was seen again at the induction center, at which time he was readily accepted for service. His apparent only anxiety was his concern about his mother’s adjustment to his military service.

Patient D

A selectee, greatly interested in entering military service, disclosed upon psychiatric examination a rather serious, closely circumscribed neurosis which embarrassed him tremendously. His difficulty lay in the fact that he was unable to urinate unless he did so by applying an 8- or 10-inch wooden or iron pipe to the head of the penis, thus urinating through the tube.

Since, in all other regards, he seemed to be reasonably well adjusted and had a good work and social history, the conclusion was reached that the man might be amenable to brief hypnotherapy.

His history disclosed that as a small boy he had urinated through a knothole in a wooden fence bordering a golf course. He was apprehended from in front and behind and was severely punished, embarrassed, and humiliated. His reaction had been one of a repetition compulsion, which he had solved by securing a number of metal or wooden tubes. These he had carried with him constantly. He gave his story frankly and fully, though much embarrassed by it.

A deep trance was readily induced, and the history already given was confirmed. His attitude toward military service was found to be good, and he was actually willing to enter military service with his handicap, provided it occasioned him no significant embarrassment.

A long, detailed explanation in the form of posthypnotic suggestions was given to him about how this could be done. He was urged to secure a length of bamboo 12 inches long,* to mark it on the outside in quarter inches, to use that in urinating. This he was to hold with his thumb and forefinger, alternately with the right and left hand as convenient, and to flex the other three fingers around the shaft of the penis. Additionally, he was instructed to try with his thumb and forefinger to sense the passage of urine through the bamboo. No actual mention was made of feeling the passage of urine through the urethra with the other fingers. He was also told that in a day or two, or a week or two, he might consider how long the bamboo needed to be and whether or not he could saw off ¼, ½ or even 1 inch, but that he need not feel compelled to do so. Rather he should let any reduction in the length of the bamboo come about easily and comfortably, and he should be interested only in wondering on what day of the week he might reduce the length of

bamboo. Also, he was told to be most certain to have the three fingers grasping the shaft of the penis so that he could notice better the flow of urine through the bamboo. As for military service, he would be rejected at the present, but arrangements would be made to have him called up in three months' time for a special psychiatric examination. At that time he would undoubtedly be accepted.

> * A tube definitely longer than those he had been using was suggested. His acceptance of the longer tube, constituted a reality acknowledgment that the writer could do something about the tube—namely, make it longer. Equally significant is the unrecognized implication that the writer could make it shorter. Additionally, the tube was neither wood nor iron, it was bamboo. Thus, in essence, three transformation processes—longer, shorter, and material—had been initiated.

The interview was closed with two final, posthypnotic suggestions. The first was directed to a total amnesia for the entire trance experience. The other was concerned with the securing and preparation of the bamboo with no conscious understanding of the purpose.

About three months later his local draft board sent him for a special psychiatric examination to the writer, the consulting psychiatrist for that draft board. The young man was surprised and delighted. He explained that he had obeyed instructions, that he had been greatly astonished and bewildered to find himself buying the bamboo and then much embarrassed by the sudden rush of memories. At first distressed by his violation of the amnesia instructions, he soon began to develop a tremendous sense of hope and belief that he would solve his problem. He practiced urinating with the bamboo tube for about a week, then reached the conclusion that he could saw off about ½inch, and was much puzzled when he actually sawed off a full inch. This pleased him greatly, and he wondered when he would saw off some more, and he realized suddenly that it would occur on a Thursday. (Why Thursday could not be explained.) On that occasion he sawed off 2 inches, and a few days later another inch. At the end of the month he had a ¼ inch ring of bamboo left. While using it one day, he realized that the flexion of the three fingers around the shaft of the penis gave him a natural tube. Therefore, he discarded the remains of the original bamboo and took great delight in urinating freely and comfortably. He did so with both the right and left hand and even experimented by extending the little finger; then he realized that he could urinate freely without resort to any special measure. He was then taken to the lavatory and asked to demonstrate. He immediately raised the question, "Where are you going to stand? Behind me?" Thereupon he laughed and said, "This is not a board fence. That belongs in my past history. You can stand where you want. It makes no difference to me."

A week later he was called up for induction. He was amused by his past difficulties and wondered why he had not had "enough brains" to figure out his particular problem by himself. He was assured that people usually do not know how to handle such simple things, that they have difficulty because of trying too hard.

The total duration of the therapeutic trance, somnambulistic in character, was less than an hour.

The entire procedure and its outcome demonstrate the ease and effectiveness with which symptomatology can be utilized to secure a transformation of a neurotic problem. The incapacitating wooden or metal tube was transformed into bamboo, then into the cylinder formed by the middle, third, and little finger, and then into the tube constituted by the phallus.

Comment

In both of these patients anxiety, precipitated by unhappy reactions of other people, existed in relation to a natural function. Therapy was accomplished by systematically utilizing this anxiety by a process of redirecting and transforming it. By thoroughly confusing and distracting Patient C, his anxiety about a wet bed was transformed into anxiety about a dry bed. Then his anxiety about his wet bed-home relationships was transformed into anxiety about relatives. The final transformation became that of his mother's anxiety about his military service.

For Patient D the transformation of anxiety progressed from: kind of tube; to sensing the passage of urine; to the shortening of the tube; to the question of the day for shortening the tube; and finally, into the unimportant question of where the writer would stand.

Thus, for both patients, the utilization of anxiety by a continuance and a transformation of it provided for a therapeutic resolution into a normal emotion permitting a normal adjustment, known to have continued for nine months while in service. Contact was then lost.

SYMPTOM AMELIORATION

Not infrequently in neurotic difficulties there is a surrender of the personality to an overwhelming symptom-complex formation, which may actually be out of proportion to the maladjustment problem. In such instances therapy is difficult, since the involvement of patients in their symptomatology precludes accessibility. In such cases a technique of symptom amelioration may be of value. In the two following cases an overwhelming, all-absorbing symptom-complex existed; therapy had to be based upon an apparently complete acceptance of the symptoms, and it was achieved by ameliorating the symptoms.

Patient E

A 17-year-old, feebleminded boy made poor adjustment when sent to a training school for delinquents. Within a month he had developed a rapidly alternating flexion and extension of the right arm in the horizontal plane at the cardiac level. When he was seen some six weeks later in the hospital, a diagnosis had been made of a hysterical reaction, probably on the basis of masturbation fears and his maladjustment in the training school. Physical examination disclosed essentially a glove anesthesia extending up to the elbow of the right arm and the rapid (135 times a minute) flexion and extension of that arm.

Both the anesthesia and the muscular activity disappeared upon physiological sleep and reappeared upon awakening.

Because of his low intelligence, I.Q. 65, efforts at psychotherapy proved futile, and hypnotherapy was suggested.

Accordingly, hypnosis was employed in daily sessions for three weeks before a sustained trance could be obtained. Although he went into a trance readily, he would immediately drift into physiological sleep and would have to be awakened and a new trance induced. Finally, by the measure of hypnotizing him in the standing position and walking him back and forth, a prolonged trance could be secured. The trance state, however, had no effect upon his symptoms.

Efforts made to reduce the frequency of his arm movements failed. His only response was, "Can't stop. Can't stop." Similarly, efforts to discuss his problem or to elicit information failed. His communications were in essence, "My arm, my arm, I can't stop it."

After daily sessions for a week, during which time an intern ostentatiously made repeated counts each day of the movements per minute, a new technique was devised. This was simply a measure of suggesting that the rate would be increased from 135 to 145 per minute and that this increased rate would persist until seen again. The next day the suggestion was offered that it would decrease to the usual 135 until seen again. Again it was increased to 145 and again decreased to 135. After several such repetitions, with the count checked repeatedly by the intern and found to be approximately correct, further progress was made by suggesting alternating increments and decrements—respectively, 5 and 10 points—of the rate of the arm movement. This was continued day after day until a rate of 10 per minute was reached. Then the technique was reversed to increase the rate to 50 movements per minute. Again it was reduced to a rate of 10 per minute. Suggestion was offered that this rate would continue for a few days, then drop to 5 per minute, and then "increase" to 20 or 30 or more a day. A few days later the rate shifted from 5 per minute to scattered, isolated movements per day. The patient himself kept count of these, the daily total ranging around 25. Next the suggestion was given that this count would diminish day by day until it was around 5, and then it would "increase to as high as 25 times a week." The patient responded as suggested, and then he was asked to "guess on what day" there would be no uncontrolled movements.

Shortly he "guessed" the day when no movements would occur and demonstrated the correctness of his conjecture.

Further "guessing" on the patient's part led within a few days to his demonstration that he was free of his disability and was continuing so. During the process of diminishing the arm movement symptom, there was noted a parallel behavior of the glove anesthesia. It waxed and waned in direct relation to the arm activity. It vanished along with that symptom.

A month later he was returned to the training school and intentionally assigned to the task of kneading bread dough by hand in the institutional bakery. A year later he was still adjusting satisfactorily.

Patient F

A mental hospital employee was referred to the writer because of sudden acute blindness which had developed on his way to work that morning. He was led into the office in a most frightened state of mind. Hesitantly and fearfully he told of having eaten his breakfast that morning, laughing and joking with his wife, and of suddenly becoming extremely disturbed by some risqué story his wife related. He had angrily left the house and decided to walk to work instead of taking the bus as was his usual custom. As he rounded a certain street corner, he suddenly became blind. He had developed a wild panic, and a friend passing along the highway in a car had picked him up and brought him to the hospital. The ophthalmologist had examined him immediately and then referred him to the writer. The man was much too frightened to give an adequate story. He did state that he and his wife had been quarreling a great deal recently and that she had been drinking at home; he had found hidden bottles of liquor. She had vigorously denied drinking.

When asked what he was thinking about as he left the house, he explained that he was much absorbed in his anger at his wife, feeling that she should not be telling off-color stories, and that he had a vague feeling of apprehension, believing that he might be heading for the divorce court.

He was asked to trace his steps mentally from his home up to the point of the sudden onset of his blindness. He blocked mentally on this. He was asked to describe that particular street corner, and his reply was that, although he had walked around it many, many times, he could not remember anything about it, that his mind was a total blank.

Since the street corner involved was well known to the writer, various leading questions were asked without eliciting any material from him. He was then asked to describe exactly how the blindness had developed. He stated that there had occurred a sudden flash of intense redness, as if he were staring directly into a hot, red sun. This redness persisted and, instead of seeing darkness or blackness, he was seeing nothing but a brilliant, blinding, saturated red color. He was oppressed by a horrible feeling that for all the rest of his life, he would never be able to see anything but an intense, glaring red. With this communication the patient became so hysterically excited that it was necessary to sedate him and put him to bed.

After the patient had been put to bed, his wife was summoned to the hospital. With much difficulty, and after many protestations of unfailing love for her husband, she finally confirmed her husband's story of her alcoholism. She refused to relate the story that had precipitated the quarrel, merely stating that it had been a risqué story about a man and a redheaded girl which had really meant nothing.

She was told where her husband had developed his sudden blindness and asked what she knew about the street corner. After much hedging she recalled that there was a service station on the opposite side of the street. This she and her husband often patronized in buying gas for their car. After still further insistent questioning, she recalled a service station attendant there who had brilliant red hair. Then finally, after many reassurances, she confessed to an affair with the attendant, commonly known as "Red." On several occasions he had made unduly familiar remarks to her in her husband's presence, which had been intensely resented. After much serious thinking she declared her intention to break off the affair, if the writer would cure her husband of his blindness, and demanded professional secrecy for her confidences. Her husband's unconscious awareness was pointed out to her, and she was told that any further betrayal would rest entirely upon her own actions.

When the patient was seen the next day, he was still unable to give any additional information. Efforts were made to assure him of the temporary nature of his blindness. This reassurance he was most unwilling to accept, and he demanded arrangements to be made to send him to a school for the blind. With difficulty he was persuaded to accept therapy on a trial basis, but on the condition that nothing be done about his vision. When he finally consented, the suggestion of hypnosis was offered as an appropriate, effective therapy for his purposes. He immediately asked if he would know what happened if he were in a trance. Such knowledge, he was told, could remain only in his unconscious, if he so wished, and thus would not occasion him trouble in the waking state.

A deep trance was readily induced, but the patient refused at first to open his eyes or test his vision in any way. However, further explanation of the unconscious mind and of amnesia and posthypnotic suggestions induced him to recover his vision in the trance state. He was shown the writer's bookplate and instructed to memorize it thoroughly. This done, he was to awaken, again blind, and with no conscious knowledge of having seen the bookplate. Nevertheless, he would, upon a posthypnotic cue, describe it adequately to his own bewilderment. As soon as he understood, he was awakened and a desultory conversation was begun.

This he interrupted upon the posthypnotic signal to give a full description of the bookplate. He was tremendously puzzled by this, since he knew he had never seen it. Confirmation of his description by others served to give him a great but mystified confidence in the therapeutic situation.

Upon rehypnosis he expressed complete satisfaction with what had been done and a full willingness to cooperate in every way. Asked if this meant he would confide fully in the writer, he hesitated, then determinedly declared that it did.

Special inquiry among his fellow workers on the previous day had disclosed him to have a special interest in a red-haired female employee.

By gentle degrees the question of this interest was raised. After some hesitation he finally gave a full account. Asked what his wife would think of it, he defensively asserted that she was no better than he, and he asked that the matter be kept in confidence.

Immediately, the questioning was shifted to a description of the street corner. He described it slowly and carefully but left mention of the gas station to the last. In a fragmentary fashion he described this, finally mentioning his suspicions about his wife and the red-haired attendant.

He was asked if his suspicions began at the time of his own interest in the red-haired girl, and what did he think he wanted to do about the entire situation.

Thoughtfully, he declared that, whatever had happened, they were both equally guilty, especially since neither had endeavored to establish a community of interests.

Inquiry was then made about his wishes concerning his vision. He expressed fear of recovering it immediately. He asked if the "horrible, bright redness" could be made less glaring, with now and then brief flashes of vision which would become progressively more frequent and more prolonged until finally there was a full restoration. He was assured that everything would occur as he wished, and a whole series of appropriate suggestions was given.

He was sent home on sick leave, but returned daily for hypnosis, accompanied by his wife. These interviews were limited to a reinforcement of the therapeutic suggestions of slow, progressive visual improvement. About a week later he reported that his vision was sufficiently improved to permit a return to work.

About six months later he returned to state that he and his wife had reached an amicable agreement for a divorce. She was leaving for her home state and he had no immediate plans for the future. His interest in the red-haired girl had vanished. He continued at his work uneventfully for another two years and then sought employment elsewhere.

Comment

The procedure with these two patients was essentially the same. The underlying causation was not therapeutically considered. Patient E's intellectual limitations precluded this, and Patient F had demonstrated the violence of his unwillingness to face his problem. Hence for both an amelioration of the overwhelming symptom formation was effected. By a process of alternating increments and decrements a control of E's symptom complex was effected.

For Patient F the reduction of the blinding redness, permission to remain blind and yet to have progressively more frequent and clearer flashes of vision was a parallel procedure.

As a consequence of the amelioration of their symptoms both patients were enabled to make their own personal adjustments.

CORRECTIVE EMOTIONAL RESPONSE

The following case histories concern intensely emotional problems. Therapy was achieved in one case by a deliberate correction of immediate emotional responses without rejecting them and the utilization of time to palliate and to force a correction of the problem by the intensity of the emotional reaction to its definition.

For the second patient the procedure was the deliberate development, at a near-conscious level, of an immediately stronger emotion in a situation compelling an emotional response corrective, in turn, upon the actual problem.

Patient G

An attractive social service student at the hospital entered the writer's office one evening without an appointment. She was clad in scanty shorts and a halter and she sprawled out in the armchair, declaring, "I want something." Reply was made, "Obviously so, or you would not be in a psychiatrist's office." Coquettishly she expressed doubt about wanting psychotherapy and was informed that an actual desire was necessary for therapeutic results.

After some silent thinking she declared that she needed and wanted psychotherapy, that she would state her problem, and then the writer could decide if he were willing to have her as a patient. She expressed the belief, however, that upon hearing her problem, she would probably be ejected from the office.

Thereupon she plunged into her story: "I have a prostitution complex—for the past three years—I want to go to bed with every man I see—most of them are willing—it doesn't make any difference what they are or who they are, drunk or sober, old or young, dirty or clean, any race, anything that can look like a man. I take them singly, in groups, any time, any place. I'm disgusting, filthy, horrible. But I've got to keep on doing it and I want to stop. Can you help me or should I go?"

She was asked if she could control her activities until the next session. Her reply was, "If you'll take me as a patient, I won't do anything tonight. But I will have to give you a new promise in the morning and another at night and keep that up every day until I'm over it."

She was told that she could have the next three days to test her sincerity, and for those three days she reported twice daily at the office to renew her promises. This promise renewal became a routine for her.

During a three-hour session on the fourth day, the patient devoted herself to an intense, verbal self-flagellation by recounting in full detail first one and then another of her experiences. With extreme difficulty she was induced to give such facts as her full name, birth date, home address, etc. Only by constant interruption of her accounts was it possible to secure the following limited additional history:

Her mother was a "shallow-minded social climber, a complete snob, who is peaches and cream to those she thinks useful and a back-biting cat to everybody else. She rules my father and me by shrill shrieking. I hate her."

Her father was a "big businessman, a nice guy with plenty of money, means well, I love him, but he's nothing but a dirty, stinking grease-spot under my mother's thumb. I'd like to make a man out of him so he'd slap her down."

Both parents taught her to "hate sex, it's nasty they say, and they haven't ever to my knowledge slept in the same bedroom. I'm the only child. I hate sex, and it should be beautiful."

With that she launched into a continuance of her verbal self-flagellation for the rest of the session.

The next three-hour session was equally futile. She devoted herself, despite numerous attempts at interruption, to a bitter, morbid, repetitious account of her experiences.

At the following session, as she entered the office, she was told emphatically, "Sit down, shut up, and don't you dare to open your mouth!"

Peremptorily she was told that the writer would thenceforth take charge of all interviews, that no more time would be wasted, that the course of therapy would be dictated completely by the writer, and that she was to express her agreement by nodding her head and keeping her mouth shut. This she did.

Thereupon, with little effort, a deep, somnambulistic trance was induced, and she was told that thenceforth she would have an amnesia for trance experiences unless otherwise indicated by the writer.

Despite the trance state, however, she was found to be no more accessible than in the waking state—with one exception. She did not speak unless so instructed, but when she did talk, it was exclusively on the subject of her affairs. No more history could be obtained.

Efforts to circumvent her compulsive narration by disorientation, Crystal-gazing, automatic writing, and depersonalization resulted only in more specific, detailed accounts.

At the next session, in a deep, somnambulistic trance, she was instructed emphatically:

> We both want to know why you are so promiscuous. We both want to know the cause of your behavior. We *both know that that knowledge is in your unconscious mind.*

> For the next two hours you will sit quietly here, thinking of nothing, doing nothing, just knowing that your unconscious is going to tell you and me the reason for your behavior.
>
> *It will tell the reason clearly, understandably, but neither you nor I will understand until the right time comes, and not until then.*
>
> You don't know how your unconscious will tell. I won't know what it tells until after you do, but I will have the reason, and at the right time, in the right way, you will know and I will know. Then you will be all right.

At the end of two hours she was told that the time had come for her unconscious to tell the reason. Before she had time to get frightened, she was handed a typewritten sheet of discarded manuscript. (See Appendix for discussion of this kind of technique.) She was then told:

> Look at this—it's a typewritten page—words, syllables, letters. Don't read it—just look at it. The reason is there—all the letters of the alphabet are there, and they spell the reason. You can't see it. In a minute I'm going to lock that sheet up in my desk with the reason unread. When the times comes, you can read it, but not until then.
>
> Now put the sheet face up on the desk, take this pencil, and in a random fashion, in a scrambled fashion, *underline those letters, syllables, words that tell the reason—quickly*."

In a puzzled manner she rapidly made nine scattered underlinings, while the writer made a numerical notation on another sheet, of the relative positions of the underlinings.

Immediately the sheet was taken from her and locked up face down in a desk drawer.

Then she was told, "Only one thing remains to be done. That is to decide the time when the reason is to be fully known. Come back and tell me tomorrow. Now wake up."

Upon awakening, she was given an appointment for the next day and dismissed. She took her departure without giving her usual promise.

The next morning she again failed to appear to give her promise. However, she kept her late-afternoon appointment, explaining, "I almost didn't come because I have only two silly words to say. I don't even know if I'll keep any more appointments with you. Well, anyway, I'll say the two words—I'll feel better—'Three weeks.'"

The reply was made, "According to the calendar, that would be four o'clock, August the 15th." She answered, "I don't know."

Thereupon, using a posthypnotic cue, a deep trance was induced. She was asked if she had anything to say. She nodded her head. Told to say it, she uttered, “Three weeks, August 15th, four o’clock.”

She was awakened and asked when she wanted another appointment. Her reply was that she would like to discuss her plans for the coming year and a possible thesis she might write.

For the next three weeks she was irregularly seen for discussion of her scholastic plans and extracurricular reading. There was no discussion of her problem nor were there any more promises.

During that three weeks she attended a party where a personable young man, newly arrived at the hospital and an advisee of the writer, attempted to seduce her. She laughed at him and gave him the choice of informing the writer of his misbehavior or having her relate it, and she succeeded in so intimidating him that he confessed.

At four P.M., August 15th, she entered the office, remarking, “It’s four o’clock, August the 15th. I don’t know why I’m here, but I had a strong feeling that I had to come. I wanted to and I didn’t want to. There is something awfully scary about coming. I wish I didn’t have to.”

She was answered by, “You first came to me for therapy. Apparently you drifted away. Maybe so, maybe not. Our sessions were usually three hours long. I used hypnosis. Shall I hypnotize you, or can you finish therapy in the waking state? Just remember both your conscious and your unconscious mind are present. If you want to go to sleep, you can. But at all events, sit down in that chair, be quiet, and at the end of an hour, you name a time by saying, ‘I’ll be ready at ..... and give a specific time.”

Uncomprehendingly she sat down and waited awake. At five o’clock she remarked, “I’ll be ready at six-thirty, “ and continued to wait quietly in a puzzled fashion.

At six-thirty the desk drawer was unlocked and the sheet of paper handed to her.

She turned it over and around in a puzzled fashion, scrutinized the underlinings, suddenly paled, became rigid, gave voice to an inarticulate cry, and burst into choking, shuddering sobs, gasping repeatedly, “That’s what I tried to do.”

Finally, in better control of herself, she said, “The reason is here—read it.”

The underlined material read:

i wa nt to f uc K f author*
*The actual numerical order of the underlining was:
1. to
2. i
3. nt 4. wa
5. uc
6. f
7. K
8. f
9. author, with a line joining 8 and 9.

She explained, "It was any man, every man, all the men in the world. That would include father. That would make him a man, not a grease spot under my mother's thumb. Now I know what I have been trying to do, and I don't have to any more. How horrible!"

She reacted by further intense sobbing but finally declared, "That's all in the past now. What can I do?"

The suggestion was offered that she undergo a complete physical examination to check the possibility of venereal disease. To this she agreed.

She completed her next year's training successfully and was not heard from until several years later. Then it was learned from a colleague that she was most happily married and is the mother of three children. Subsequent personal inquiry confirmed the happiness of her marriage.

COMMENT

The entire management of this case was essentially that of a strong dictatorial father with a "bad" child. Her initial emotional attacks upon the writer were immediately corrected by a careful choice of words but without a nullification of her emotions.

Her contempt for her father was corrected by the acceptance of her identification of the writer as a father-surrogate and the utilization of absolute dictatorial authority over her and essentially forcibly continuing it.

The tremendously strong and compelling emotions deriving from her problem were corrected by the emotions of the waiting period, which culminated in the distressing, painful emotionality of the final session.

Patient H

A young man, normally weighing 170 pounds, married a voluptuously beautiful girl, and his friends made many ribald jests about his impending loss of weight.

About nine months later he sought psychiatric advice from the writer because of two problems. One was that he no longer could tolerate his fellow workers jesting about his weight loss of over 40 pounds. More hesitantly he added that the real problem was something else entirely. In fact, it was the failure to consummate the marriage.

He explained that his wife promised each night to permit consummation, but at his first move she would develop a severe panic and would fearfully and piteously persuade him to wait until the morrow. Each night he would sleep restlessly, feeling intensely desirous and hopelessly frustrated. Recently, he had become greatly frightened by his failure to have an erection despite his increased sexual hunger.

He asked if there could be any help for either himself or his wife. He was reassured, and appointment was made for his wife. He was asked to tell his wife the reason for the consultation and to ask her to be prepared to discuss her sexual development since puberty.

They arrived promptly for an evening appointment, and he was dismissed from the room. She told her story freely, though with much embarrassment. She explained her behavior as the result of an uncontrollable, overpowering terror which she vaguely related to moral and religious teachings. Concerning her sexual history, she exhibited a notebook in which the date and hour of onset of every menstrual period had been recorded neatly.

Examination of this amazing record disclosed that for 10 years she had menstruated every 33 days, and that the onset was almost invariably around 10 or 11 A.M. There were a few periods not on the scheduled date. None of these was early. Instead, they were occasional delayed periods, recorded by actual date and with the scheduled date marked by an explanatory note such as, “Been sick in bed with bad cold.” It was noted that her next period was not due for 17 days.

When asked if she wanted help in her marital problem, she first declared that she did. Immediately, however, she became tremendously frightened; sobbingly, and with much trembling she begged the writer to let her “wait until tomorrow.”

She was finally quieted by the repeated assurance that she would have to make her own decision.

As the next measure she was given a long, vague, general discourse upon marital relations, interspersed more and more frequently with suggestions of fatigue, disinterestedness, and sleepiness until a fairly good trance state had been induced.

Then, accompanied by emphatic commands to ensure continuance of the trance, a whole series of suggestions was given insistently and with increasing intensity. These were to the effect that she might, even probably would, surprise herself by losing forever her fear by suddenly, unexpectedly, keeping her promise of tomorrow sooner than she thought. Also, all the way home she would be completely absorbed with a satisfying but

meaningless thought that she would make things happen too fast for even a thought of fear.

Her husband was seen separately and assured of a successful outcome for the night.

The next morning he reported ruefully that, halfway home, 17 days too early, her menstrual period began. He was relieved and comforted by the specious statement that this signified the intensity of her desire and her absolute intention to consummate the marriage. He was given another appointment for her when her period was over.

She was seen again on a Saturday evening. Again a trance was induced. This time the explanation was given her that a consummation must occur, and that the writer felt that it should occur within the next 10 days. Furthermore, she herself should decide when. She was told that it could be on that Saturday night or Sunday, *although the writer preferred Friday night*; or it could be on Monday or Tuesday night, *although Friday was the preferred night*; then again, it could be Thursday night, *but the writer definitely preferred Friday*. This listing of all the days of the week with emphasis about the writer's preference for Friday was systematically repeated until she began to show marked annoyance.

She was awakened and the same statements were made. Her facial expression was one of intense dislike at each mention of the writer's preference.

The husband was seen separately and told to make no advances, to be passive in his behavior, but to hold himself in readiness to respond, and that a successful outcome was certain.

The following Friday he reported, "She told me to tell you what happened last night. It happened so quick I never had a chance. She practically raped me. And she woke me up before midnight to do it again. Then this morning she was laughing, and when I asked her why, she told me to tell you that it wasn't Friday. I told her it was Friday and she just laughed and said you would understand that it wasn't Friday." No explanation was given to him.

The subsequent outcome was a continued, happy marital adjustment, the purchase of a home, and the birth of three wanted children at two-year intervals.

Comment

The psychosomatic response of a 17-day early menstrual period in a woman so sexually rigid is a remarkable illustration of the intensity and effectiveness with which the body can provide defenses for psychological reasons.

The rationale of the 10-day period, the naming of the days of the week, and the emphasis upon the writer's preference may be recognized easily. Ten days was a sufficiently long period in which to make her decision and this length of time was, in effect, reduced to

seven days by naming them. The emphasis upon the writer's preference posed a most compelling, unpleasant, emotional problem. Since all the days of the week had been named, the passage of each day brought her closer and closer to the unacceptable day of the writer's preference. Hence, on Thursday, only that day and Friday remained. Saturday, Sunday, Monday, Tuesday, and Wednesday had all been rejected. There, consummation had to occur either on Thursday as her choice or on Friday as the writer's choice.

The procedure employed in the first interview was obviously wrong, but fortunately it was beautifully utilized by the patient to continue her neurotic behavior and to punish and to frustrate the writer for his incompetence.

The second interview was more fortunate. A dilemma she could not recognize of two alternatives was created for her—the day of her choice or of the writer's preference. The repeated emphasis upon the latter had evoked a strong, emotional response, corrective in effect upon her emotional problems. The immediate need to punish the writer and to frustrate his preference transcended her other emotional problem. The consummation effected, she could then taunt the writer with the declaration that last night was not Friday, happily secure that he would understand.

In brief, the resolution of this emotional problem, substantiated by the therapeutic results, was integral to, and contingent upon, an emotional response of corrective effect.

GENERAL COMMENTS

Essentially the purpose of psychotherapy should be the helping of the patient in that fashion most adequate, available, and acceptable. In rendering the patient aid, there should be full respect for and utilization of whatever the patient presents. Emphasis should be placed more upon what the patient does in the present and will do in the future than upon a mere understanding of why some long-past event occurred. The sine qua non of psychotherapy should be the present and the future adjustment of the patient, with only that amount of attention to the past necessary to prevent a continuance or a recurrence of past maladjustments.

Why Patient H refused to permit a consummation of the marriage is of interest only to others, not to her—she is too happy with her children, her marriage, and her home to give even a passing, backward glance at the possible causation of her behavior. To assume that that original maladjustment must necessarily come forth again in some disturbing form is essentially to assume that good learnings have neither intrinsic weight nor enduring qualities but that the only persisting forces in life are the errors.

As an analogy, whatever may be the psychogenic causation and motivation of arithmetical errors in grade school, an ignorance thereof does not necessarily preclude mathematical proficiency in college. And if mathematical ineptitude does persist, who shall say that a potential concert violinist must properly understand the basic reasons for his difficulties in the extrapolation of logarithms before entering upon a musical career?

In other words, in this writer's opinion, as illustrated by the above case histories, the purposes and procedures of psychotherapy should involve the acceptance of what the patient represents and presents. These should be utilized in such a fashion that the patient is given an impetus and a momentum, making the present and the future become absorbing, constructive, and satisfying.

As for the patient's past, it is essential that the therapist understand it as fully as possible but without demanding or compelling the patient to achieve the same degree of special erudition. It is out of the therapist's understandings of the patient's past that better and more adequate ways are derived to help the patient to live in the future. In this way the patient does not become isolated as a neurosis of long duration to be dissected bit by bit, but can be recognized as a living, sentient human being with a present and a future as well as a past.

APPENDIX

There are many variations of the technique used in the case of Patient G, and in the writer's experience they are all often useful, especially in expediting therapy. They are employed by impressing most carefully and emphatically upon a patient the idea that the unconscious mind can and will communicate highly important, even inaccessible, information central to a problem but not necessarily in an immediately recognizable form. Then, as a result of some concrete or tangible performance, the patient develops a profound feeling that the repressive barriers have been broken, that the resistances have been overcome, that the communication is actually understandable, and that its meaning can no longer be kept at a symbolic level.

Essentially, the procedure is a direct clinical utilization of projective test methodology, with the patient's performance committing him decisively to a direct, relatively immediate understanding.

1. The "random" selection from a shelf of a book or books, and thereby unwittingly designating a meaningful title.

2. The checking of dates on a calendar—in one instance a highly important, "forgotten" street address; in another, the age at which a strongly repressed traumatic experience occurred.

3. The spontaneous offer to "count the people in that cartoon" with an oversight of one of the children in it—secret doubts about the paternity of one of her own children.

4. The writing of a series of casual sentences with a misspelled word, a misplaced word, or varied spacing of words in one or more sentences.

5. The writing of a "silly" question-seeking instruction preparatory for marriage to George, she wrote, "Will I marry Harold?" who was known to her only as a casual acquaintance of a friend. She actually married a man named Harry.

6. Scrawling at random on paper, shading a line here and there, and subsequently "finding the lines that make a picture."

7. Drawing a series of related or unrelated pictures, smudging or crossing out one or more partially or completely—the people on the street, with the old lady thoroughly smudged and his recognition of his mother—hostility.

8. The writing of a deliberately false, descriptive account of some casual event—15 people at that party had untidy, straight black hair and unduly long noses.

9. Writing a list of casual words and "underlining one or more which would be or should be difficult or impossible to talk about" —the list was one of various items observed while walking down the street with the one word *flowers* repetitiously included but not underlined—his repressed fears of being a latent "pansy."

10. Tearing out an uninteresting advertisement from some magazine and bringing it to the next session—a picture of doughnuts and his sudden realization of the extent of his loss of interest in his wife.

11. Picking up and handing over something, just anything: in one instance a pencil stub—phallic inferiority; in another, a burned match—fear of beginning impotence.

12. Glancing briefly at each page in a newspaper. When this has been done, the additional instruction of, "Give a page number quickly" —the alimony story and secret fears about the marital situation.

13. "When you get up and move your chair to the other side of that table, your unconscious mind will then release a lot of important information. Perhaps it will take your unconscious even longer than five or ten minutes to do it, or perhaps it will not be until the next session" —ten years ago giving mother one-half hour early her four-hour dose of tonic and mother's cardiac death five minutes later.

14. Writing to a dutifully loved father a letter filled with unreasonable complaints and hostility and handing it over to be read—an immediate, severe, psychogenic asthmatic attack.

Pediatric Hypnotherapy

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, July, 1958, 1, 25-29.

As an introduction to what constitutes "Pediatric Hypnotherapy," the question may well be asked, What is the difference between hypnotherapy on the small-sized child, on the medium-sized child, on the large-sized child, and on that older, taller child we encounter so frequently in our offices? Therapy of any kind properly parallels the physical examination in adaptation to the patient as a reality object possessed of needs requiring recognition and definition. And any therapy used should always be in accordance with the needs of the patient, whatever they may be, and not based in any way upon arbitrary classifications.

Psychologically oriented forms of therapy properly employed need always be in relationship to the patient's capacity to receive and to understand. Pediatric hypnotherapy is no more than hypnotherapy directed to the child with full cognizance of the fact that children are small, young people. As such, they view the world and its events in a different way than does the adult, and their experiential understandings are limited and quite different from those of the adult. Therefore, not the therapy but only the manner of administering it differs.

In this connection, and of the utmost importance in the use of hypnosis, is the fact that there governs children, as growing, developing organisms, an ever-present motivation to seek for more and better understandings of all that is about them. This is one of the things that adults so often lose, and which facilitates so greatly the use of hypnosis with all patients.

Children have a driving need to learn and to discover, and every stimulus constitutes, for them, a possible opportunity to respond in some new way. Since the hypnotic trance may be defined, for purposes of conceptualization, as a state of increased awareness and responsiveness to ideas, hypnosis offers to the child a new and ready area of exploration. The limited experiential background of the child, the hunger for new experiences, and the openness to 'new learnings render the children good hypnotic subjects. They are willing to receive ideas, they enjoy responding to them—there is only the need of presenting those ideas in a manner comprehensible to them. This, as in all other forms of psychotherapy for all types of patients, is a crucial consideration.

But such presentation needs to be in accord with the dignity of the patient's experiential background and life experience—there should be no talking down to, or over the head of, the patient. There needs to be the simple presentation of an earnest, sincere idea by one person to another for the purpose of achieving a common understanding and a common

goal and purpose. The mother croons a lullaby to her nursing infant, not to give it an understanding of the words but to convey a pleasing sense of sound and rhythm in association with pleasing physical sensations for both of them and for the achievement of a common goal and purpose. The child that is cuddled properly, handled in an adequate way, placed at the breast in the right way with the proper "hypnotic touch" is not so likely to develop colic. By "hypnotic touch" is meant no more than the type of touch that serves to stimulate in the child an expectation of something pleasurable, and that is continuously stimulating to the child in a pleasing way.

It is the continuity of the experience that is of importance—it is not just a single touch or pat or caress, but a continuity of stimulation that allows the child, however short its span of attention, to give a continued response to the stimulus. So it is in hypnosis, whether with adults or children, but especially is it so with children. There is a need for a continuum of response-eliciting stimuli directed toward a common purpose.

The child at the breast needs the lullaby continued and the nipple between its lips, even after it has satisfied its hunger and is falling asleep. It needs those continuing stimuli until the physiological processes of sleep and digestion serve to replace them. Similarly in child hypnosis there is a need for a continuity of stimulation, either from without or from within, or a combination of both. Hypnosis, whether for adults or children, should derive from a willing utilization of the simple, good, and pleasing stimuli that serve in everyday life to elicit normal behavior pleasing to all concerned.

Another consideration in using hypnosis therapeutically with children is the general character of the approach to the child. No matter what the age of the child may be, there should never be any threat to the child as a functioning unit of society. Adult physical strength, intellectual strength, force of authority, and weight of prestige are all so immeasurably greater to children than their own attributes that any undue use constitutes a threat to their adequacy as individuals. And since hypnosis is dependent upon a cooperation in a common purpose, a feeling of goodness and adequacy is desirable for both participants. That sense of goodness and adequacy is not to be based upon a sense of superiority of one's own attributes, but upon a respect for the self as an individual dealing rightfully with another individual, with each contributing a full share to a joint activity of significance to both. There is a need, because of the child's lack of experiential background and understanding, to work primarily with, and not on, the child. The adult can better comprehend passive participation.

Nor can there be a linguistic condescension to the child. Comprehension of language always precedes verbal facility. There should not be a talking down to the child, but rather a utilization of language, concepts, ideas, and word pictures meaningful to children in terms of their own learnings. To speak in "baby talk" is usually an insult and a mockery, since any intelligent child knows that the adult possesses vocal facility. One does not imitate the accent of an adult, but one can use a word or phrase respectfully abstracted from the speech of the other. Thus one can speak of "dem bums", but cannot rightfully say "Toity-foist Street." So it is with infantile and childish vocalization.

Similarly, respect must be given to the child's ideational comprehension with no effort to derogate or minimize the child's capacity to understand. It is better to expect too great a comprehension than to offend by implying a deficiency. For example, the surgeon who told four-year old Kristi, "Now that didn't hurt at all, did it?" was told with bitter, scornful contempt, "You're poopid! It did, too, hurt, but 1 didn't mind it." She wanted understanding and recognition, not a falsification, however well-intended, of a reality comprehensible to her. For one to tell a child, "Now this won't hurt one bit" is courting disaster. Children have their own ideas and need to have them respected, but they are readily open to any modification of those ideas intelligently presented to them. Thus, to tell the child, "Now this could hurt a lot, but I think that maybe you can stop a lot of the hurt, or maybe all of it," constitutes an intelligent appraisal of reality for the child and offers an acceptable idea of a reasonable and possible responsive participation of an inviting character.

Children must be respected as thinking, feeling creatures, possessed of the capacity to formulate ideas and understandings and able to integrate them into their own total of experiential comprehension, but they must do this in accord with the actual functioning processes they themselves possess. No adult can do this for them, and any approach to the child must be made with awareness of this fact.

To illustrate how one approaches a child and utilizes hypnotic techniques, the following personal example may be cited:

Three-year-old Robert fell down the back stairs, split his lip, and knocked an upper tooth back into the maxilla. He was bleeding profusely and screaming loudly with both pain and fright. His mother and I went to his aid. A single glance at him lying on the ground, screaming, his mouth bleeding profusely and blood spattered on the pavement, confirmed the existence effort an emergency requiring prompt and adequate measures.

No effort was made to pick him up. Instead, as he paused for breath for fresh screaming, he was told quickly, simply, sympathetically, and emphatically, "That hurts awful, Robert. That hurts terrible."

Right then, without any doubt in his mind, my son knew that I knew what I was talking about. He could agree with me and he knew that I was agreeing completely with him. Therefore he could listen respectfully to me, because I had demonstrated that I understood the situation fully. *In pediatric hypnotherapy there is no more important problem than so speaking to the patient that he can agree with you and respect your intelligent grasp of the situation as judged by him in terms of his own understandings*.

Then I told Robert, "And it will keep right on hurting."

In this simple statement I named his own fear, confirmed his own judgment of the situation, and demonstrated my good intelligent grasp of the entire matter and my entire agreement with him, since right then he could foresee only a lifetime of anguish and pain for himself.

The next step for him and for me was to declare, as he took another breath, “And you really wish it would stop hurting.” Again, we were in full agreement, and he was ratified and even encouraged in this wish, and it was his wish, deriving entirely from within him and constituting his own urgent need.

With the situation so defined, I could then offer a suggestion with some certainty of its acceptance. This suggestion was, “Maybe it will stop hurting in a little while, in just a minute or two.”

This was a suggestion in full accord with his own needs and wishes, and because it was qualified by a “maybe it will,” it was not in contradiction to his own understandings of the situation. Thus he could accept the idea and initiate his responses to it.

As he did this, a shift was made to another important matter, important to him as a suffering person, and important in the total psychological significance of the entire occurrence—a shift that in itself was important as a primary measure in changing and altering the situation.

Too often, in hypnotherapy or any utilization of hypnosis, there is a tendency to overemphasize the obvious and to reaffirm unnecessarily already accepted suggestions, instead of creating an expectancy situation, permitting the development of desired responses. Every pugilist knows the disadvantage of over-training; every salesman knows the folly of overselling. The same human hazards exist in the application of hypnotic techniques.

The next procedure with Robert was a recognition of the meaning of the injury to Robert himself—pain, loss of blood, body damage, a loss of the wholeness of his normal narcissistic self-esteem, of his sense of physical goodness so vital in human living.

Robert knew that he hurt, that he was a damaged person; he could see his blood upon the pavement, taste it in his mouth, and see it on his hands. And yet, like all other human beings, he, too, could desire narcissistic distinction in his misfortune, along with the desire even more for narcissistic comfort. Nobody wants a picayune headache, but since a headache must be endured, let it be so colossal that only the sufferer could endure it. Human pride is so curiously good and comforting! Therefore, Robert’s attention was doubly directed to two vital issues of comprehensible importance to him by the simple statements, “That’s an awful lot of blood on the pavement. Is it good, red, strong blood? Look carefully, Mother, and see. I think it is, but I want you to be sure.”

Thus, there was an open and unafraid recognition in another way of values important to Robert. He needed to know that his misfortune was catastrophic in the eyes of others as well as his own, and he needed tangible proof thereof that he himself could appreciate. Therefore, by declaring it to be “an awful lot of blood,” Robert could again recognize the intelligent and competent appraisal of this situation in accord with his own actually unformulated, but nevertheless real, needs.

Then the question about the goodness, redness, and strongness of the blood came into play psychologically in meeting the personality meaningfulness of the accident to Robert. Certainly, in a situation where one feels seriously damaged, there is an overwhelming need for a compensatory feeling of satisfying goodness. Accordingly, his mother and I examined the blood on the pavement, and we both expressed the opinion that it was good, red, strong blood, thereby reassuring him not on an emotionally comforting basis only, but upon the basis of an instructional, to him, examination of reality.

However, we qualified that favorable opinion by stating that it would be better if we were to examine the blood by looking at it against the white background of the bathroom sink. By this time Robert had ceased crying, and his pain and fright were no longer dominant factors. Instead, he was interested and absorbed in the important problem of the quality of his blood.

His mother picked him up and carried him to the bathroom, where water was poured over his face to see if the blood "mixed properly with water" and gave it a "proper pink color." Then the redness was carefully checked and reconfirmed, following which the "pinkness" was reconfirmed by washing him adequately, to Robert's intense satisfaction, since his blood was good, red, and strong and made water rightly pink.

Then came the question of whether or not his mouth was "bleeding right" and "swelling right." Close inspection, to Robert's complete satisfaction and relief, again disclosed that all developments were good and right and indicative of his essential and pleasing soundness in every way.

Next came the question of suturing his lip. Since this could easily evoke a negative response, it was broached in a negative fashion to him, thereby precluding an initial negation by him and at the same time raising a new and important issue. This was done by stating regretfully that, while he would have to have stitches taken in his lip, it was most doubtful if he could have as many stitches as he could count. In fact, it looked as if he could not even have 10 stitches, and he could count to 20. Regret was expressed that he could not have 17 stitches, like Betty Alice, or 12, like Allan, but comfort was offered in the statement that he would have more stitches than Bert, or Lance, or Carol, his siblings. Thus the entire situation became transformed into one in which he could share with his older siblings a common experience with a comforting sense of equality and even superiority.

In this way he was enabled to face the question of surgery without fear or anxiety, but with hope of high accomplishment in cooperation with the surgeon and imbued with the desire to do well the task assigned him—namely, to "be sure to count the stitches." In this manner no reassurances were needed, nor was there any need to offer further suggestions regarding freedom from pain.

Only seven stitches were required, to Robert's disappointment, but the surgeon pointed out that the suture material was of a newer and better kind than any that his siblings had

ever had, and that the scar would be an unusual "W" shape, like the letter of his Daddy's college. Thus the fewness of the stitches was well compensated.

The question may well be asked at what point hypnosis was employed. Actually, hypnosis began with the first statement to him and became apparent when he gave his full and undivided interested and pleased attention to each of the succeeding events that constituted the medical handling of his problem.

At no time was he given a false statement, nor was he forcibly reassured in a manner contradictory to his understandings. A community of understandings was first established with him, and then, one by one, items of vital interest to him in his situation were thoughtfully considered and decided, either to his satisfaction or sufficiently agreeably to merit his acceptance. His role in the entire situation was that of an interested participant, and adequate response was made to each idea suggested.

Another example that may be briefly cited is that of the belligerent two-year-old in her crib, who wished no dealings with anybody and was prepared to fight it out on that line for the rest of her life. She had a favorite toy, a rabbit. As she was approached and her jutting jaw and aggressive manner was noted, the challenge was offered, "I don't think your rabbit knows how to sleep."

"Wabbit tan too," and the battle was on.

"I don't think your rabbit can lie down with its head on the pillow, if you show it how."

"Wabbit tan too! See!"

"And put its legs and arms down nice and straight like yours?"

"Tan too! See!"

"And close its eyes and take a deep breath and go to sleep and stay asleep?"

"Wabbit sweep!" a declaration made with pleased finality, and Kristi and her rabbit continued to sleep in a satisfactory trance state.

The entire technique, in this instance, was nothing more than that of meeting the child at her own level and as an individual, presenting ideas to which she could actively respond and thus participate in achieving a common goal acceptable to her and to her adult collaborator.

This type of technique has been employed many times for the single reason that the primary task in pediatric hypnosis is the meeting of the child's needs of the moment. Those are what the child can comprehend, and once that need has been satisfied, there is the opportunity for the therapist to discharge in turn his own obligations.

To conclude, these two case reports have been presented in considerable detail to illustrate the case of the naturalistic hypnotic approach to children. There is seldom, if ever, a need for a formalized or ritualistic technique. The eidetic imagery of children, readiness, eagerness and actual need for new learnings, their desire to understand and to share in the activities of the world about them, and the opportunities offered by "pretend" and imitation games all serve to enable children to accept and to respond competently and well to hypnotic suggestions.

In brief, a good hypnotic technique is one that offers to the patients, whether child or adult, the opportunity to have their needs of the moment met adequately, the opportunity to respond to stimuli and to ideas, and also the opportunity to experience the satisfactions of new learnings and achievements.

Hyp*., IV, 2, April 1956, pp. 83-88. .Conduct problems in children and hypnosis, *Diseases of the Nerv. Syst*., XVI, 8, August 1955, pp. 3-7.

Utilization of Patient Behavior in the Hypnotherapy of Obesity: Three Case Reports

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, 1960, 3, 112-116.

Requisite to effective hypnotherapy—and the same holds true for experimental hypnosis—is the adequate communication of ideas and understandings to the hypnotized person. Since the object of hypnotherapy is not the intellectual clarification of understandings but the attainment by the patient of personal goals, this cannot be achieved by a simple reliance upon the inherent values of the ideas and understandings to be presented. Rather, communications need to be presented in terms of the patient's personal and subjective needs, learnings, and experiences, whether reasonable or unreasonable, recognized or unrecognized, so that there can be an acceptance and a response and a feeling of personal fulfillment.

To illustrate this need to center the therapeutic use of hypnosis about the individual personality needs and attitudes of the patient, three instances of obesity previously unsuccessfully treated by other procedures will be cited.

CASE 1

A physician's wife in her late forties entered the office and explained that she wished a single interview during which hypnosis was to be employed to correct her obesity. She added that her normal weight was 120 pounds, but that her present weight was 240, and that for many years she had weighed over 200 pounds despite repeated futile attempts to reduce under medical supervision. She stated that in recent years she had been slowly gaining to her present weight, and that she was distressed about her future because, "I enjoy eating—I could spend all the time in the world just eating." Additional history was secured, but the only thing of particular note was her somewhat anxious, unnecessarily repeated assertions that she enjoyed eating and liked to while away time by eating for purely gustatory pleasure.

Since she was insistent upon a single interview and hypnosis, an effort was made to meet her wishes. She was found to be an unusually responsive subject, developing a profound trance almost immediately. In this trance state an understanding of time distortion as a subjective experience, particularly time expansion, was systematically taught to her. She was then instructed to have her physician husband prescribe the proper diet for her and to supervise her weight loss. She was henceforth to eat each meal in a state of time distortion, with time so expanded and lengthened that, as she finished each portion of food, her sense of taste and feeling of hunger for that item would both be completely satiated, as if she had been eating for "hours on end with complete satisfaction." All of

this instruction was given repetitiously until it seemed certain she understood fully, whereupon she was aroused and dismissed.

The patient, together with her husband, was seen nine months later. Her weight had been 120 lbs. for the past month, and her husband declared that her weight loss had occurred easily and without any medical complication. Both she and her husband spoke at length about their improved personal, social, and recreational activities, and she commented that, even though she ate much less, her eating pleasures had been intensified, that her sense of taste and smell were more discerning, and that a simple sandwich could be experienced with as much subjective pleasure as a two-hour dinner.

CASE 2

A patient weighing 180 pounds explained half-laughingly, half-sobbingly, that her normal weight was about 125 pounds, but that for over 15 years she had weighed 170 or more "most of the time."

During these years she had been under medical supervision many times for weight reduction. She had always cooperated with the physician, adhering to the recommended diets, obeying every instruction, always losing at least the prescribed poundage each week, usually more. Each time she reduced, she established a goal-weight which varied from 120 to 130 lbs. As she approached this predetermined weight, she invariably experienced much disturbing behavior of an obsessive-compulsive character.

When within 5 or 10 pounds of her goal, she would weigh herself repetitiously throughout the day, and the nearer she came, the more frequent became the weighings with increasing anxiety. When the scales showed exactly the chosen weight, and not until then, she would rush precipitously to the kitchen and "gorge frantically," usually regaining at least 10 pounds the first week. Thereupon the reduction program would cease, and there would occur a progressive, systematic restoration of the lost weight accompanied by a feeling of despair mingled with a profound determination to engage upon another weight-reduction program soon after she had completed regaining her lost weight. She had, in the past, reduced to the goal weight as many as three times within a year, but always under the direction of a different physician.

She now sought reduction to 125 pounds, stating frankly and with some amusement, "I suppose I'll do exactly the same with you, even though you are a psychiatrist, as I do with every other doctor. I'll cooperate and I'll lose and then I'll gain it back and then I'll go to someone else and repeat the same old silly behavior." Here she burst briefly into tears. Recovering her poise she continued, "Maybe if you use hypnosis that will help, but I don't think it will even if you do hypnotize me. I'll just do the same darned thing again and again, and I'm so tired of reducing and gaining. It's just a horrible obsession with me. But I don't want any psychiatry used on me."

Further explanation on the patient's part served only to emphasize more clearly what she had already related.

In accord with her wishes hypnosis was attempted, and by the end of the hour a medium trance characterized by a considerable tendency toward spontaneous post-trance amnesia was induced. She was given a second appointment, at which time her history was taken a second time. The details were essentially the same, and she reiterated her firm belief that she would again follow her pattern of losing and gaining weight, and again she sobbed briefly. She also reaffirmed her unwillingness to accept psychiatric help and restricted emphatically any help given her to the problem of her weight. She also declared her intention of terminating her treatment if any attempt were made to deal with her psychiatrically. Repetitiously she promised her full cooperation in all other regards.

A medium trance state was readily induced, and she was asked to reiterate her promise of full cooperation. She was also induced to restate repetitiously that in the past her problems had centered around "gaining, losing, gaining, losing, gaining, gaining, gaining, losing, losing, losing," and to agree that throughout the proposed course of treatment she would keep this sequence of behavior constantly in mind.

As soon as it was felt that she had accepted these peculiarly but carefully worded statements, the assertion was offered that her treatment this time, "will be the same, yet completely different, *all of your behavior will be used*, your cooperation has been promised and will be given, and all of your behavior that you have shown so many times in the past will be used, but this time used to make you happy, used in a different way."

When it was certain that the patient knew what had been said to her, even though she did not understand what was meant or implied, she was reminded of the firmness of her resolve to cooperate completely, even as she had in the past, but this time, she was told, "things" would be "done differently" and therefore successfully and to her entire happiness and satisfaction.

Thereupon, while she was still in a medium trance, it was explained that always in the past she had approached her problem of obesity by setting a goal weight, by losing and gaining weight, by a performance of obsessional weighing, and then setting a second goal of her original overweight. These same items of behavior, it was emphasized, would again be employed but in another fashion and effectively for the medical purposes desired.

The explanation was continued to the effect that instead of letting her terminate her reducing by a process of gaining, the procedure would be reversed. Therefore, she was under obligation, as a part of her cooperation, to proceed at once, and at a reasonable rate, to gain between 15 and 25 pounds. When this gain had been made, she could then begin reducing.

The patient protested vehemently that she did not want to gain but to lose weight, but it was patiently and insistently pointed out that her reducing programs had always included obsessive weighing, losing weight, gaining weight, the setting of goal weights, and full cooperation with the physicians. No more and no less was now asked. Finally the patient

agreed to abide by the instructions. She was then aroused, and the instructions were explained again. She protested vigorously but slightly less so than in the trance state, and finally she reluctantly agreed to the proposed program.

Most unwillingly she began to increase her weight. When she had gained 10 pounds she pleaded to be allowed to begin reducing. She was reminded that an increase of 15 to 25 pounds had been prescribed, and this would be insisted upon. As she approached the gain of 15 pounds, she began weighing herself in a repetitive, obsessive manner and demanded an appointment immediately when the scales showed the 15l pound increase. At that appointment it was carefully explained to her in both the trance and the waking states that the prescribed gain had been for a weight *between* 15 and 25 pounds.

Less than a week later, after much obsessive weighing and eating, which was done with great reluctance, she reported for an interview and hesitantly stated that she had gained 20 pounds, and that this figure was exactly between 15 and 25. She pleaded to be allowed to reduce. Consent was given with the admonition that the loss of weight must not exceed the average of three pounds a week.

The patient's progress was most satisfactory. She showed none of her previous obsessive weighing as she approached the weight of 125. She had almost at once calculated the date of her goal weight when she had first begun to reduce, but she had been admonished that weight reduction was on a weekly average. Hence, she could only set the week but not the day of achieving the goal weight.

She was seen only at intervals of three to six weeks. She was always adequately praised for her cooperation in both the trance and waking states, and each time the hope was expressed that no intervening problem would develop to alter the expected week of final achievement.

She forgot her appointment for the final week, but made one for the next week. At that time she weighed 123 pounds instead of 125. She explained that she had failed to weigh herself regularly and hence did not know exactly when she had reached 125 pounds. She declared her intention to remain approximately that weight.

In the nine months that have passed since then the patient has succeeded comfortably in this resolve. In addition she has developed recreational and vocational interests, particularly golf and a book review club, and she has for the first time in her life participated in social and community affairs.

CASE 3

A physician's wife in her middle thirties sought aid for her obesity in an amused, half-hearted manner. This had begun in her junior year in high school, at which time she weighed 110 pounds, and each succeeding year of life had been marked by a progressive increase to the current weight of 270 pounds.

During the past 13 years she had sought help from one physician after another, but each time failed to secure results. Her explanation was, “Oh, I always cooperate with the diet they put me on. I always eat that and everything else I can lay my hands on. I always overeat, and I suppose I always will. As a forlorn hope, I’m trying you to see if hypnosis will work. I know it won’t, but my husband will feel better if I do try it. But I warn you not to expect too much because if I know me, and I think I do, I’ll overeat as usual.”

Hypnosis was attempted. She developed a medium to deep trance readily, but it was difficult to maintain that depth of trance. She would repeatedly arouse, laugh, and explain that she was curious why the writer would be willing to waste his time on her in view of her “unfavorable prognosis” of her own behavior. The explanation was offered to her that neither time nor effort would be wasted since it was intended to utilize her own behavior to effect therapeutic results. Her reply was, “But how can there be therapeutic results when you and I both know that I’ll eat any diet you recommend and everything else even if I have to make extra shopping trips? I’ve had too many years of overeating to give it up, and I’m here only because my husband wants me to come. I’ve always tried to cooperate, but it’s no use. I know the exact caloric value of any serving of food, but all my knowledge does not keep me from overeating. Even my teenage daughter’s embarrassment about my obesity doesn’t keep me from overeating. But I’ll play along with you, at least for a while, but nothing will work.”

Again she was assured that her own behavior would be employed to produce effective results, and she was asked to redevelop a trance state so that hypnosis could be employed. She declared that she would only awaken herself from the trance state if this were done. Even as she completed her statement, she developed a medium to deep trance but almost immediately aroused herself by laughing.

She was then asked to develop and to maintain a light trance and to listen carefully to what was said to her, to understand completely what was said, to go into a deeper trance whenever she wished, or to lighten her trance if she felt so impelled, but at all events to listen to the entire explanation about to be offered her without interrupting it by arousing from the trance. She agreed to cooperate on this basis.

Slowly, systematically, she was instructed:

1. Your weight is 270 lbs.
2. You know the caloric values of any food serving.
3. You always have and always will overeat.
4. Your own behavior has always defeated you in the past.
5. Your own behavior will be used this time to effect therapeutic results. This you do not understand.
6. You will cooperate as you always do, and you will also overeat. (The patient first shook her head vigorously at this, then sighed and slowly nodded her head affirmatively.)

When it was felt that she understood these instructions adequately, she was given the further instructions:

1. You now weigh 270 pounds, not 150 or 140, but 270 pounds. You not only will overeat but you need to eat excessively in order to support that poundage.
2. Now bear this in mind and cooperate fully: During this week overeat, *doing so carefully and willingly*, and overeat enough to support 260 pounds. That is all you need to do, overeat sufficiently to support 260 pounds. Now I am going to arouse you and dismiss you with no further discussion or even comments. You are to return at this same hour one week from today.

She was seen again a week later. Her opening remark was, "Well, for the first time in my life I enjoyed overeating, and I checked on my husband's office scales today, because I don't trust our bathroom scales. I weighed 260 pounds too, a few ounces less in fact, but I call it 260 pounds."

A trance was induced again, light in character, and she was again similarly instructed, but this time to overeat sufficiently to support 255 pounds and to report in another week's time. On that occasion a new goal was established at 250 pounds.

On the next visit she hesitantly explained that she and her husband were going on their annual two weeks' visit at her parental home, and that "I always gain on my mother's cooking, and I hesitate to go this year, but I see no way out of it."

In the trance state she was asked what weight she ought to overeat sufficiently to support on this two-week holiday. She answered, "Well, we'll really be gone 16 days, so I think I ought to eat enough to weigh a good fat 238."

She was emphatically told that she was *to overeat sufficiently to support 238 pounds and also sufficiently to gain 3, 4, or even 5 pounds*.

She returned from the trip jubilant, weighing 242 pounds, and stated happily, "I did just as you said. I gained four pounds. This is a silly game we are playing, but I don't care. It works. I like to overeat and I'm so grateful that I don't overeat as much as I used to."

A variation was introduced into the procedure by insisting that she maintain her weight unchanged on two occasions for a two-week period. Both times she reacted with impatience, declaring "That's too long a time to overeat that much."

In six months' time she has reached the weight of 190 lbs., is enthusiastic about continuing, and is in the process of window-shopping for "something that will look good on a chubby 130 or 140."

SUMMARY

The medical problem for each of these patients was the same, a matter of weight reduction, and each had failed in numerous previous attempts. By employing hypnosis a communication of special ideas and understandings ordinarily not possible of presentation was achieved in relation to personality needs and subjective attitudes toward weight reduction. Each was enabled to undertake the problem of weight loss in accord with long-established patterns of behavior but utilized in a new fashion. Thus, one patient's pleasure in eating was intensified at the expense of quantity, a change of sequence of behavioral reactions led to success for the second, and a certain willfulness of desire to defeat the self was employed to frustrate the self doubly and thus to achieve the desired goal.

Hypnosis and Examination Panics

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, 1965, 7, 356-358.

Over a period of years I have been consulted by many physicians, lawyers, Ph.D. candidates, college students, and high school students who were concerned about the "examination jitters." The vast majority were those who panicked either during the examination or immediately before it, and either failed miserably or made regrettably poor grades. Among the physicians and lawyers have been some persons who have failed the state board or bar examination as many as five times in succession and some who have failed the national specialty certification examinations twice. One particular physician had, following high school days, invariably failed every final examination, but because of his otherwise remarkably excellent record, he had always been given special extra examinations. He always passed these extra examinations with high grades, but only with extreme effort and extended time limits.

The procedure employed with these various applicants for help was essentially constant in character. First a trance was induced that might range in depth from light to somnambulistic. The subjects were then told, in essence:

> You wish to have help in passing your examination. You have sought hypnosis and you have developed the trance state that I know to be sufficient to meet your needs. You will continue in that trance state until I tell you otherwise.
>
> Now, here is the help you wish. Listen carefully and understandingly. You may not want to agree with me, but you must remember that your own ideas have led only to failures. Hence, though what I say may not seem exactly right, abide by it fully. In so doing you will achieve your goal of passing the examination. That is your goal and you are to achieve it, and I shall give you the instructions by which to do it. I cannot give you the information that you have acquired in past study, and I want you to have it available for the examination in the way I specify.
>
> First of all you are to pass this examination, not trying in the unsuccessful ways you have in the past but in the way I shall now define. *You want to pass this examination. I want you to pass it. But listen closely: You are to pass it with the lowest passing grade—*
> *not an A or a B. I know you would like a high grade, but you need a passing grade—that's all, and that is what you are to get. To this you must agree absolutely, and you do, do you not*? [An affirmation was always given.]

Next, after leaving this office I want you to feel carefree, at ease, even forgetful of the fact that you are to write an examination. But no matter how forgetful of that fact you become, you will remember to appear on time at the place of examination. At first you may not even remember why you are there, but it will dawn on your mind in time, and comfortably so.

Upon taking your place, you are to read through all the questions. Not one of them will make sense, but read them all. [The purpose of this was to give the subject an unwitting appraisal of the number of questions and the amount of time each would require.]

Then get ready to write, and read the first question again. It will seem to make a little sense and a little information will trickle into your conscious mind. By the time you have written it down, there will be another trickle keeping you writing until suddenly the trickle dries up. Then move on to the next question, and the same thing will happen. When the time is up, you will have answered all of the questions comfortably, easily, just recording the trickle of information that develops for each question.

When finished, turn in your examination paper and leave feeling comfortable, at ease, at peace with yourself.

THE RESULTS

The results have been uniformly good. This was true even for a law student who telephoned long distance to explain that he had repeatedly failed his bar examination, that he was to be reexamined the next day, that he had been hypnotized previously with no satisfactory results, that he had just been referred to the author, and that he wanted immediate last-minute help.

Subsequently he telephoned to report that he had been disappointed in the trance induced over the telephone, that nevertheless he had slept well that night, had reported in a carefree mood for the examination, had written it with no subsequent memory of what the questions were, and had remained mentally comfortable until he was notified several weeks later that he had passed the examination. He then developed a feeling of almost painful urgency to telephone the news to the author. As he offered this information over the telephone, he lost his feeling of urgency and was again mentally at peace.

The above account, with minor variations, is not at all unusual. However, of particular significance has been the effect of insisting upon a low grade, literally the “lowest passing grade.” A considerable number of these students have insistently queried the author for his reasons, pointing out that instead of low passing grades, they had received the highest possible grade they felt they were capable of earning. Indeed, A’s were common, B’s less so, and C’s only occasional. There was no instance of a grade of D being received even though, for some of the students, their daily class work was

sufficiently good that a final examination grade of D would have led to a passing grade of C. The plausible explanation offered to them has been:

> When you strive for an A, you become tense, overeager, uncertain, and doubtful, and hence you cannot function at your best. When you, obedient to the instructions I gave you, were writing to secure only a C or a D, you were comfortably confident and certain that you could do this with ease. Therefore, you wrote in a state of mental ease and confidence, free of doubt and uncertainty, and you weren't concerned about holding yourself down to a D performance or struggling with doubtful hope for an A. Hence, you were in that mental and emotional frame of thought and feeling that would ensure your optimum performance.

Long experience in psychotherapy has disclosed the wisdom of avoiding perfectionistic drives and wishes on the part of patients and of motivating them for the comfortable achievement of lesser goals. This then ensures not only the lesser goal but makes more possible the easy output of effort that can lead to a greater goal. Of even more importance is that the greater accomplishment then becomes more satisfyingly the patient's own rather than a matter of obedience to the therapist.

This method of handling examination panics has been employed with nearly 100 persons. Physicians, lawyers, candidates for a doctoral degree in medicine, psychology, religion, and education have predominated. The next larger group consisted of college seniors majoring in various fields, but especially in psychology. College juniors and sophomores were fewer in number than were college freshmen, and high school juniors and seniors made up the rest of the students so treated, except for a considerable number of job applicants undergoing a written examination for a promotion. Only one dentist has been handled in this regard.

There have been a few failures, all of whom returned to explain that they, not the author, were at fault, that they had found themselves mistrusting the help offered, and did not use it, with a consequent failure. Now they desired another "treatment" so that henceforth there would be no failures. This was done only upon their agreement to report future results, which they did with pleasure. All of these first-time failures occurred with subjects who developed only light trances and who could not seem to learn deep trances. The deeper the trance, the better pleased was the examinee with the examination results.

It must be recognized, however, that all of these applicants for assistance were highly motivated, which undoubtedly contributed to the success. Also, in the author's opinion some really did not need help.

Subsequently, the physicians and the lawyers in particular sent their wives to the author for training in hypnosis for childbirth.

Experiential Knowledge of Hypnotic Phenomena Employed for Hypnotherapy

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, April, 1966, 8, 299-309.

INTRODUCTION

In the use of hypnosis for the therapeutic handling of psychogenic problems, there is often too ready a dependence upon hypnosis itself and the immediate use of some well-known structured form of hypnotic approach. For example, the author has seen many instances where hypnotherapy was attempted by a routine use of regression by various therapists with disappointing results, and sometimes with an antagonizing of the patient toward hypnosis. Although hypnotic regression, dissociation, abreaction, and revivification may be useful in general, each patient's problem needs individual scrutiny and the structuring of the therapeutic approach to meet the individuality of the problem.

To illustrate this need, the following account is given in detail to portray the character of a problem that had to be met, the purposes that had to be served, the procedures that had to be considered and utilized in therapy, and the methods that had to be employed in devising a successful therapeutic handling of the problem.

The question of therapeutic procedure will be discussed first to present certain vital aspects of the therapeutic situation as a background for a general understanding of the total problem.

One of the considerations was that therapy would have to be successful on the first completed effort. If there were a failure, there could be no opportunity for any second effort by a revision of therapeutic measures or any measure of "second guessing." One and only one opportunity existed for a successful outcome. Both the patient and the author were aware of this fact, a matter so much in evidence that no mention of it was needed.

The problem was one of long duration and it had many times been confirmed and accepted by respected authoritative persons. Additionally, the patient had been aided and abetted in circumventing his problem most successfully many times. He was now confronted inescapably with the need to confront his problem in a situation vital to his whole future with no possibility of any circumvention as had always been done successfully in the past.

He approached the author with a request for help by means of hypnosis but with no adequate understanding that hypnosis could help him only by making more available to him his own potentials for self-help. Nor was he in any frame of mind to be given such understanding. He "knew" beyond all doubt that he was helpless, and he simply surrendered himself to the author with complete dependence upon what the author could do. Hence. any therapeutic procedure would have to be patterned to permit an inclusion of this mistaken understanding by the patient but doing so without invalidating therapy.

The idea of circumvention had become a fixed idea, it was always by the same method, and it had always proved to be the "right and only" method. Now he was barred from circumvention, *hence he had to depend entirely upon the author*.

Since this was the patient's fixed belief, hypnotherapy would have to include circumvention which would not be so recognized by him at the time, since in his own mind he was rigidly convinced that circumvention was impossible. Therefore the structuring of the therapeutic procedure would have to be around something in which the patient fully believed but also fully believed to be impossible of utilization.

The patient himself unwittingly gave the author a rather full statement of how this circumvention could be achieved but which the author did not recognize at the time. Nor did the author recognize, at least consciously and probably not unconsciously, the meaningfulness of the patient's informative statement until after structuring and restructuring the complete plan, and to the author's chagrin he realized he had not listened sufficiently carefully to the patient's own significant statement so vital to the final plan of therapeutic procedure.

Finally, in developing any therapeutic plan that must succeed upon the first effort, the author realized that he would have to do much speculative work and would have to follow the trail of many of his own thoughts on the matter that would turn out to be useless. In this presentation the useless work done will not be reported. The fruitful work only will be reported—and in brief form since the kind, not the extent of the work, is all that is important.

THE PROBLEM

A patient, a professional man seeking certification in a medical specialty, sought the author's aid. His story was that since high schooldays oral examinations had been nightmarish ordeals. Invariably he developed a multitude of psychosomatic symptoms ranging from mild to severely disabling. He had always been an excellent student, and none of his teachers and instructors, upon seeing the state of his physical collapse when attempting to meet the needs of an oral examination, had ever doubted the genuineness of his reactions.

With a feeling of shame and humiliation when confronted with the possibility of an oral examination, he usually secured a physician's statement affirming his inability to comply and recommending, as a medical necessity, that he be given a written examination. Such

medical statements usually stated that there would be no objection to making the written examination much more rigorous and searching than the oral examination would ordinarily be. Invariably he received an excellent grade, since he was a most brilliant and dedicated student.

This special disability had haunted him throughout high school, college and medical school. On several occasions only his earnestness, brilliance, unassuming and modest behavior, and the actual breadth of his knowledge induced some of his instructors to make special allowance for his handicap, or to "humor" him, since a few resented the situation.

State board examinations were trying ordeals for him when both written and oral examinations were required. Only the unusual excellence of the written part of the examination and the documentation of his past experiences induced the two state boards of medical examiners which required an oral examination to accord him special consideration. The reason for examinations by several state boards was his desire to inform himself about the practice of medicine in various parts of the country.

In the actual practice of medicine this patient was well respected and his competence was readily recognized. He experienced no personal problems, and his home and marital adjustments were excellent. He had consulted several psychotherapists, all of whom had regarded his problem as a circumscribed manifestation that did not warrant therapy.

He finally decided to secure certification in a certain specialty. The examining board was considerate about substituting an additional written examination for the customary oral examination part. He received his certification without difficulty. Some years later he decided upon additional certification in an allied field and undertook extensive training for that purpose.

He applied for admission to the examination conducted by the specialty board in that field. He received a letter of acceptance accompanied by a letter from the president of the board of examiners and signed by him. This letter stated that all examinees, in accord with a newly established policy of examination, were required without exception to take an oral examination lasting a minimum of four hours. This would be conducted by the president of the board and two other examiners. The patient recognized the president's name at once as that of a classmate he had had in high school, college, and medical school. That man was fully aware of the patient's oral examination problem; moreover, he had carried throughout the years an unreasoning, intense, and bitter hatred for the patient. With the passage of years occasional encounters at medical meetings had disclosed no abatement of that man's hatred, for which the patient knew no basis and for which no provocation was needed to elicit some unpleasant manifestation.

The patient consulted a colleague who also intended to take the examination at the same time. This colleague had received a letter of acceptance containing the same information, but it was signed by the secretary of the board. He wrote to two other friends with whom

he had taken specific postgraduate courses and who were also taking the examination. Their letters were similar in content to his but were signed by the board secretary.

The patient then said simply, “There you have it. The term of office for that man is four years. I need to be certified this year. I know for an absolute certainty that I cannot measure up to an oral examination. I have no doubts about knowing my stuff. I could pass any written examination with flying colors. But I also know with absolute certainty that I cannot take an oral examination, much less one conducted by a man who hates me bitterly for no reason that I know of and who knows my weakness. I regard my situation as hopeless unless hypnosis can do something for me. That is why I have come to you, and I place myself unreservedly in your hands. I am your patient if you will accept me. If you do, you will have my full cooperation in anything that you wish to do or anything that you may wish me to do.” This placing of all responsibility upon the author was immediately apparent, as well as his fixed limited understanding of his situation.

INITIAL PROCEDURES AND APPRAISAL OF PROBLEM

He was assured that he was accepted as a patient and he was asked to give in full detail every item of symptomatology he had ever developed in connection with oral examinations. He was asked to execute this task as a simple recounting rather than as a vivification of his symptoms as he recited them.

The patient thoughtfully, slowly, and in a most orderly and systematic fashion detailed his symptoms fully. They were many and included intense fear, uncontrollable tremors, excessive perspiration, nausea and vomiting, palpitation, bladder and bowel incontinence, severe vertigo, and a final physical collapse resembling shock. He added, with a reflective smile, that there seemed to be no direct correlation between the severity of his symptoms and the importance or unimportance of the examination. The only requisite was that the oral examination must be definitely recognized as being an examination. A recitation offered no difficulty. He explained further that even in taking examinations for an automobile driver’s license, he was forced to the measure of taking a pen and a pad of paper with him. When asked a question, he would simply write the answer on the paper pad and then “read it aloud.” This behavior had occasioned some lifted eyebrows, but it was a measure by which he “could avoid the oral examination situation.” Even such questions as his age and the number of years he had been driving an automobile had first to be written and then “read” to the examining clerk.

The patient was then told that he would not be given any therapeutic or otherwise helpful hypnotic suggestions until he had been hypnotized a sufficient number of times to give him an adequate experiential background for therapy. To accomplish this he might be used as an experimental subject in a current project. To this he readily agreed.

He proved to be an excellent somnambulistic subject, but several hours were spent merely eliciting the various hypnotic phenomena repeatedly. He was then used as an experimental subject in special work in which the author was interested with intentional additions for him requiring wide use of deep trance phenomena. The reason for such use

of him in this experimental work was to secure some measure of his competence for prolonged hypnotic work of any type.

In the meantime the problem of how to help him was being given consideration.

His initial account and all subsequent inquiries indicated that his problem was of a limited, circumscribed character. After much thought it was reasoned that therapy would need to be similarly circumscribed. That the patient would have to take additional oral examinations other than the one impending was considered to be most unlikely. Hence, there would be no need to devise a therapeutic design to meet future contingencies.

Another consideration was that any measure that met the patient's needs would also have to include elements that were definitely not therapeutic but might even serve to enhance his own pattern of circumscribed neurotic structure by a utilization of it. This would be occasioned by the fact that a vital part of the situation to be met was of an unalterable character—namely, the man who hated him and who would be examining him. Any therapeutic or helpful plan would have to include this fact and be structured accordingly. Furthermore, there could be no clouding or falsification of this significant aspect of the situation to be met.

The patient, in the time spent with him, had shown himself to be of good strong character, readily able to face all ordinary challenges of life. His war record had been excellent in combat service. Apparently his Achilles heel was only the matter of oral examinations, compounded in this instance by an examiner's intense hatred.

That a simple direct or even indirect therapeutic approach be made was ruled out by several important factors. Foremost was the fact that he came for help in relationship to a specific impending examination, not for therapy. Also, there were his fixed and rigid "certainties" about his condition. These could not be immediately changed; help by the author as the patient understood matters was only to permit success in the examination. Other psychotherapists had assured him he did not need therapy. Also, the usual therapeutic methodologies would take too much time, much more time than was available for him. Then, too, ordinary psychotherapy by whatever school of thought could quite conceivably fail.

Therefore, some plan of procedure had to be devised whereby the patient's needs as he understood them had to be met. It could not include direct or even indirect suggestion, since such suggestions would be in contradiction to the patient's fixed understandings. To attempt some direct procedure such as regression—direct, or indirect by dissociation—offered no promise of success. Nor could there be risked a failure of any sort with hypnosis, since failure would lessen greatly or actually destroy his remaining hope of achieving success.

Since the patient was so rigidly convinced that he had no means whatsoever of his own with which to meet his problem, it was finally decided to devise a "therapeutic" (as he would or might construe whatever the author did) procedure that would give to him

various new ways and means of dealing successfully with the impending examination. That it would actually be therapeutic in the usual sense of the word was not of importance. What was important was that the patient would be given entirely new ways of reacting and responding of a sort that would preclude the development of his long-established pattern of behavior. Further thought suggested that the rigid, limited, circumscribed character of his problem be employed to structure the final procedure. To do so might enable him to enter the examination room with his medical knowledge readily available, this to be presented adequately as needed by wholly new and different methods of reacting and responding. All of this would be so structured that it could be achieved within a highly restricted circumscribed frame of reference.

Having reached these conclusions, a systematic plan of therapeutic work was devised. Previous hypnotic work which served primarily to enable the patient to develop a trance satisfactorily was repeated in large part and fitted into the following plan described in detail.

THE THERAPEUTIC PROCEDURE

A deep somnambulistic hypnotic trance was induced on repeated occasions in the patient, and each time he was asked to experience fully, in a fashion entirely unrelated to his problem, all of the various phenomena of the deep trance. Some of this work fitted into a current experimental project, but the patient had no knowledge of what the experimental work was. Most of the work done with him was merely to ensure adequate experiential learning by the patient. Thus, he learned to develop positive and negative visual and auditory hallucinations, superficial and deep anesthesia, regression, revivification, dissociation, selective amnesia, partial or total amnesia, hypermnesia, posthypnotic suggestion, depersonalization, automatism, and time distortion. The patient was given to understand that many of these learnings would be of no service to him, and he was allowed to think that the author was meeting the needs of personal experimental work. In no way was he allowed to realize that this additional work might serve a definite purpose for him—namely, that of preventing him from attaching any of his anxiety and fears to any of those learnings or from distorting those learnings in any way by an overeagerness to benefit from them. Also, the knowledge that the author was already engaged in an hypnotic experiment of which he knew nothing furthered this needed distraction of the patient from the author's work with him. It may be added that if the author had not already been engaged in some experimental work, he would have immediately devised some that would have required the recording of data, this fact of recording being unobtrusively disclosed to the patient without revealing the data. This measure is often most effective in circumventing the hindrance caused by too intense an interest by the patient in his own therapy.

When the author was fully satisfied that the patient was adequately trained, the plan of therapy that had been devised was put into action. This plan was based upon (1) the ability to hallucinate visually, (2) the ability to dissociate from the self and to dissociate the self from objects, (3) the ability to maintain a coherent train of thought while verbally expressing another or while attending auditorially to the utterances of another person, (4)

the ability to execute posthypnotic suggestions, (5) the ability to develop amnesia, (6) the ability to behave like an automaton, (7) the ability to distort and to transform realities, and (8) the ability to present an appearance of alert, attentive consciousness, however deep a trance state might develop. Since all instructions given to the patient were permissive in character, the patient was entirely at liberty to utilize these various learnings as best befitted him in the impending situation.

THE RESULTS

In essence, the patient utilized all of the instructions given to him, not always in the order or manner intended by the author but rather in accord with his own understandings of what he was to do. What actually happened is best related in the patient's own words.

"As soon as I got back home, I realized I had to see you again. So I called for an appointment. I had a feeling it was urgent and that you also wanted to see me right away. I literally didn't remember anything until my wife met me at the airport. I read the good news on her face and then I remembered that I had telephoned the good news to both of you. I was in a complete mental daze while going there. I knew I was completely clear-headed and at ease during the examination. I knew I didn't miss a single question. I remembered that they told me my diploma would arrive in about three weeks. Then I telephoned you and my wife. But I forgot all this. Then I must have come home in a daze. I don't remember even checking out of my hotel or catching my plane. I knew where I was. I was just without any memories of what had occurred while I was away from home when my wife met me at the airport. When she said how glad she was I had passed, I could remember notifying her and you. That's all, though. So I told her that I had to go to the office right away on something urgent, and as soon as I got there, I telephoned you and called a cab. Will you put me in a trance and help me to remember?"

The author replied, "The important thing is that you passed your examination. It really is not necessary to induce a trance for a systematic orderly account of what happened. *You can remember now while completely alert and wakeful*."

In an astonished tone of voice the patient began, "That's right. I was in a daze all the way there. I acted like a robot. I said and did all the right things. I had my notice with me telling me where and at what hour to report. I was there about 20 minutes early. Sat like a robot. Walked in the examination room when the girl called me. My 'friend' showed all his teeth in his smile. They needed cleaning. He said, 'Glad to see you, Jack. Sorry we can't make any special arrangements for you.' But all the time he was speaking, I was looking at his face. It looked as young as when we were in high school. Then I saw it getting older and older, changing like the face of Dorian Grey in the movie. But I just said, 'It's all O.K. with me. I'm ready to go anytime.' Then he said, 'Just take a seat in that chair there.' I looked at it and wondered what a nice chair like that was doing there, but I sat down facing the three of them.

"Then he fired the first question. I heard every word of it, but I kept watching the way his mouth moved. It looked so interesting in such a peculiar way. Then when I told him the

answer I knew he wanted but didn't think I knew, you should have seen the look on his face. I knew that he knew my answer was right. But he looked as if he just couldn't believe something about me. I couldn't figure out what it was. Then he asked me a great long question. I tipped my head a bit to hear him better and looked past him, and he disappeared. Just his voice was there. Heard every word but as I heard the words, pages from textbooks appeared before my eyes. I could see the page numbers, and certain paragraphs were in large print. I looked at them carefully while I listened to the words, and when the words stopped, I just summarized what was in those paragraphs. I thought I gave a pretty good summary, but just then my 'friend' came back looking mad. Before I could figure out why, he picked up a sheet of paper and began reading a page-long typewritten question. As he began reading to me, a large sheet of white paper appeared before me, and every word he read showed up in big black print, and I kept reading right along with him about a word or two behind him. When he finished, I just looked that sheet of paper over carefully a few seconds and explained that there were three different possible interpretations. So I told him what they were. You should have seen the agony on his face. That man was in pain." Here the patient interrupted himself to say, "Now I know what really happened. I was in some kind of hypnotic state, and you must have taught me how to use it in the examination situation. It's obvious that I was hallucinating and that I was behaving automatically some of the time. There's probably some things I did that I don't know the technical terms for."

He was assured that his interpretation was entirely correct, but that the author wanted him to continue with his account.

The patient resumed, "Well, then the next man introduced himself and I realized that my 'friend' hadn't done the proper thing. This man looked like an awful nice fellow, and he spoke as if he really needed some help on a problem that was troubling him, so I told him exactly what he needed to know."

Here the patient interrupted himself again, "That's exactly what happened with each of the other two examiners. They each looked like a person you would like to know, and when either of them asked me a question, they looked like they needed help, and so I listened carefully and then I told them what they needed to know. Oh, yes, at the end of an hour and a half they nodded to each other and then to my 'friend.' He looked madder than ever. Then those two stood up and both shook hands with me and congratulated me. Then my 'friend' stepped over and shook my hand and congratulated me and I wondered why, and why he didn't get a rug for his baldness and have the hair on his ears clipped. That was it."

To this the author replied, "Not entirely. Tell me a bit more about what you did in relation to your so-called friend."

"In complete detail? I remember everything and can do it, or will a summary be sufficient?"

He was told that a summary would be satisfactory.

"Well, there was that question where I could see myself standing behind him looking over his shoulder and reading what he was reading and then reading the answer. Then once he seemed to be trying to sing a silly song, so I recited some medical prose. Then he seemed to be beating time while I was talking to him, and I would purposely rephrase what I was saying to get him off beat.

"Oh, yes! There are two especially interesting things, one that puzzled me and both that I enjoyed. Well, several that I enjoyed. The puzzler was where 'friend Henry' looked to be about a block away so I could barely see him. Couldn't recognize him, but I could hear his voice right in front of me. I tried to figure out whether he had moved away from me or if I had moved away from him, but how could his voice be right in front of me? So I replied to him and never did figure that one out till now. But the best ones were when Henry asked about some specific condition or some syndrome and I actually felt myself in white uniform on the ward examining a patient. Each time the patient was Henry and he was in terrible condition—looked awful—and I explained the condition very carefully so that the interns with me could understand fully. I was just one of the fellows taking postgraduate work making rounds with the interns and really enjoying myself.

"In fact, not once did I know what I was there in that examination room for. I just was interested in how I saw things, and I did and said all the right things. Did you teach me how to do all those things in those hypnotic sessions I had with you? And did you make me have amnesia so I just wouldn't worry and fret and get into a horrible stew?"

He was told that such was the case and that he had been taught various other things, all for the purpose of permitting an adequate examination performance with no neurotic distress. He was also told that he was at liberty to ask more questions of the author and also free to remember or to forget his examination experience. However, it was stressed that he retain any measure of learning that might be useful to him and that he could feel comfortably certain that he need never use his hypnotic learnings except appropriately and in times of special need.

The patient has been seen repeatedly many times since then in a casual way. He has referred patients to the author, and he would, if asked, do hypnotic work with the author. He is not interested in employing hypnosis himself, but he has stated that his approach to patients and their problems has been changed for the better. This he explained as, "Perhaps I am unconsciously using hypnotic techniques."

DISCUSSION

It is at once apparent that an unrecognizable (to him) circumvention of the examination situation had been effected. There had been also a bizarre distortion of it, fully as bizarre as his own neurotic behavior that disabled him. This distortion of the examination situation had been amusing, puzzling, even bewildering, but in no way distressful, nor did it interfere with the examination procedure. Posthypnotic suggestion had served to enable him to present an appearance of ordinary wakefulness, alertness, and responsiveness.

Well-learned forms of the various types of hypnotic behavior were posthypnotically employed by him in his own private personal manner of meeting the requirements of the examination.

Paradoxically, such an elaborate procedure was not evolved for the patient's sake. A general explanation can be found in the question, "Why do neurotic and psychotic patients so frequently develop such elaborate psychological structures to give expression to their illness?" Undoubtedly because the expression. they do give is so inadequate. As for the patient, why did he have such elaborate and so many and such intense symptoms? Nausea and vomiting alone were sufficient. Certainly bladder and bowel incontinence were more than adequate to prevent an oral examination. Then why were there all the other symptoms? Did they serve some other purposes or relate to unrecognized significances? As in the case with other patients, the author simply does not know. Nor does he know of anybody who has ever really understood the variety and purposes of any one patient's multiple symptoms despite the tendency of many psychiatrists to hypothecate, to their own satisfaction, towering structures of explanation often as elaborate and bizarre as the patient's symptomatology.

As for the therapy evolved for this patient, it was he who developed it, not the author. The patient was taught simply how to experience various hypnotic phenomena. Thus he learned how to develop a negative hallucination for the author, for a part of the author such as his hand, his head, or his torso. He was taught to alter visual stimuli by experiencing them as coming from near at hand or from a remote distance. He was taught to hallucinate printed pages and printed words and various other objects, as well as movements by the author or by objects in the office. He learned to change and to distort visual stimuli. He could see the author smiling and experience it as frowning, and vice versa. He learned to see tears streaming down the face in a picture on the author's desk, he saw that face burst into a smile, and then he saw that face in the picture talking and he hallucinated the apparently spoken words. He saw a black-and-white picture in bright colors. He experienced visually a small oblong ashtray as square, as a circle, as tall, as flat, as transparent, as opaque, as of many different colors, as twisted into various shapes, as floating in midair, as moving back and forth or up and down rapidly, slowly, in various rhythms. In each of these teachings care was taken to make sure he understood the nature or kind of experience he was to learn; but, unless absolutely necessary, never the degree or extent of the suggested experience. Thus it was he who decided that a negative hallucination for a part of the author's body should be of the hand, the foot, the head, or the torso. The shapes in the twisting of the ashtray were determined entirely by him, and no effort was made to inquire what those shapes were. The words hallucinated as spoken by the face in the picture remained unknown to the author. The *kind* of task was the author's responsibility in this hypnotic teaching of the subject. The content was the patient's. *All of the teachings that he had been given or that would be given to him by the author*, he was told, *he was to use profitably and well in any needful situation*.

In relation to the auditory field one precaution was emphasized—namely, that he would hear clearly and easily every verbal stimulus and that he would listen most understandingly to all utterances. If he wished, he might have the speaker standing up,

sitting down, or leaning on a chair, but always he was to hear clearly and understand thoroughly.

Each of the various hypnotic phenomena was developed in this same detailed fashion until the author was convinced of the patient's competence. Great care was taken to ensure his appearance as a person alert, attentive, interested, understanding, responsive, and fully wide awake regardless of what hypnotic phenomena he was experiencing.

Posthypnotic suggestion and amnesia, while taught with the same meticulous care, were used directly by the author to ensure certain things. These wet e that the patient make the trip to the city where the examination was held with a generalized amnesia, but with a responsive alertness to meet every expected or unexpected development concerning the trip itself. Thus he made the trip and appeared in proper time for the examination but with an amnesia for, and a total unconcern about, the purpose of the trip. In his own words, "I just went comfortably. I read a novel that I had long wanted to read and I took it with me." His telephone calls to the author and to his wife were both the outcome of posthypnotic suggestion. He was told that he might forget telephoning his wife, but that he could "read" that fact upon seeing her and that this might make him realize the importance of promptly seeing the author, who knew the hour of his return flight. The amnesia on the way there was to prevent any building up of tension, and on the way back it served to let him rest without sensing unduly his fatigue or building up an elated tension over his probable success.

The final interview with the author was to give the patient a full recollection of all that occurred, all or any part of which he was at liberty to remember or to forget. Since then he has forgotten much that occurred, but of noteworthy significance is the fact that he can speak of his past oral examination experiences casually and that he took his next examination for a renewal of his driver's license quite unconcernedly. As for his "friend Henry," the patient now speaks of him as a rather absurdly emotional man.

BACKGROUND OF EXPERIMENTATION

Since 1935 the author has many times induced hypnotic trances in normal college students to discover if they could take an examination successfully in a college course while in a posthypnotic trance state. The results were always equal to, or better than, what might have been expected in relation to their class grades. Unless special understandings had been given to the students, they always developed persistent spontaneous amnesia for having taken the examination, which had to be removed by the author. In some instances this amnesia was allowed to persist for as long a period as a year.

These experiences led the author to induce in professional persons the development of posthypnotic trance states during which they might give to students or colleagues (even psychiatrists) a prepared or impromptu lecture, present patients at a staff conference, discharge a day's duties on the ward, or spend a social evening or day with friends without the trance state being detected. They always succeeded, and similarly developed spontaneous amnesia which had to be removed by the author.

A third-year resident in psychiatry, who was an experimental subject of the author's but who was unaware of this special work, asked to be taught autohypnosis. Without inducing a hypnotic trance, the author casually and conversationally outlined various methods of autohypnosis, intending to give more adequate instruction later. About a month afterward, before any further instruction had been given, the author received a telephone call from the resident, who declared, "I must see you. It's four o'clock in the afternoon, and there's something I do not understand. May I come to your office?"

Upon arriving at the office, the resident stated very simply, "This morning I dressed to go to town [Detroit] for some shopping with a friend. I looked at the clock on the dresser and it was a few minutes of eight. I saw that I had just time to meet Dr. —— , have breakfast, and then catch the bus to town. I took a second look at the clock, and it read four o'clock. Then I noticed that the sun was shining through the west window, and then I turned and looked at the rest of the room. There was my bed all made up, with a lot of packages on it. I looked at some of the wrappings. They were from stores in Detroit. I opened a couple of them. They were things I had promised myself to buy months ago, but had completely forgotten about. That's when I knew I ought to see you, and here I am. Put me in a trance and see if my unconscious knows anything at all about this, because I don't."

The author gave a cue used in experiments with this subject, and a somnambulistic trance ensued. The subject, with open eyes, smiled and waited expectantly. The author then asked, "Do you know what happened?" The reply was, "I do now, but I don't when I'm awake." The author asked, "What do you want me to do?" "Ask me about everything, then wake me up and tell me." The author answered, "Would it be all right if I just awakened you and let you remember everything sequentially?" "I think that would be better, so wake me up so I can start."

The subject aroused from the trance state, appeared astonished, and said, "I'm sure you must know everything, but I'm just beginning to remember. Today I was off duty, and I had arranged to go to Detroit by bus with Dr. ——, who was also off duty, after we had breakfast together. But just after I looked at the clock I went into an autohypnotic trance. I had been thinking about autohypnosis since the day you discussed it with me. I had been impressed by your statements that, in developing autohypnosis, you cannot tell your unconscious mind all the things it should do and how it should do them, because that would be making it a conscious task. And it's also a useless task because your unconscious mind already knows what you know a lot better than you do. So I knew that I would have to go into autohypnosis unexpectedly. Now I have just remembered that this morning my unconscious mind simply took over, and there I was in an autohypnotic trance. Now I'll tell you what happened, because I am remembering things one by one just as they happened."

Then there followed a long, sequential detailed narrative of the day's events, with interspersed comments. The account included conversations with Dr. —— (also a psychiatrist) and with other friends, an accidental meeting with two former high-school classmates who had not been seen for more than eight years, eating lunch with Dr. ——

and the two friends at a favorite restaurant, shopping in various stores, purchasing four items long wished for but always previously forgotten, returning on the bus with Dr. —— putting the packages on the bed, and then turning to look at the clock as a self-determined cue for awaking.

This account was then related by both the resident and the author to various members of the hospital psychiatric staff. A few of them indignantly declared, with all the weight of their lack of knowledge, that a person in a hypnotic trance would necessarily act "like a zombi." This was disputed with equal indignation by Dr. ——.

A few weeks later, at a staff conference, the same resident presented several patients, discussed the clinical records, and answered questions adequately, even those asked by some unexpected visitors at the staff conference. The fact that the resident was in an autohypnotic trance throughout the conference was recognized only by the author, although it was strongly suspected by another staff member (not Dr. ——). He later demanded confirmation of his suspicions from the author. This being given, he emphatically discredited to his colleagues the "zombi" misunderstandings which had been previously expressed. To substantiate his statements, he called upon the resident, who was found to have a total and seemingly unbreakable amnesia for that particular staff conference, even when confronted by the typewritten record.

The fact was then established that behavior in an autohypnotic state may be difficult to differentiate from ordinary waking behavior. The author was then called upon to "restore" the resident's "loss of memory." A few cues given to the resident served to effect a recovery of the amnestic material along with a full awareness of the previous conscious unawareness. The resident then disclosed that such an occurrence had been secretly intended but for a much later staff conference.

Burden of Responsibility in Effective Psychotherapy

Milton H. Erickson

Reprinted with permission from *The American Journal of Clinical Hypnosis*, January, 1964, 6, 269-271.

The following case material is presented because it offers so concisely and clearly a modus operandi in hypnotherapy with a type of patients who have had long experience in failing to derive desired benefits from extensive, traditionally oriented therapy. The three persons reported upon are typical of dozens of others that this author has seen over the years, and the results obtained have been remarkably good despite the fact that the patients were seen on only one occasion for an hour or two.

In each instance hypnosis was used for the specific purpose of placing the burden of responsibility for therapeutic results upon the patient himself after he himself had reached a definite conclusion that therapy would not help and that a last resort would be a hypnotic "miracle." In this author's understanding of psychotherapy, if a patient wants to believe in a "hypnotic miracle" so strongly that he will undertake the responsibility of making a recovery by virtue of his own actual behavior and continue that recovery, he is at liberty to do so under whatever guise he chooses, but neither the author nor the reader is obliged to regard the success of the therapy as a hypnotic miracle. The hypnosis was used solely as a modality by means of which to secure their cooperation in accepting the therapy they wanted. In other words, they were induced by hypnosis to acknowledge and act upon their own personal responsibility for successfully accepting the previously futilely sought and offered but actually rejected therapy.

CASES 1 AND 2

A telephone call was received in the office from a man who stated that he wanted an appointment. He refused to give any reason except that it was for a proper medical reason he preferred to explain in person.

At the interview the man stated that he was suffering from Buerger's disease, that he was a diabetic, and that he had cardiac disease and high blood pressure—" Too much for a man with a family the size of mine and only 50 years old." He went on, "That isn't all. I've been psychoanalyzed for eight months for five hours a week. During that time my insulin dosage has had to be increased, I've gained 40 pounds, my blood pressure has gone up 35 points, and from 1½packs of cigarettes I have gone up to 4½packs a day. I am still the psychoanalyst's patient, I have an appointment with him for Monday, but he is paid up to date. He says he is slowly uncovering the psychodynamics of my self-destructive behavior. I myself think that I'm digging my grave with power tools."

Then with utter gravity he asked, “Would it be unethical for you, knowing that I am another physician’s patient, to give me the benefit of two hours of hypnotherapy this afternoon? My analyst disapproves of hypnosis, but he certainly hasn’t done me any good.”

The simple reply was made that, from my point of view, the question of professional ethics did not enter into the situation at all, that every patient, including mine, has the right to seek from any duly trained and licensed physician whatever proper help he desires, that medical ethics should properly be centered about the patient’s welfare rather than a physician’s desire to keep a patient.

He was then told to close his eyes and repeat his story from beginning to end, to do this slowly, carefully, to drop out the question of ethics and in its place to specify what he wanted from the author. This he was to do slowly, thoughtfully, appraisingly, and as he did so, the mere sound of his own voice would serve to induce in him a satisfactory trance in which he could continue to talk to the author, listen to the author, answer questions, *do anything asked of him by the author and that he would find himself under a most powerful compulsion to do exactly that which was indicated*.

The man was taken aback at these unexpected instructions, but leaned back in his chair, closed his eyes, and slowly began his recitation with pertinent additions. Shortly his voice began to trail off, indicating that he was developing a trance, and he had to be told several times to speak more loudly and clearly.

No mention was made of the question of ethics, but with a wealth of detail *he outlined the therapy which he thought to be indicated*. He was asked to repeat this several times, and each time he did so more positively, emphatically, and inclusively.

After four such repetitions the author pointed out that he, as a physician, had offered no advice or therapeutic or corrective suggestions, that every item in that regard had come from the patient himself, *and that he would find himself under the powerful compulsion arising from within him to do everything that he thought was indicated*. To this was added that he could remember any selected parts of his trance state, but regardless of what he remembered or did not remember *he would be under a most powerful compulsion to do all that he himself thought to be indicated*.

He was aroused, a casual conversation initiated, and he left.

A year later, in excellent physical shape, he brought in an old childhood friend of his and stated very briefly, “I eat right, I sleep good, my weight is normal, my habits regular, my diabetes is under good control, my Buerger’s disease has not progressed, my blood pressure is normal, I never went back to my analyst, my business is better than ever, I’m a new man and my whole family thanks you. Now this man is my boyhood pal, he’s got emphysema, a very bad heart, look at his swollen ankles, and he smokes like a chimney. He’s been under a doctor’s care for years.” (This man was smoking one cigarette and had another out of the package ready to light.)

"Treat him the way you did me, because I told him you talked to me in a way that just takes complete hold of you."

He left the office with the new patient remaining.

Essentially the same procedure was carried out, checking against the first patient's file as this was done, and almost precisely the same words were used that were applicable.

At the close of the interview the man left, leaving his cigarettes behind him.

Six months later a long distance call was received from the first patient, stating, "Well, the news is bad but you should feel good. Joe died last night in his sleep from a coronary attack. After he left your office, he never smoked another cigarette, his emphysema was much better, and he enjoyed life instead of worrying all the time about running out of cigarettes and about the cigarettes making his condition worse."

CASE 3

A telephone call was received early in the morning. A man's voice said, "I've just realized that my condition is an emergency. How soon can I come in?" He was told that a cancellation had just been received and he could be seen in one hour's time. At the specified time a 32-year-old man walked in, smoking a cigarette, and stated hastily, "I'm a chronic smoker. I need help. I've been in psychotherapy twice a week for two years. I want to quit smoking. I can't. Look! I've got six packs in my pockets right now so I can't run out of them. My analyst says I am making progress, but I was only carrying two packs a day when I first went to him. Then slowly I increased my reserve and emergency supplies until it is up to six packs a day. I'm afraid to leave home without at least six packs in my pocket. I read about you. I want you to hypnotize me out of smoking."

He was assured that *this could not be done*, but that the author would like to have him retell his story slowly, carefully, with his eyes closed, and to give it in good detail, letting his unconscious mind (he was a college graduate) take over all dominance, and that, as he related his story, he was to specify in full and comprehensive detail exactly what it was he wished in relation to cigarettes, but that during his narrative he would find himself going unaccountably into a deep and deeper trance without any interruption of his story.

The procedure and results were almost exactly comparable to the two preceding cases.

Two years later another telephone call was received from the same man asking for a half-hour appointment at noon and volunteering to pay an hour's fee. He again declared it to be an emergency.

Exactly at noon he came striding into the office and remarked. "You won't recognize me. You only saw me for an hour two years ago. I am Mr. X, and I had had two years of analysis for excessive smoking with only an increase in my smoking. I can't remember

what went on when I saw you, but I do know that I haven't smoked a cigarette since then. It's embarrassing, too, because I can't even light one for my girl. I've tried many times, but I can't.

"But I went back to that analyst, and he took all the credit for my stopping smoking. I didn't tell him about you. I thought I needed to see him about what he called a character defect in me. Here I am with a college education, and the longest I've worked at a job has been three months. I can always get a job, but I'm 34 now, and four years of psychoanalysis has wound up with my last job lasting only five weeks. But I'm 34 now, and I've got the promise of another job with a future to it. Now I want you to do something about whatever is wrong with me because I've quit the analyst. I've had better jobs than the one coming up, but there is nothing to hold me to it. It will be the same old story. Now, hypnotize me and do what I should have had you do two years ago, whatever that was."

His former case record was looked up to refresh the author's memory. As precisely as possible the technique of the previous occasion was followed, and he was again dismissed.

Two years later he was still at the "new job" but had been promoted to a managerial position which he has held for over a year. A chance meeting with him disclosed this fact and also that he is married and a father and that his wife voluntarily gave up smoking.

SUMMARY

Three of a long series of similar cases are reported here to illustrate the use of hypnosis as a technique of deliberately shifting from the therapist to the patient the entire burden of both defining the psychotherapy desired and the responsibility for accepting it. Often this is the most difficult part of psychotherapy. In all the patients this author has handled successfully in this manner, all had a history of a steady, persistent search for therapy, but a failure to take the responsibility of accepting it. Additionally, all such patients with whom the author has had a known success were of a superior intelligence level.

In traditional ritualistic and conventional psychotherapies much, often futile, effort is made to induce patients to assume adequately the responsibility for their own behavior and for future effort. This is done without regard for the patients' consciously thinking and firmly believing as an absolute truth the futility of any effort on their own part. But utilizing hypnosis as a technique of deliberately and intentionally shifting to the patients their own burden of responsibility for therapeutic results and having them emphatically and repetitiously affirm and confirm in their own thought formulations and their own expressed verbalizations of their own desires, needs and intentions at the level of their own unconscious mentation, forces the therapeutic goals to become the patient's own goals, not those merely offered by the therapist he is visiting.

That this procedure always is successful is not true. There are many patients who want therapy but do not accept it until adequately motivated. There are other patients whose

goal is no more than the continuous seeking of therapy but not the accepting of it. With this type of patient hypnotherapy fails as completely as do other forms of therapy.

Use of Symptoms as an Integral Part of Hypnotherapy

Milton H. Erickson

Reprinted with permission from The American Journal of Clinical Hypnosis, July, 1965, 8, 57-65.

In dealing with any type of patient clinically there is a most important consideration that should be kept constantly in mind. This is that the patient's needs as a human personality should be an ever-present question for the therapist to ensure recognition at each manifestation. Merely to make a correct diagnosis of the illness and to know the correct method of treatment is not enough. Fully as important is that the patient be receptive of the therapy and cooperative in regard to it. Without the patient's full cooperativeness therapeutic results are delayed, distorted, limited, or even prevented. Too often the therapist regards patients as necessarily logical, understanding, in full possession of their faculties—in brief, as reasonable and informed human beings. Yet it is a matter of common knowledge often overlooked, disregarded, or rejected that patients can be silly, forgetful, absurd, unreasonable, illogical, incapable of acting with common sense, and very often governed and directed in their behavior by emotions and by unknown, unrecognizable, and perhaps undiscoverable unconscious needs and forces which are far from reasonable, logical, or sensible. To attempt therapy upon a patient only apparently sensible, reasonable, and intelligent when that patient may actually be governed by unconscious forces and emotions neither overtly shown nor even known, to overlook the unconscious mind for possible significant information, can lead easily to failure or to unsatisfactory results. Nor should seemingly intelligent, rational, and cooperative behavior ever be allowed to mislead the therapist into an oversight of the fact that the patient is still human and hence easily the victim of fears and foibles, of all those unknown experiential learnings that have been relegated to his unconscious mind and that he may never become aware of or ever show just what the self may be like under the outward placid surface. Nor should therapists have so little regard for their patients that they fail to make allowance for human weaknesses and irrationality. Too often it is not the strengths of the person that are vital in the therapeutic situation. Rather, the dominant forces that control the entire situation may derive from weaknesses, illogical behavior, unreasonableness, and obviously false and misleading attitudes of various sorts.

Therapists wishing to help their patients should never scorn, condemn, or reject any part of a patient's conduct simply because it is obstructive, unreasonable, or even irrational. The patient's behavior is a part of the problem brought into the office; it constitutes the personal environment within which the therapy must take effect; it may constitute the dominant force in the total patient-doctor relationship. Since whatever patients bring into the office is in some way both a part of them and a part of their problem, the patient should be viewed with a sympathetic eye appraising the totality which confronts the therapist. In so doing therapists should not limit themselves to an appraisal of what is good and reasonable as offering possible foundations for therapeutic procedures.

Sometimes—in fact, many more times than is realized—therapy can be firmly established on a sound basis only by the utilization of silly, absurd, irrational, and contradictory manifestations. One's professional dignity is not involved, but one's professional competence is.

To illustrate from clinical experience, case history material will be cited, some from a nonhypnotic therapeutic situation, some from situations involving the use of hypnosis.

CASE REPORT 1

George had been a patient in a mental hospital for five years. His identity had never been established. He was simply a stranger around the age of 25 who had been picked up by the police for irrational behavior and committed to the state mental hospital. During those five years he had said, "My name is George," "Good morning," and "Good night," but these were his only rational utterances. He uttered otherwise a continuous word-salad completely meaningless as far as could be determined. It was made up of sounds, syllables, words, and incomplete phrases. For the first three years he sat on a bench at the front door of the ward and eagerly leaped up and poured forth his word-salad most urgently to everyone who entered the ward. Otherwise, he merely sat quietly, mumbling his word-salad to himself. Innumerable patient efforts had been made by psychiatrists, psychologists, nurses, social service workers, other personnel, and even fellow patients to secure intelligible remarks from him, all in vain. George talked only one way, the word-salad way. After approximately three years he continued to greet persons who entered the ward with an outburst of meaningless words, but in between times he sat silently on the bench, appearing mildly depressed but somewhat angrily uttering a few minutes of word-salad when approached and questioned.

The author joined the hospital staff in the sixth year of George's stay. The available information about his ward behavior was secured. It was learned also that patients or ward personnel could sit on the bench beside him without eliciting his word-salad so long as they did not speak to him. With this total of information a therapeutic plan was devised. A secretary recorded in shorthand the word-salads with which he so urgently greeted those who entered the ward. These transcribed recordings were studied, but no meaning could be discovered. These word-salads were carefully paraphrased, using words that were least likely to be found in George's productions, and an extensive study was made of these until the author could improvise a word-salad similar in pattern to George's, but utilizing a different vocabulary.

Then all entrances to the ward were made through a side door some distance down the corridor from George. The author then began the practice of sitting silently on the bench beside George daily for increasing lengths of time until the span of an hour was reached. Then, at the next sitting, the author, addressing the empty air, identified himself verbally. George made no response.

The next day the identification was addressed directly to George. He spat out an angry stretch of word salad to which the author replied, in tones of courtesy and responsiveness,

with an equal amount of his own carefully contrived word-salad. George appeared puzzled and, when the author finished, George uttered another contribution with an inquiring intonation. As if replying the author verbalized still further word-salad. After a half-dozen interchanges, George lapsed into silence, and the author promptly went about other matters.

The next morning appropriate greetings were exchanged employing proper names by both. Then George launched into a long word-salad speech to which the author courteously replied in kind. There followed then brief interchanges of long and short utterances of word-salad until George fell silent and the author went to other duties.

This continued for some time. Then George, after returning the morning greeting, made meaningless utterances without pause for four hours. It taxed the author greatly to miss lunch and to make a full reply in kind. George listened attentively and made a two-hour reply, to which a weary two-hour response was made. (George was noted to watch the clock throughout the day.)

The next morning George returned the usual greeting properly but added about two sentences of nonsense. The author replied with a similar length of nonsense. George replied, "Talk sense, Doctor." "Certainly, I'll be glad to. What is your last name?" "O'Donovan, and it's about time somebody who knows how to talk asked. Over five years in this lousy joint" . . . (to which was added a sentence or two of word-salad). The author replied, "I'm glad to get your name, George. Five years is too long a time" . . . (and about two sentences of word-salad were added).

The rest of the account is as might be expected. A complete history sprinkled with bits of word-salad was obtained by inquiries judiciously salted with word-salad. His clinical course—never completely free of word-salad, which was eventually reduced to occasional unintelligible mumbles—was excellent. Within a year he had left the hospital, was gainfully employed, and at increasingly longer intervals returned to the hospital to report his continued and improving adjustment. Nevertheless, he invariably initiated his report or terminated it with a bit of word-salad, always expecting the same from the author. Yet he could, as he frequently did on these visits, comment wryly, "Nothing like a little nonsense in life, is there, Doctor?" to which he obviously expected and received a sensible expression of agreement to which was added a brief utterance of nonsense. After he had been out of the hospital continuously for three years of fully satisfactory adjustment, contact was lost with him except for a cheerful postcard from another city. This bore a brief but satisfactory summary of his adjustments in a distant city. It was signed properly, but following his name was a jumble of syllables. There was no return address. He was ending the relationship on his terms of adequate understanding.

During the course of his psychotherapy he was found hypnotizable, developing a medium to deep trance in about 15 minutes. However, his trance behavior was entirely comparable to his waking behavior, and it offered no therapeutic advantages, although repeated tests were made. Every therapeutic interview was characterized by the judicious use of an appropriate amount of word-salad.

The above case represents a rather extreme example of meeting a patient at the level of his decidedly serious problem. The author was at first rather censoriously criticized by others, but when it became apparent that inexplicable imperative needs of the patient were being met, there was no further adverse comment.

The next report is decidedly different. Although no psychosis was involved, there existed such an irrational rigidity of emotional conviction that the patient appeared to be inaccessible.

CASE REPORT 2

A man in his early forties approached a dentist friend of the author, explaining his situation at great length, perspiring freely as he did so and manifesting much fear and trepidation. His account was that he had recently read a news story about the use of hypnosis in dentistry. This reminded him of his college days, when he had many times acted as a hypnotic subject for experimental purposes in the psychology laboratory. In these experiences he easily and invariably achieved the somnambulistic state with profound amnesias still persisting for his trance experiences as such, but with a still present fair memory of the experimental accounts subsequently shown to him.

For some reason not recalled by him but referred to as "some horribly painful experience connected with dentistry in some way" he had not visited a dentist for over 20 years despite the fact that he was well aware that he was seriously in need of dental care. His direct explanation was, "I just can't bring myself to see a dentist. Dentistry is a painful thing. It has to be painful. There are no ifs, ands, or buts about it. Dentistry has to be connected with pain. Even with an anesthetic there is pain after it wears off. No matter what you do in dentistry, there is someplace that becomes terribly sensitive." There was more of this almost irrational obsessional thinking, but the foregoing is an adequate example.

The news story about hypnodontia made him hopeful that in some way his terror of dentistry could be overcome. Hence he made telephone calls about hypnodontia until he located the author's friend.

That dentist agreed to see him and in a preliminary session gave the patient a careful explanation of hypnoanesthesia. The man developed an excellent somnambulistic trance and easily developed glove anesthesia and then a profound anesthesia of the fingers as tested by overflexing forcibly the terminal phalanx. The dentist then attempted to produce mandibular anesthesia. This failed completely, arousing the dentist's intense interest in the problem apparently confronting him. An entire evening was spent the next day by the dentist endeavoring by one technique or another to produce dental anesthesia. The patient could develop surgical anesthesia anywhere except in relation to his mouth. Instead of anesthesia a seeming hyperesthesia developed.

Another dentist well-experienced in hypnosis was called in to work with the patient hypnotically. The two dentists spent an intensive afternoon and evening with a profoundly somnambulistic hypnotic subject who was surgically anesthetic and able to withstand any painful stimulus they were willing to administer to his body. The patient had his eyes open throughout the trance, and he was most interested in his hypnoanesthesia.

However, a touch on the patient's lip, chin, or the angle of his jaw would result in a flood of perspiration, a flushing of the skin, and complaints that the slightest touch seemed to be extremely painful, and the patient would break down hypnotically established neck and body rigidity in order to wince and to withdraw from such touches.

Other dentists were questioned for suggestions and advice to no avail, and the patient was finally sent to the author together with a typed account of the findings of the two dentists and with a typed example of the patient's verbalizations about dental pain.

The interview with the patient and the induction of a deep trance permitted an easy confirmation of the report by the dentists.

Scrutiny of the typed account of his obsessive-like utterances about pain and dentistry, and close listening when he verbalized afresh his convictions about dentistry and pain, suggested a possible likely course of action. Since the dentists had expressed their interest in any experimental work the author might do, the patient was dismissed with an instruction to make an appointment with the first dentist. When the appointment was made, the dentist telephoned his friend and the author.

At the proper time the patient appeared and at the author's request took a seat in the dental chair with his face flushed and perspiring and in a general state of utter fear. In spite of that he developed a deep somnambulistic trance in rapport with the two dentists as well as the author.

The intended approach to dental anesthesia and its rationale had been previously discussed with the dentists, and it was agreed the entire procedure should be done with no preliminary preparation of the patient.

When all was in readiness, the patient, still in a deep somnambulistic trance, tremulous, and with his face flushed and perspiring, was asked to listen closely to a reading of a typed account of his statements about dentistry and pain, which included the statements quoted above. He listened with utter intensity, and as the last statement was read, he was told seriously and impressively, "You are entirely right, absolutely right, and you summarize it most adequately in one of your statements. Let me read it again, `No matter what you do in dentistry there is always some place that becomes terribly sensitive.' You are completely correct. As you sit there in the dental chair, the dentist will be to your right. Hence, you may now, at once, safely extend your left hand and arm, there to let it stay suspended as if frozen rigidly in place. And you may turn your face and see it there, and as you do so you will note that your left hand, so completely out of reach of

everything, safe from any touch, from the slightest breath of air, is becoming so terribly, so awfully, so horribly hypersensitive, so unbelievably hypersensitive that in another minute all of the sensitivity of your entire body will drain into that hand. And since the dentist in working with you will not touch your hand where all the hypersensitivity is, he can easily do all the dental work you need. Now make an unforgettable mental note of just where that hypersensitive left hand is, and turn your head and let the dentist go to work."

The patient turned his head, fearfully voiced a plea that the dentist be careful of his left hand, and, comforted by the dentist's reassurance, opened his mouth in complete readiness.

The facial flush and the perspiration had vanished. It was noted that his left hand was flushed and perspiring. The dentist then took charge completely and, by means of posthypnotic suggestions, convinced the patient that each time he sat in the dental chair, he would develop left-handed hyperesthesia so that his dental work could be done. At no time was any oral anesthesia ever suggested.

The rationale of this approach is rather clear and simple. The patient was rigidly fixated on the idea that a painful hypersensitivity must inevitably accompany dentistry. Attempts at oral anesthesia fixated his attention on oral sensations. Acceptance of his neurotic belief and employing it to create hypnotically an area of extreme hypersensitivity met his need to be able to experience pain without having to do so. Thus all pain expectation was centered in his hand, resulting in an anesthesia of the rest of his body, including his mouth.

On the occasion of the termination of the last dental visit, the dentist tested the patient for pain sensitivity elsewhere in his body and found that a general surgical anesthesia existed.

This second case represents the hypnotic utilization, with an augmentation of it, of the actual barrier to the patient's capacity to develop the needful manifestation that he wished. It is true that the logic of the entire procedure is decidedly specious, but it must be borne in mind that the patient's total attitudinal set was equally specious. Cold hard logic, presentation of scientific facts, any sensible reasonable approach would have been useless. Utilizing the patient's own neurotic irrationality to affirm and confirm a simple extension of his neurotic fixation relieved him of all unrecognized unconscious needs to defend his neuroticism against all assaults. A systematic analysis of exactly what kind of thinking the patient brought into the office led readily to the solution of his problem. This same sort of situation existed in the third case to be cited immediately.

CASE REPORT 3

A thrice-divorced young woman sought psychiatric help "for just one problem, that's all, and I will tell you the problem right away, but I don't want any treatment for anything else. That you must promise me."

The gist of her story was that at age 18 she had impulsively married a handsome and, as she discovered later, dissolute man of 25 very much against parental wishes. The wedding night she discovered that he was a secret alcoholic, and the attempted consummation of the marriage in his state of intoxication was a hideous travesty to her. He blamed her entirely, berated her unmercifully, described her rudely as "having a refrigerated derriere," left her alone, and spent the night with a prostitute. Nevertheless, she continued to live with him hopefully despite his continued use of the description that he had bestowed on her the first night. After some months of wretched effort to prove to him that she was a woman of normal sexuality, she secured a divorce, secretly fearing that he was correct in his appraisal of her lack of sexuality.

A year later, in an overcompensatory effort to avoid the kind of trouble she had encountered in her first marriage, she married a highly effeminate man whose latent homosexuality disclosed itself on their wedding night by his horrified aversion to her body. His reason for marrying her, since she did have some wealth in her own name, was to secure "proper social standing in the community." He was completely outraged and incensed by her "indecent haste" to consummate the marriage and administered a rather rigidly prim reprimand. He spent the night, as she learned later, with a male friend who helped him bemoan his unfortunate plight. Her reaction was one of complete self-blame, no understanding of her husband's actual sexuality, and she succeeded in convincing herself that he had applied the same derogatory description of her as had her first husband. The marriage continued for nearly a year, chiefly by virtue of the fact that he spent most of his nights at his mother's apartment. An actual attempt at consummation after about four months proved to be only a revolting experience for him and a conviction, because of her entire lack of response to him, that she was absolutely lacking in sexual feelings.

After they finally got a divorce, she secured employment and gave up any hope of a normal life. After about two years, while living a very sheltered, retiring life, she met by chance a man five years her senior who was successfully engaged in an exciting, but to soberer minds, a somewhat questionable, promotional activity in real estate. His charm, his easily likeable personality, his knowledge of the world, his attentiveness and courtesy led her to make a third venture into matrimony.

They were married in the morning and then went to an expensive suite in a hotel in a nearby town, where he spent the day with her presenting innumerable plausible reasons in an effort to persuade her to turn over to him all of her property for him "to develop," thus to secure larger returns.

As he presented his arguments with increasing persuasiveness but with no display of emotional interest in her, a recollection of the beginnings of her first marriage raised sickening doubts in her mind. Her husband, becoming impatient with her slowness to accept his arguments, suddenly noted the horrified, doubting expression on her face. Infuriated, he threw her on the bed and had violent intercourse with her while he denounced her for her lack of response, ridiculed her, told her how he had spent the

previous night with a responsive prostitute; he finally walked out on her "to find someone who didn't have what my first husband said I had." A divorce was promptly secured by her.

Now she was interested in a young man who met the approval of her lawyer, her banker, her parents, her minister, and her friends. She desperately wanted to marry him, yet was equally desperate in her desire not to cause him any unhappiness. Her purpose in seeking psychiatric aid was to have her "deficiency corrected." With extreme embarrassment, in plain simple Anglo-Saxon so that there could be no possibility of any misunderstanding by the author, she made matters painfully clear. She wanted, no more, no less, the chill she felt continuously, no matter what she wore, no matter how warm the seat she sat on, to be removed from her buttocks. This wretchedly cold feeling had been present, painfully present, since the first evening of her third marriage. The prompt dissolution of that marriage had not lessened the feeling of a subjectively recognizable coldness that had developed following the third husband's devastating criticism of her. This had plagued her continuously, and she found herself to be too embarrassed to seek medical aid. Recently, in night school courses she was taking, she had read about hypnosis, hypnotic phenomena, and hypnotherapy. Seeing the author's name given as a reference, she had come to Arizona for immediate, direct, and specific therapy.

Her desire for therapy was almost irrational in its intensity. She was convinced of the circumscribed character of her problem and could not even listen to any attempted exposition of the general character of her difficulties. She was rigidly certain that once the "coldness" was removed, all would be well. She asserted an absolute willingness to cooperate in any way to achieve her goal of a slightly elevated temperature in place of the gluteal coldness. In the desperateness of her desire for help it was not possible for her to see the humorous effect of her use of vulgar language to ensure the author's exact understanding of her problem in terms of the exact words that had been used to describe it to her originally.

After a laborious three-hour effort to secure her interest in the author's views, it became apparent that therapy would have to be accomplished, if possible at all, in full accord with her persistent demands.

Much speculative thought was given to the content of her limited understandings to devise some kind of therapeutic approach. Since she wanted hypnosis desperately, she became an easy somnambulistic subject, as is sometimes the case with this type of patient. Indeed, she was one of the most receptive and amenable subjects the author has encountered, and she agreed readily to accept and act upon any hypnotic suggestion given her. The specious explanation given her was that, since she wanted her problem corrected by hypnosis, it was requisite that she be thoroughly trained in all hypnotic phenomena so that every possible necessary hypnotic element requisite for her cure would be experientially known to her. Actually, the real purpose was to develop in her a receptiveness, a responsiveness, a feeling of complete acceptance, and a willingness to execute adequately any suggestion offered her.

The next step was to ask her to make a systematic study by filling her bathtub with water of increasingly higher temperature until the water was hot enough to produce goose bumps on her legs, which were the only part of her to be immersed in the bathtub. After much labor she succeeded in achieving this. She was then presented with a laboriously detailed explanation of how an overloading of the thermal receptors by excessive warmth would overflow into the cold receptors of the skin, thereby resulting in gooseflesh. The success of this venture, in the author's opinion, played a large part in the successful therapy. It supplied her with indisputable visual proof that heat can produce the concomitants of coldness and that this could be done in a definitely limited area of the body. From that point on there existed for her no doubts or fears of the author's understandings or competence.

Therapy was then continued by inducing a deep trance and by carefully worded suggestions, making her feel privately—a feeling just to be enjoyed within herself—an exaggerated, utterly intense, and inordinate pride in having the secret knowledge shared only with me that at least a part of her body could experience heat by a subjective cold response. Thus, by repetitious suggestion it was emphatically impressed upon her that this must always and forever be regarded as her own private pleasurable joy. The reason for this secrecy was to intensify her feeling and to preclude any disparagement by anyone in whom she might confide.

Then, bit by bit, suggestions were cautiously given her that, just as her calves had developed cold receptor responses to heat, so could the cold receptors of her thighs, of her buttocks, and her abdomen. Her acceptance of these ideas was ensured by a sudden shift to a discussion of the "thrills and tingles of complete happiness and ecstatic joy that race so delightfully up and down the spine of the little girl who receives the new dolly so desperately wanted and never really expected."

This complex idea was impressed upon her with much repetition and with careful changes in the key words of "thrills" and "tingles" by making the phrase "thrills and chills and tingles" and then in a random fashion omitting one and then another of the three words. Also, since she came from a northern state and had a reasonably happy childhood, the "tingling delights of sledding down hill on a tinglingly cold day," "the rapturous joys of a cold, cold dish of ice cream on a hot summer's day," and similar plays on words associated with pleasures safely remote in her history, were woven into a whole series of suggestions.

This was repeated for a number of sessions, always impressing upon her the need for an unconscious retention of the ideas, the need to incorporate them, and everything else she had been taught in therapy, into the warp and woof of her very existence, and yet to keep the knowledge of all this safely secret forever from her conscious mind, just knowing in some vague and satisfying way that she possessed within her a knowledge and an understanding of a personal value, beauty, and happiness.

Very rapidly there occurred a marked change in her general behavior. The tension, the urgency, the overall anxiety disappeared; she went for long scenic drives, and she began speaking of visiting Phoenix again.

Then one day she entered the office hesitantly, diffidently, blushing deeply and keeping her eyes downcast. After about 15 minutes, almost in the voice of a small child, she asked, "Can I tell you a secret, a very important secret that's all mine., my special secret that belongs all to me?" The reply given her was, "I think that if you think it over very carefully, you will find that you probably can tell your psychiatrist because he will understand."

After another seven minutes she said softly, "I've got to tell it in a special way that I know you will understand. It's what I said when I first came to you, only it's all different now." Then, in completely vulgar terms, with many blushes, she stated in essence, "I like being a frozen-posteriored creature."

To the author that signified that she needed no further therapy, and the years that have passed, her successful fourth marriage, her completion of college during the first years of this marriage, and her subsequent entrance happily into the pleasures of motherhood have all confirmed the success of therapy.

And what was her problem? An impulsive marriage in the best of good faith, but a wretchedly mistaken marriage as she immediately discovered; a second mistaken marriage to correct the trauma of the first, promptly discovered to be another mistake that was slowly corrected only so far as the marital state was concerned, but with only an intensification of her traumas; a third desperate marriage entered in good faith to correct, if possible, the injuries of the past, which only resulted in further injury. Then came the acute realization of her therapeutic needs when a genuinely good marriage presented itself.

And what was her therapy? An unhappy succession of events had progressively emphasized the trauma centering about a vital need in her life, her fulfillment as a woman. These events had degraded her in her own eyes and had led her unconsciously to summarize her total unhappiness in a circumscribed way. Then she sought circumscribed therapy, only circumscribed therapy. This was presented to her in such a fashion that, even as she had circumscribed everything, she was in a position to enlarge properly her whole problem. Her thinking about her problem had been emotionally repressed, largely at an unconscious level. Her therapy permitted her to do the same type of thinking but to include in it not only the events leading to her problem but the emotional values dating all the way back to her childhood. Then, once she had achieved her goals, at the level of unconscious motivation she felt compelled to verbalize her original presenting complaint but with a totally different meaning and perspective. By doing this she freed herself from any dependency upon the therapist and then could go her way, finding her own proper goals in life.

CONCLUDING COMMENT

These three different case histories are presented to illustrate the importance in therapy of doing what appears to be most important to the patient, that which constitutes an expression of the distorted thoughts and emotions of the patient. The therapist's task should not be a proselytizing of the patient with his own beliefs and understandings. No patient can really understand the understandings of his therapist nor does he need them. What is needed is the development of a therapeutic situation permitting the patient to use his own thinking, his own understandings, his own emotions in the way that best fits him in his scheme of life.

Each of the patients reported on has no real understanding of what their therapist thinks, knows, believes, likes, or dislikes. They know primarily that in some peculiar way they began to unsnarl their lives in a fashion as inexplicable as was the fashion in which they had once snarled their thinking and their emotions.

Hypnosis in Obstetrics: Utilizing Experiential Learnings

Milton H. Erickson

Unpublished manuscript, circa 1950s.

To present in 20 minutes the subject of hypnosis in obstetrics is a rather difficult task. However, I shall assume that my major obligation is to present to you certain general considerations and then to rely upon your own interests and desires for more detailed information which will lead you into further exploration of this topic.

I shall begin by defining hypnosis, as one needs to understand it in a clinical sense. It is a state of consciousness—not unconsciousness or sleep—a state or consciousness or awareness in which there is a marked receptiveness to ideas and understandings and an increased willingness to respond either positively or negatively to those ideas.

It derives from processes and functionings within the patient. The operator is merely someone who can offer intelligent advice and instruction to the patient and thus elicit from the patient the behavioral responses best fitted to the situation.

Hypnosis is not some mystical procedure, but rather a systematic utilization of experiential learnings—that is, the extensive learnings acquired through the process of living itself. For example, mention may be made of hypnotic anesthesia, or hypnotic amnesia, but these are no more than learnings of everyday living utilized in an orderly, controlled, and directed fashion. For example, nearly everyone has had the experience of losing a painful headache during a suspense movie without medication of any sort. Similarly, everyone has developed an anesthesia for the sensation of shoes on the feet, glasses on the face, and a collar around the neck.

Comparably we all know how effectively the news of the sudden, unexpected death of a loved one can instantly destroy a ravenous appetite or even completely arrest the physiological processes of digestion already under way.

All of us have a tremendous number of these generally unrecognized psychological and somatic learnings and conditionings, and it is the intelligent use of these that constitutes an effectual use of hypnosis.

In obstetrics, as in no other field of medicine, the patient occupies a dominant role for months as an individual undergoing an extensive progressive alteration, not only somatically but psychologically, in all personal, social, economic and temporal relationships. Hence, there comes into play throughout pregnancy, as well as delivery, a multitude of forces deriving from the personality as a whole and from the special attitudes, beliefs, understandings, learnings, and conditionings acquired during the patient's lifetime.

The history of obstetrics is marked by a continual striving to introduce into the delivery room various procedures intended to facilitate delivery and to render it a pleasing experience both to the patient and to the physician. Medications of many varieties, surgical procedures, and mechanical aids have all been introduced from time to time, with various acclaims, but the obstetrician's search for improved methodologies still continues with an awareness that the search should embrace every avenue of understanding and not be restricted to a further development of just one field of understanding.

It is for this reason that there is a growing interest in the use of hypnosis in obstetrics. The slow progressive development of psychosomatic medicine since the 1920s, and the many experimental and clinical studies demonstrating effectively the extensive interrelationships between the mental functioning of the individual and his physiological processes, have now served to make many people aware that a business worry or a hysterical fear can manifest itself in a stomach ulcer, colitis, chronic backache, or migrainous headaches—just to cite common examples.

Against this general background of the general understandings derived from psychosomatic medicine, hypnosis is gaining increasing acceptance in obstetrics as a significant scientific methodology. And it is gaining that acceptance not because it is a mystical art or a dramatic procedure of thrusting needles through tissues and suggesting, “arms as rigid as iron bars.” Instead, it is gaining acceptance because of its valuable ability to enlist as fully as possible the patient's own capabilities and potentialities at both psychological and physiological levels of functioning.

It matters not whether the use of hypnosis in obstetrics is called psychosomatic obstetrics, or systematic education of the mother in childbirth as a normal physiological process, or the *Grantley Dick Read Method of Childbirth Without Fear*, or progressive sychosomatic relaxation, or simply hypnosis in obstetrics. The essential consideration is the enlistment of the expectant mother as an adequately responsive participant in a normal physiological process of great personal and social significance.

Now the questions arise:

1. At what time, or when, does one use hypnosis in obstetrics?
2. Who can be hypnotized?
3. What are the dangers?
4. What type of case warrants its use?
5. How is it done?
6. Where can a knowledge of hypnotic techniques be obtained?
7. What specifically can hypnosis accomplish, both generally and in individual cases?
8. And finally, just what excuse is there for using hypnosis when there are many other methods?

To take up the last question first, whenever there is a wealth of remedies for any one condition, their inadequacy is thereby signified. For example, each week a new tranquilizer comes on the market, guaranteed to cure everything, until replaced by next week's preparation with the same claims.

But more seriously, the real need for introducing hypnosis into the obstetrical field is the opportunity it offers to secure from the patient full, earnest, happy, and confident cooperation with the physician during pregnancy, delivery, and the postpartum period. Anything that can effect good cooperation between patient and physician in achieving an important goal is worthy of consideration.

Perhaps the next question should concern the dangers of hypnosis.

In over 30 years of experimental and clinical work with hypnosis I have not been able to discover any harmful effects, nor have colleagues with extensive experience in the use of hypnosis reported any to me—despite repeated inquiries. I do know that people of little and even no experience with hypnosis will gladly tell all manner of tales about the harmfulness of hypnosis, sometimes even believing the tales themselves. And I do know that stupid or uninformed people sometimes use hypnosis in the wrong way, but any harm that results comes not from the hypnosis, but from the mistaken or misdirected behavior associated with hypnosis.

As for the next question—who can be hypnotized—the answer is simply that any normal person and some abnormal persons can be hypnotized, provided there is adequate motivation. In pregnancy there is usually a great deal of motivation to achieve a delivery and a postpartum recovery of a most pleasing sort, hence the motivation among informed obstetrical patients is high.

As for the question of where one can learn medical hypnosis, I can state emphatically, in agreement with the AMA recommendations, that it can best be learned and should only be learned under medical, or dental, or psychological auspices. There are instructors who are reputable and competent clinicians as well as teachers; they can meet the needs of physicians interested in hypnosis as a professional methodology. Instruction by quacks, stage hypnotists, charlatans who brag about being the world's fastest hypnotists, and the numerous variously named American Institutes of Accredited Hypnotists, are all to be avoided in the same way a physician would avoid taking instruction in physical examination from a chiropractor. Medical teaching properly should always be on a high ethical and professional level, and the stage hypnotist or the charlatan with no degree or with a diploma-mill degree does not qualify.

As for the appropriate time at which to use hypnosis in obstetrics, the answer is that some obstetricians prefer the last trimester, some the first trimester, but actually it should be a matter of clinical choice and judgment. If employed only for the delivery and postpartum period, the third trimester is adequate time.

However, it is only reasonable to employ hypnosis to meet the problems of nausea and vomiting and weight gain during pregnancy, since the patient's full cooperation in all regards is desired, and hypnosis is a method of securing that full cooperation and participation.

As for the type of case warranting the use of hypnosis, the answer is simply any case in which you wish full, free, and easy cooperation to the patient's fullest capacity. Such cases range from the mother who is happily anticipating her child to the anxious, tense, hysterically fearful woman who dreads the entire experience and who consequently needs special care and attention.

As for the final question—what specifically can hypnosis do in general and in the individual case? —the comprehensive reply can be offered that it enables a woman to undergo her pregnancy, her delivery, and the postpartum period in that fashion most nearly in accord with her needs and her psychological and physiological capabilities.

It is not in any way a replacement for other obstetrical procedures, but it is a scientific adjunct that serves greatly to reduce the need for some other medical procedures. For example, while in some cases hypnosis may produce complete anesthesia, in others it serves primarily to reduce extensively the amount of medication or chemoanesthesia required. But primarily hypnosis serves to permit the patient to cooperate much more adequately with her physician and to participate more satisfactorily.

Whether the patient is in a light trance, a medium trance, or a deep trance, the following general effects can be achieved.

1. The patient can be taught physical relaxation, adjustment to progressive changes in physical sensations and alterations, and a feeling of comfort and well-being, so desirable in pregnancy.
2. Weight changes, nausea and vomiting, and fear and anxiety states are much more adequately handled.
3. An attitude of cooperation and understanding can be developed, with greater trust and confidence in the physician and his or her competence.
4. The patient can be taught, in accord with her actual capacities to learn, an anesthesia or an analgesia or an amnesia for the discomfort of labor, and thus she can enter the delivery room and participate at a full level of awareness, and do so enjoyably, in the actual experience of childbirth.
5. The patient's behavior during the postpartum period can be directed toward the promotion of sleep, physical comfort, freedom from anxiety, and feelings of physical comfort and well-being.
6. The patient's breast behavior and her attitudes and anxieties in this regard can be handled more adequately.

To summarize, obstetrics is a branch of medicine that centers around a patient-physician relationship extending over a period of many months and involving a physiological process of profound psychological significance and paramount in importance to the

patient. Hypnosis, facilitating as it does a receptiveness and a responsiveness to ideas, is of value in every aspect wherein instruction, advice, counsel, guidance, direction, reassurance, comfort, and all those manifold values of interpersonal relationships are so significant.

A Therapeutic Double Bind Utilizing Resistance

Milton H. Erickson

Unpublished manuscript, 1952.

A 12-year-old boy, 5 feet 10 inches tall and weighing 170 pounds, was brought almost forcibly into the office by his irate and despairing parents. He was described as sullen, rebellious, stubborn, hardheaded, uncooperative, self-willed, lazy, and a chronic bed-wetter. They explained that he had had a wet bed every day of his life and that they had reached the absolute limit of their patience in attempting every known method of curing him other than taking him to a psychiatrist. They now wished to turn the, forbidding task over to the writer, and they would be willing to limit their participation to a simple morning inspection of his bed. They were promptly instructed to relegate this task entirely to the household maid.

Systematic questioning disclosed the following information: The father was an inch taller and 10 pounds heavier than his son. The father's interests were restricted to his business and to philosophical reading. The mother was a demanding woman, interested in drama and club work. She was an inch shorter than her son, but equaled his weight. The boy's interests were negligible. He had no interest in athletics nor in such groups as the Boy Scouts, nor did he seem to have any friends. He enjoyed comic books and "eating." He usually spent the weekends "forgetting" to do either his schoolwork or his assigned chores at home. He was not interested in schoolwork, was content with poor grades, and expressed the hope that he would not have to go to high school. He spent his summers swimming—a skill at which he was most proficient.

As the first measure of therapy, the parents were instructed to relinquish completely all interest in the therapy of their son for a period of at least six months—to make no inquiry or show interest in any way. To this they readily agreed.

TRANCE INDUCTION UTILIZING RESISTANCE

The boy was then invited into the office. He expressed an unwillingness for an interview and offered the statement that he was "tired enough to go to sleep" and that he would rather go home. Reply was made that he could defeat the purpose of the office interview by deliberately going to sleep and not listening to what the writer had to say. He accepted this as a challenge and proved to be an excellent hypnotic subject to the rather simple testing of suggestion—"Just go to sleep, just don't listen to me; you can sleep restfully and comfortably, even if I do talk" —and similar such suggestions until a deep trance was secured.

He was then instructed that he did not need to bother to listen, but that he could understand everything that was said to him; however, he would nonetheless sleep

restfully and comfortably. Thus it became possible to meet both his personal needs and those of the therapeutic situation. An explanation was then offered that because of his parents it would be necessary to see him repeatedly, but that the writer would try to make it as infrequent as possible.

Therapy was then begun by stating that his parents had demanded that the writer correct the bed-wetting problem, but that the parents were regarded as somewhat unreasonable in this matter. The conclusions were elaborated in the following fashion, while he continued in a deep trance:

> Your parents want you to have a permanently dry bed right away, and that is simply unreasonable. In the first place, you have been too darned busy to bother to learn to have a dry bed. You have a great big beautiful frame, with great big powerful muscles to handle it. Your chassis is one that took a lot of energy to build and it is almost as big as your father's and you are only 12 years old. It took an awful lot of energy to build a body as big and strong as that one you've got, and you didn't have any energy left over for such unimportant things as a dry bed or mowing grass or being a teacher's pet. But you will soon be full-grown, bigger than your father, and you haven't got far to go to beat him. Then you'll have all that energy and horsepower you have been putting into growing to spread around to the other things you want, like a permanently dry bed. In fact, you are so close to being finished with building that great big powerful body that you've probably already got extra energy to spare.
>
> But let's get it straight. I don't think it's reasonable to expect you to have a permanently dry bed this month—it's only the first part of January. I don't even expect you to have just one dry bed this week. That's too darned soon. It's not reasonable. But what puzzles me is whether you will have a dry bed next week on Wednesday or on Thursday. I don't know and you don't know and we'll have to wait to find out, and that is a long wait because today is only Monday of this week and you really won't know until Friday of next week whether you will have a dry bed on Wednesday or Thursday of next week.

The double-bind suggestions were variously worded and repeated in the above verbose casual manner, thus to ensure the patient's acceptance of them and to avoid any resistance on his part.

The suggestions were continued: "You can come in next Friday and let me know whether it was Wednesday or Thursday, and you will just have to wait and see."

On the specified Friday he entered the office to report happily that he had had a dry bed on both Wednesday and Thursday.

The discouraging remark was made to him, "Let's be reasonable about this. You just can't expect to have that happen again too soon. It just isn't reasonable to expect you to begin to have a permanently dry bed this month, even if January is a long month."

The patient looked first troubled and then rebellious at these comments, as he settled back resentfully in his chair and looked away from the writer. Comment was offered that he probably felt tired enough to sleep, and a new trance was promptly induced by the original technique.

On this occasion posthypnotic suggestions were carefully given to ensure ready trance development with the minimum of time expenditure. Also, instruction was given for him to have a general amnesia for all office events but a ready understanding and recall of everything necessary in the office. Therapeutic suggestions were continued:

> It really was interesting to wait and see whether it was Wednesday or Thursday, but you were sure surprised when Thursday came along with another dry bed. A nice surprise, too, but it can't always happen yet—it's too darned soon.
>
> Of course, I don't know when your next batch of dry beds will come along, this month or early in February, but it's too soon for your permanently dry bed in January, and February is a short month. So, what puzzles me is will your permanently dry bed begin on St. Patrick's Day or on April 1st, which is April Fool's Day, or on any day between March 17th and April 1st. But let's get it straight. Whatever day your permanently dry bed begins is strictly your business. It is none of my business. That just belongs to you as your own private business, and even though I would like to know if it's St. Patrick's Day or April Fool's Day, or any day in between, it is still strictly none of my business and even though I want to know, don't tell me. That's something that just belongs to you.

The above double-bind suggestions were reiterated in various ways to ensure his acceptance of the idea that only the date was in doubt, not the actuality of the permanently dry bed.

Thereafter the patient was seen at irregular intervals. Double-bind suggestions were variously employed to reinforce the general ideas already given and to emphasize the purported rationale of the argument originally presented to the patient. There was no direct seeking of information, nor were direct therapeutic suggestions given. After the first two sessions the interviews tended to be casual, friendly boy-man conversations, rather than doctor-patient interviews. Occasionally a trance state was induced for some "extra sleep just to spread that extra energy around."

The weeks of March and April passed with neither comment nor inquiry, but a carefully worded telephone inquiry of the household maid late in April disclosed that there had been a continuously dry bed for some weeks. Early in May the patient, during a casual conversation, commented that one of his friends was a bed-wetter and that he would like to help this friend, and would the writer be willing to see that boy professionally? This indirect communication was the one and only reference made to the original problem. The patient is still a personal friend, has become a most successful college student, and from time to time refers bed-wetters for therapy.

Utilizing the Patient's Own Personality and Ideas: "Doing It His Own Way"

Milton H. Erickson

Unpublished manuscript, 1954.

A newly married 22-year-old man entered the office with the specific request that he be hypnotized and his practice of irresponsible, reckless driving be corrected. He added, however, that he doubted that he could be hypnotized and that he even had doubts about the need to alter his driving. His reason for the latter belief was his long experience in stunt driving, in which he had learned to wreck cars deliberately and to emerge unscathed. The only current justification for changing his driving behavior was the fact that he always took his wife with him, but even so, his car was in good condition, and his confidence in his ability to meet any driving hazard was unlimited. He denied any other reason for his visit and was explicit in his demand that the writer limit himself to the stated purpose.

TRANCE INDUCTION AND POSTHYPNOTIC SUGGESTION

The patient developed a fairly deep trance, affirmed his need to change his driving behavior, explained that he averaged around 90 miles an hour on the straightaway, and often reached speeds of 70 to 90 miles on mountain roads. When he was asked what he wished the writer to do, he explained that the writer could do nothing at all, that he himself would have to quit speeding, and that he would have to do it his own way, and only in his own way. He explained further that nothing that the writer could do or say would help, but that he did want help in some way from the writer.

Accordingly, he was asked how soon he wished to drive sensibly and in accord with the legal limits. His reply was that it was now early April and that by the first of May he should be driving properly. He was then asked to explain what he thought he would have to do. He merely repeated his previous statement that he would have to quit in his own way.

This statement was seized upon and repeated to him in various wordings as a posthypnotic suggestion, but without altering the meaning. This was done repetitiously in a most insistent, compelling manner. This acceptance of a patient's declaration and turning it back upon him in the form of posthypnotic suggestions is often a most effective therapeutic procedure. It gives the patient a feeling of being committed to his own intentions and wishes, and intensifies his ability to act accordingly, without a feeling that he is being forced to accept proffered help. For a patient as independent-minded as this young man, it was of crucial importance to *utilize his own ideas* rather than attempt to impose those of the therapist.

He was awakened with the suggestion that nothing sufficiently important for conscious recollection had been said. Upon awakening he commented that he probably was too difficult to hypnotize, that his own request for help appeared rather useless, and that obviously it was up to him to do it his own way. Regretfully he took his departure.

Two weeks later he appeared at the office to report that he was "still driving like a fool" and taking his wife with him on all his trips. He added that, somehow, he would have to quit in his own way. Again he left reluctantly.

Two weeks later he reported again, this time jubilant, declaring that he had handled things in his own way. His story was that the previous week, on his day off, he had overhauled his car completely with the aid of a friend. When this task was finished, he announced to his wife that he was taking a ride over a certain mountain road she had frequently asked him to travel. However, he refused to take her or his friend. Ten miles down the road he came to a long stretch of reasonably straight road. Immediately he decided to have a final fling at speeding and rejoiced at such an opportunity to do it without making his wife frightened. He reached the speed of 90 miles an hour, but before he came to the end of the open stretch, he discovered that he was losing control of the car. Before he could formulate any ideas, he realized that he would have to abandon the car. He succeeded in leaping out of it, suffering only minor bruises in so doing, just before it hurtled down the mountainside.

The long walk back home was spent in repetitious thinking of, "You've done it your own way." He explained what he had done to his wife, and later purchased another car that he began driving safely and within legal limits. Three months later he dropped into the office casually to comment that he was still driving safely. To this he added it had been rather expensive for him to do it in his own way and that he had merely wasted his time and money seeing the writer, except that possibly the writer had given him some psychological impetus.

Introduction to the Study and Application of Hypnosis for Pain Control

Milton H. Erickson

Proceedings of the International Congress for Hypnosis and Psychosomatic Medicine, edited by J. Lassner Springer Verlag, Berlin, Heidelberg, New York.
Reprinted with permission of Springer Verlag.

INTRODUCTION

Hypnosis is essentially a communication of ideas and understandings to a patient in such a fashion that he will be most receptive to the presented ideas and thereby motivated to explore his own body potentials for the control of his psychological and physiological responses and behavior. The average person is unaware of the extent of his capacities of accomplishment which have been learned through the experiential conditionings of this body behavior through his life experiences. To the average person in his thinking, pain is an immediate subjective experience, all-encompassing of his attention, distressing, and to the best of his belief and understanding, an experience uncontrollable by the person himself. Yet as a result of experiential events of his past life, there has been built up within his body—although all unrecognized—certain psychological, physiological, and neurological learnings, associations, and conditionings that render it possible for pain to be controlled and even abolished. One need only think of extremely crucial situations of tension and anxiety to realize that the severest of pain vanishes when the focusing of the sufferer's awareness is compelled by other stimuli of a more immediate, intense, or life-threatening nature. From common experience one can think of a mother suffering extremely severe pain and all-absorbed in her pain experience. Yet she forgets it without effort or intention when she sees her infant dangerously threatened or seriously hurt. One can think of men seriously wounded in combat who do not discover their injury until later.

There are numerous such comparable examples common to medical experience. Such abolition of pain occurs in daily life in situations where pain is taken out of awareness by more compelling stimuli of another character. The simplest example of all is the toothache forgotten on the way to the dentist's office, or the headache lost in the suspenseful drama portrayed at the cinema. By such experiences as these in the course of a lifetime, be they major or minor, the body learns a wealth of unconscious psychological, emotional, neurological, and physiological associations and conditionings. These unconscious learnings, repeatedly reinforced by additional life experiences, constitute the source of the potentials that can be employed through hypnosis to control pain intentionally without resorting to drugs.

CONSIDERATIONS CONCERNING PAIN

While pain is a subjective experience with certain objective manifestations and accompaniments, it is not necessarily a conscious experience only. It occurs without conscious awareness in states of sleep, in narcosis, and even under certain types of chemoanesthesia as evidenced by objective accompaniments and as has been demonstrated by experimental hypnotic exploration of past experiences of patients. But because pain is primarily a conscious, subjective experience, with all manner of unpleasant, threatening, even vitally dangerous emotional and psychological significances and meanings, an approach to the problem it represents can be made frequently by hypnosis—sometimes easily, sometimes with great difficulty, and the extent of the pain is not necessarily a factor. In order to make use of hypnosis to deal with pain, one needs to look upon pain in a most analytical fashion. Pain is not a simple, uncomplicated noxious stimulus. It has certain temporal, emotional, psychological, and somatic significance. It is a compelling motivating force in life's experience. It is a basic reason for seeking medical aid.

Pain is a complex, a construct, composed of past remembered pain, of present pain experience, and of anticipated pain of the future. Thus, immediate pain is augmented by past pain and is enhanced by the future possibilities of pain. The immediate stimuli are only a central third of the entire experience. Nothing so much intensifies pain as the fear that it will be present on the morrow. It is likewise increased by the realization that the same or similar pain was experienced in the past, and this and the immediate pain render the future even more threatening. Conversely, the realization that the present pain is a single event which will come definitely to a pleasant ending serves greatly to diminish pain. Because pain is a complex, a construct, it is more readily vulnerable to hypnosis as a modality of dealing successfully with it than it would be were it simply an experience of the present.

Pain as an experience is also rendered more susceptible to hypnosis because it varies in its nature and intensity, and hence, through life experiences, it acquires secondary meanings resulting in varying interpretations of the pain. Thus the patient may regard his pain in temporal terms, such as transient, recurrent, persistent, acute, or chronic. These special qualities each offer varying possibilities of hypnotic approaches.

Pain also has certain emotional attributes. It may be irritating, all-compelling of attention, troublesome, incapacitating, threatening, intractable, or vitally dangerous. Each of these aspects leads to certain psychological frames of mind with varying ideas and associations, each offering special opportunities for hypnotic intervention.

One must also bear in mind certain other very special considerations. Long continued pain in an area of the body may result in a habit of interpreting all sensations in that area as pain in themselves. The original pain may be long since gone, but the recurrence of that pain experience has been conducive to a habit formation that may in turn lead to actual somatic disorders painful in character.

Of a somewhat similar character are iatrogenic disorders and disease arising from a physician's poorly concealed concern and distress over his patient. Iatrogenic illness has a most tremendous significance because in emphasizing that if there can be psychosomatic disease of iatrogenic origin, it should not be overlooked that, conversely, iatrogenic health is fully as possible and of far greater importance to the patient. And since iatrogenic pain can be produced by fear, tensions, and anxiety, so can freedom from it be produced by the iatrogenic health that may be suggested hypnotically.

Pain as a protective somatic mechanism should not be disregarded as such. It motivates the patient to protect the painful areas, to avoid noxious stimuli, and to seek aid. But because of the subjective character of the pain, there develop psychological and emotional reactions to the pain experience that eventually result in psychosomatic disturbances from unduly prolonged protective mechanisms. These psychological and emotional reactions are amenable to modification and treatment through hypnosis in such psychosomatic disturbances.

To understand pain further, one must think of it as neuro-psycho-physiological complex characterized by various understandings of tremendous significance to the sufferer. One need only to ask the patient to describe his pain A hear it variously described as dull, heavy, dragging, sharp, cutting, twisting, burning, nagging, stabbing, lancinating, biting, cold, hard, grinding, throbbing, gnawing, and a wealth of other such adjectival terms.

These various descriptive interpretations of the pain experience are of marked importance in the hypnotic approach to the patient. The patient who interprets his subjective pain experience in terms of various qualities of differing sensations is thereby offering a multitude of opportunities to the hypnotherapist to deal with the pain. To consider a total approach is possible, but more feasible is the utilization of hypnosis in relation first to minor aspects of the total pain complex and then to increasingly more severely distressing qualities. Thus, minor successes will lay a foundation for major successes in relation to the more distressing attributes of the neuro-psycho-physiological complex of pain, and the understanding and cooperation of the patient for hypnotic intervention are more readily elicited. Additionally, any hypnotic alteration of any single interpretive quality of the pain sensation serves to effect an alteration of the total pain complex.

Another important consideration in the matter of the understanding of the pain complex is the recognition of the experiential significances of various attributes or qualities of subjective sensation, and their differing relationships in such matters as remembered pain, past pain, immediate pain, enduring pain, transient pain, recurrent pain, enduring persistent pain, intractable pain, unbearable pain, threatening pain, etc. In applying these considerations to various of the subjective elements of the pain complex, hypnotic intervention is greatly accelerated. Such analysis offers greater opportunity for hypnotic intervention at a more understanding and comprehensive level. It becomes easier to communicate ideas and understandings through hypnosis and to elicit the receptiveness and responsiveness so vital in securing good response to hypnotic intervention. It is also important to recognize adequately the unrecognized force of the human emotional need to demand the immediate abolition of pain, both by the patient himself and by those in

attendance on him. In hypnotic intervention there is a need to be aware of this and not to allow it to dominate a scientific hypnotic approach to the problem of pain.

HYPNOTIC PROCEDURES IN PAIN CONTROL

The hypnotic procedures in handling pain are numerous in character. The first of these, most commonly practiced but frequently not genuinely applicable is the use of *direct hypnotic suggestion for total abolition of pain*. With a certain limited number of patients, this is a most effective procedure. But too often it fails, serving to discourage the patient and to prevent further use of hypnosis in his treatment. Also, its effects, while they may be good, are sometimes too limited in duration, and this may limit the effectiveness of the *permissive indirect hypnotic abolition of pain*. This is often much more effective, and although essentially similar in character to direct suggestion, it is worded and offered in a fashion much more conducive of patient receptiveness and responsiveness.

A third procedure for hypnotic control of pain is the utilization of *amnesia*. In everyday life we see the forgetting of pain whenever more threatening or absorbing experiences secure the attention of the sufferer. An example is the instance already cited of the mother enduring extreme pain, seeing her infant seriously injured, and forgetting her own pain in the anxious fears about her child. Then of quite opposite psychological character is the forgetting of painful arthritis, headache, or toothache while watching an all-absorbing suspenseful drama on a cinema screen.

But amnesia in relationship to pain can be applied hypnotically in a great variety of ways. Thus one may employ partial, selective, or complete amnesias in relationship to selected subjective qualities and attributes of sensation in the pain complex as described by the patient as well as to the total pain experience.

A fourth hypnotic procedure is the employment of *hypnotic analgesia*, which may be partial, complete, or selective. Thus, one may add to the patient's pain experience a certain feeling of numbness without a loss of tactile or pressure sensations. The entire pain experience then becomes modified and different and gives the patient a sense of relief and satisfaction, even if the analgesia is not complete. The sensory modifications introduced into the patient's subjective experience by such sensations as numbness, an increase of warmth and heaviness, relaxation, etc., serve to intensify the hypnotic analgesia to an increasingly more complete degree.

Hypnotic anesthesia is a fifth method in treating pain. This is often difficult and may sometimes be accomplished directly, but is more often best accomplished indirectly by the building of psychological and emotional situations that are contradictory to the experience of the pain and which serve to establish an anesthetic reaction to be continued by posthypnotic suggestion.

A sixth hypnotic procedure useful in handling pain concerns the matter of suggestion to effect the *hypnotic replacement or substitution of sensations*. For example, one cancer patient suffering intolerable, intractable pain responded most remarkably to the

suggestion of an intolerable, incredibly annoying itch on the sole of her foot. Her body weakness occasioned by the carcinomatosis and hence inability to scratch the itch rendered this psychogenic pruritis all-absorbing of her attention. Then hypnotically, there were systematically induced feelings of warmth, of coolness, of heaviness and of numbness for various parts of her body where she suffered pain. And the final measure was the suggestion of an endurable but highly unpleasant and annoying minor burning-itching sensation at the site of her mastectomy. This procedure of replacement substitution sufficed for the last six months of the patient's life. The itch of the sole of her foot gradually disappeared, but the annoying burning-itching at the site of her mastectomy persisted.

Hypnotic displacement of pain is a seventh procedure. This is the employment of a suggested displacement of the pain from one area of the body to another. This can be well illustrated by the instance of a man dying from prostatic metastatic carcinomatosis and suffering with intractable pain, particularly abdominal pain, in both the states of drug narcosis and deep hypnosis. He was medically trained and understood the concept of referred and displaced pain. In the hypnotic trance he readily accepted the idea that, while the intractable pain in his abdomen was the pain that would actually destroy him, he could readily understand that equal pain in is left hand could be entirely endurable, since in that location it would not have its threatening significances. He accepted the idea of referral of his abdominal pain to his left hand, and thus remained free of body pain and became accustomed to the severe pain in his left hand, which he projected carefully. This hand pain did not interfere in any way with his full contact with his family during the remaining three months of his life. It was disclosed that the displaced pain to the left hand often gradually diminished, but the pain would become increased upon incautious inquiry.

This possibility of displacement of pain also permits a displacement of various attributes of the pain that cannot otherwise be controlled. By this measure these otherwise uncontrollable attributes become greatly diminished. Thus the total complex of pain becomes greatly modified and made more amenable to hypnotic intervention.

Hypnotic dissociation can be employed for pain control, and the usual, most effective methods are those of *time and body disorientation*. The patient with pain intractable to both drugs and hypnosis can be hypnotically reoriented in time to the earlier stages of his illness, when the pain was of minor consideration. And the disorientation of that time characteristic of the pain can be allowed to remain as a posthypnotic continuation through the waking state. Thus the patient still has his intractable pain, but it has been rendered into a minor consideration, as it had been in its original stages.

One may sometimes successfully reorient the patient with intractable pain to a previous time predating his illness and, by posthypnotic suggestion, effect a restoring of the normal sensations existing before his illness. However, although intractable pain often prevents this as a total result, pleasant feelings predating his illness may be projected into the present to nullify some of the subjective qualities of his pain complex. Sometimes this effects a major reduction in pain.

In the matter of *body disorientation* the patient is hypnotically dissociated and induced to experience himself as apart from his body. Thus one woman with the onset of unendurable pain, in response to posthypnotic suggestions, would develop a trance state and experience herself as being in another room while her suffering body remained in her sickbed. This patient explained to the author when he made a bedside call, "Just before you arrived, I developed another horrible attack of pain. So I went into a trance, got into my wheelchair, came out into the living room to watch a television program, and left my suffering body in the bedroom." And she pleasantly and happily told about the fantasized television program she was watching. Another such patient remarked to her surgeon, "You know very well, Doctor, that I always faint when you start changing my dressings because I can't endure the pain, so if you don't mind, I will go into a hypnotic trance and take my head and feet and go into the solarium and leave my body here for you to work on." The patient further explained, "I took a position in the solarium where I could see him [the surgeon] bending over my body, but I could not see what he was doing. Then I looked out the window, and when I looked back he was gone, so I took my head and feet and went back and joined my body and felt very comfortable." This particular patient had been trained in hypnosis by the author many years previously, had subsequently learned autohypnosis, and thereafter induced her own autohypnotic trance by the phrase, "You know very well, Doctor." This was a phrase that she could employ verbally or mentally at any time and immediately go into a trance for the psychological-emotional experience of being elsewhere, away from her painful body, there to enjoy herself and remain until it was safe to return to her body. In this trance state, which she protected very well from the awareness of others, she would visit with her relatives, but experience them as with her in this new setting while not betraying that personal orientation.

A ninth hypnotic procedure in controlling body pain, which is very similar to replacement or substitution of sensations, is *hypnotic reinterpretation of pain experience*. By this is meant reinterpreting for the patient in hypnosis of a dragging, gnawing, heavy pain as a feeling of weakness, of profound inertia, and then as relaxation with the warmth and comfort that accompanies muscular relaxation. Stabbing, lancinating, and biting pains may sometimes be reinterpreted as sudden startle reactions, disturbing in character but momentary and not painful. Throbbing, nagging, grinding pain has been successfully reinterpreted as the unpleasant but not distressing experience of the rolling sensations of a boat during the storm, or even as the throbbing that one so often experiences from a minor cut on the fingertip and of a no greater distressing character. Full awareness of how the patient experiences pain is requisite for an adequate hypnotic reinterpretation of his pain sensation.

Hypnotic time distortion, first described by Cooper and then later developed by Cooper and Erickson (1959) is often a most useful hypnotic measure in pain control. An excellent example is that of the patient with intractable attacks of lancinating pain which occurred approximately every 20 to 30 minutes, night and day, and which lasted from five to 10 minutes. Between the attacks the patient's frame of mind was essentially one of fearful dread of the next attack. By employing hypnosis and teaching him time distortion, it was possible to employ, as is usually the case in every pain patient, a combination of several

of the measures being described here. In the trance state the patient was taught to develop an amnesia for all past attacks of pain. He was then taught time distortion so that he could experience the five- to 10-minute pain episodes in 10 to 20 seconds. He was given posthypnotic suggestions to the effect that each attack would come as a complete surprise to him, that when the attack occurred, he would develop a trance state of 10 to 20 seconds' duration, experience all of the pain attack, and then come out of the trance with no awareness that he had been in a trance or that he had experienced pain. Thus the patient, in talking to his family, would suddenly and obviously go into the trance state with a scream of pain, and perhaps 10 seconds later come out of the trance state, look confused for a moment, and then continue his interrupted sentence.

An eleventh hypnotic procedure is that of offering *hypnotic suggestions effecting a diminution of pain*, but not a removal, when it has become apparent that the patient is not going to be fully responsive. This diminution is usually brought about best by suggesting to the hypnotized patient that his pain is going to diminish imperceptibly hour after hour without his awareness that it is diminished until perhaps several days have passed. He will then become aware of a definite diminution either of all pain or of special pain qualities. By suggesting that the diminution occur imperceptibly the patient cannot refuse the suggestion. His state of emotional hopefulness, despite his emotional despair, leads him to anticipate that in a few days there may be some diminution, particularly that there may be even a marked diminution of certain of the special attributes of his pain experience. This in itself serves as an autosuggestion to the patient. In certain instances, however, he is told that the diminution will be to a very minor degree. One can emphasize this by utilizing the ploy that a one percent diminution of his pain would not be noticeable, nor would a 2 percent, nor a 3 percent, nor a 4 percent, nor a 5 percent diminution, but that such an amount would nevertheless be a diminution. One can continue the ploy by stating that a 5 percent diminution the first day and an additional 2 percent the next day still would not be perceptible. And if on the third day there occurred a 3 percent diminution, this, too, would be imperceptible. But it would total a 10 percent diminution of the original pain. This same series of suggestions can be continued to a reduction of pain to 80 percent of its original intensity, then to 70 percent, 50 percent, 40 percent, and sometimes even down to 10 percent. In this way the patient may be led progressively into an ever-greater control of his pain.

However, in all hypnotic procedures for the control of pain one bears in mind the greater feasibility and acceptability to the patient of indirect as compared with direct hypnotic suggestions, and the need to approach the problem by indirect and permissive measures and by the employment of a combination of various of the methodological procedures described above.

SUMMARY

Pain is a subjective experience, and it is perhaps the most significant factor in causing people to seek medical aid. Treatment of pain as usually viewed by both physician and patient is primarily a matter of elimination or abolition of the sensation. Yet pain in itself may be serving certain useful purposes to the individual. It constitutes a warning, a

persistent warning of the need for help. It brings about physical restriction of activity, thus frequently benefiting the sufferer. It instigates physiological changes of a healing character in the body. Hence, pain is not just an undesirable sensation to be abolished, but rather an experience to be so handled that the sufferer benefits. This may be done in a variety of ways, but there is a tendency to overlook the wealth of psycho-neuro-physiological significances pain has for the patient. Pain is a complex, a construct composed of a great diversity of subjective interpretative and experiential values for the patient. Pain, during life's experience, serves to establish body leanings, associations, and conditionings that constitute a source of body potentials permitting the use of hypnosis for the study and control of pain. Hypnotic procedures, singly or in combination, for major or minor effects in the control of pain described for their application are:

- Direct Hypnotic Suggestion for Total Abolition of Pain
- Permissive Indirect Hypnotic Abolition of Pain
- Amnesia
- Hypnotic Analgesia
- Hypnotic Anesthesia
- Hypnotic Replacement or Substitution of Sensations
- Hypnotic Displacement of Pain
- Hypnotic Dissociation
- Reinterpretation of Pain Experience
- Hypnotic Suggestions Effecting a Diminution of Pain.

Therapy of a Psychosomatic Headache

Milton H. Erickson

Quoted from the *Journal of Clinical and Experimental Hypnosis* (October, 1953, I (4), 2-6).

INTRODUCTION

Too often, trite observations are made to disparage experimental findings. For example, a professor of internal medicine, after reading a psychiatric report upon a single patient, remarked that one case proves nothing. Reply was made that a single instance of an untried medication administered to only one patient with lethal results proved much more than could possibly be desired. The nature and character of a single finding can often be more informative and valuable than a voluminous aggregate of data whose meaning is dependent upon statistical manipulation. This is particularly true in the field of human personality where, although each individual is unique in all of his experiential life, single instances often illustrate clearly and vividly aspects and facets of general configurations, trends, and patterns. Rather than proof of specific ideas, an illustration or portrayal of possibilities is often the proper goal of experimental work.

In a comparable fashion another type of assumption places limitations unwarrantedly upon experimental findings. For example, many psychotherapists regard it as almost axiomatic that therapy is contingent upon making the unconscious conscious. When thought is given to the unmeasurable role that the unconscious plays in the total experiential life of a person from infancy on, whether awake or asleep, there can be little expectation of doing more than making some small parts of it conscious. Furthermore, the unconscious as such, not as transformed into the conscious, constitutes an essential part of psychological functioning. Hence, it seems more reasonable to assume that a legitimate goal in therapy lies in promoting an integrated functioning, both singly and together, and in complementary and supplementary relationships, as occurs daily in well-adjusted living in contrast to the inadequate, disordered, and contradictory manifestations in neurotic behavior.

THE PATIENT

To illustrate the above considerations, the following case history is reported.

A professionally trained female employee of a state hospital was referred to the writer for therapy after extensive medical study. Her complaint was one of severe headaches, for which numerous medical studies had found no physical basis, and severe personality disturbances manifested in quarrelsomeness and uncooperativeness. At the time she was seen, she had been given notice of her discharge to take effect either immediately or, if she sought therapy from the writer, in six weeks' time.

Under these adverse circumstances, the patient sought out the writer, explained the situation bitterly, and declared that she was confronted with "the choice of wiring home for transportation money or being messed around with by a damn hypnotist." (The fact that the writer was wholly innocent of any part of her situation was totally disregarded by her.) She added ungraciously, "So here I am. What do you want? Go ahead."

An effort was made to secure her history, but she was uncommunicative and remained so throughout the course of therapy. The only material obtained was the following fragments:

For the past four years, beginning when she parted ties with her childhood home, she had been suffering from intense, unlocalized headaches. These sometimes occurred twice a week and were accompanied by nausea, vomiting, and physical incapacitation from two to four hours' duration. Also they were always associated with intense, inexplicable emotional disturbances characterized by extreme quarrelsomeness, bitterness, and violent verbal attacks on everyone about her. Usually these emotional disturbances presaged the headaches, and upon recovery from that symptom she would remain seclusive, subdued, and somewhat socially adjusted for a day or two until the next attack.

Every attempt to secure more adequate information from her failed. She resented any questions or even casual conversation about herself. Also, she was embittered by the fact that she had been given notice of her impending discharge and only then had been referred for psychotherapy, "as if to make up for firing me."

This behavior of hers had caused her to lose one position after another as well as all of her friends and even the possibility of making new friends. Hence, she felt most lonely and wretched about her situation.

THERAPEUTIC PROCEDURE

She was unfriendly and uncooperative at the first interview and so was told only that hypnosis might possibly be of value but that it would first be necessary to see her during one of her headache seizures. A few days later word was received that she was confined to bed with a sudden headache. She was found to be pale and drawn in appearance. She flinched whenever she moved her head or body, and was dazed, slow, and unresponsive in her general behavior.

A few hours later she was found recovered from her headache, spasmodic and excitable in her movements. She spoke in a high-pitched tone of voice, scolded and excoriated everybody, and seemed to take a sadistic delight in making cutting, painful remarks. She was most unwilling to discuss her condition, denounced the hypnotist, and demanded to be left alone. The next day her characteristic depressive reaction set in, and she was silent, seclusive, but would occasionally make self-condemnatory remarks.

A few days later, in a pleasant, affable mood, she approached the hypnotist spontaneously for hypnotic therapy. However, she dismissed all attempts at questioning, declaring politely but emphatically that her only problem was her headaches and that all therapy should be directed entirely to that one symptom. If this were done, she explained, her other difficulties would vanish, since they all derived from the headaches and her reactions to them.

Finally it became necessary to accept her on her own terms, with the mental reservation to resort to experimental measures.

Repeated attempts at hypnosis produced only light trances, but these were capitalized upon to secure her cooperation as a demonstration subject for a teaching clinic. By this measure it was possible to induce a profound trance in which she was given adequate training and instruction to permit the induction of profound trances in the future.

During the course of the next four weeks a total of 15 profound trances were induced. These trances were utilized to give repeatedly, emphatically, and insistently the following suggestions, until, more or less under duress, she accepted them and agreed to obey them:

> 1. Should a headache develop unexpectedly, or should she develop the irritability that experience had taught her presaged a headache, she was to go to bed at once and sleep soundly for at least half an hour. This, she was told repeatedly, would serve to abort either of the manifestations.
>
> 2. Following this half-hour of sleep she was then to spend at least an hour, preferably more, in mentally reviling, denouncing, condemning, and criticizing anybody and everybody she wished, giving free rein to her fantasies as she did so. This was to be done at first in obedience to the instructions given her, but sooner or later she was to carry out these instructions solely because of her own sadistic desires.
>
> 3. She was further told that, after she had secured adequate emotional satisfaction from these fantasized aggressions, she was to sleep soundly and restfully another half-hour. Then she might awaken and go about her work freely and comfortably with no need to "hate herself." This would be possible, it was explained, because obedience to the foregoing instructions would result in a hypnotic sleep that would persist until she finally awakened to go about her work in a rested, comfortable fashion. Of all this she would know only that she had gone to bed, fallen asleep, and had finally awakened feeling comfortable and rested in every way.

During the first three weeks the subject obeyed these instructions a half-dozen times by excusing herself from her work, returning to her room, and falling asleep. She would remain in this sleep from two to three hours and then rouse up and seem refreshed and comfortable. Several check-ups during periods when she was sleeping disclosed her to be in a trance state, but not in good rapport with the writer.

During the fourth week a new procedure was introduced. This was also in the form of a posthypnotic suggestion to the effect that on a certain day, at a specified hour, she was to develop a severe headache. As this developed, she was to fight against it and to persist in working until she could no longer stand it. Then she was to go hastily to her room and obey the first series of suggestions.

These instructions were carried out fully. At 1 P.M. on that day, three hours after her headache had begun, she returned to work, socially adjusted in a satisfactory fashion. Her only complaint was a comment on her ravenous hunger, since she had missed her lunch. On previous occasions such an event had often been seized upon to justify her irritability. Thus, she had been given experimental proof of the effectiveness of hypnotic suggestion and of the possibility of a good therapeutic response.

About a week later, in another trance state, she was given posthypnotic instructions to develop at a given time the emotional disturbance that often presaged a headache. As this developed, she was to resist it, to control her tongue except for a few disagreeable remarks, and finally to develop an overwhelming desire to return to her room, to which she would finally yield. There she was to follow the routine suggested previously.

All instructions were obeyed, and after nearly three hours of sleep she returned to her work in a pleasant frame of mind.

These two special trance sessions were purposely included in the course of therapeutic or instructive trances as a measure of forcing the subject to act responsively upon the earlier trance instructions. Subsequent trance states in which the suggestions cited above were given were augmented in force by reference to the experiential values of the posthypnotically induced headache and emotional disturbances and the benefits of following instructions.

In addition, every effort was made to impress upon her the future effectiveness of the general procedure and the desirability of yielding at once to the posthypnotic suggestions.

The last trance session was devoted to a general review of the instructions given to her, the posthypnotic disturbances suggested to her, her learned ability to meet the whole general problem, and the future applicability of the procedure in the event of further headaches and emotional disturbances.

Repeatedly during trance sessions efforts were made to learn the content of her thinking during the periods of mental aggression, but she proved uncommunicative. It was, she declared, “too terrible” to relate.

Questioning in the waking state disclosed her to have a complete amnesia for all except the superficial facts that she had been hypnotized repeatedly and that there had been a number of occasions on which she felt a headache developing, and that this had been warded off by a compulsive need to sleep. Every effort to secure additional data from her

failed. She did attribute her change in behavior to the hypnosis, but was not curious about what had been done.

THE RESULTS

After leaving the hospital, she was not seen for three months. At the next meeting with her she related that she had only two threatened headaches, but had promptly warded them off with a little sleep, and that they had been the happiest three months of her life.

Immediately she began to thank the writer effusively, declaring that her freedom from headaches was unquestionably the result of his hypnotic work. Efforts to secure her reasons for this conclusion elicited only more expressions of certainty, conviction, and gratitude, but with no evidence of any true understanding or knowledge of what had occurred therapeutically.

She was interrupted in her thanks and the suggestion was given insistently that adequate expression of gratitude could come only from continued satisfactory adjustment in the future. With this remark the interview was closed.

More than 15 years have elapsed, and the therapeutic outcome has been good. She secured a position in another part of the country and has been promoted progressively until she is now a department head. Each Christmas a greeting card expressing briefly her gratitude is received. Occasionally a business letter is received, asking for references concerning somebody the writer knows, or recommending to him somebody needing therapy or a job placement.

One additional fact is that acquaintance has been made with several persons who have worked for her. They have been found to entertain the highest regard, personal liking, and respect for her and to be most enthusiastic about her charming personality.

In response to a specific letter of inquiry she stated that she had on the average three headaches a year, but that these responded readily to brief rest. She expressed the belief that these headaches were “different” from her former headaches, and she attributed them to reading without her glasses.

She is now in her early forties, unmarried, wholly content, absorbed in her work and the creature comforts of her tastefully decorated apartment. She was described by a competent psychiatrist who knew her well, but nothing of the above history, as “one of those delightful people you like to number among your friends. She looks upon men as charming companions but nothing more. She’s most enthusiastic about her work and inspires everyone who works under her. After the day is over she likes her home, or the theater, or concerts, or has some of us in for a social evening. She is content and happy. You must have enjoyed knowing her.”

COMMENT

A definitive discussion, even of a single aspect of this case history, is impossible since it is restricted entirely to overt symptoms. The only things known are what the therapist tried to do, but not the experiential significances thereof to the patient, and the subsequent, definitely successful therapeutic results.

At most it can be said that an experimental procedure was employed which in some manner permitted the patient's unconscious, distorted and disorganized in its functioning, to achieve a satisfactory role in the total experiential life of the patient, and to do so without becoming a part of the conscious. That such an outcome was possible with one patient suggests strongly that a comparable procedure could be adapted satisfactorily to the therapeutic needs of other patients.

Migraine Headache in a Resistant Patient

Milton H. Erickson

Unpublished manuscript, 1936.

An admonition from William Alanson White, M.D., then Superintendent of St. Elizabeth's Hospital, was given to this writer early in his psychiatric career, and a year or so later he was again given the same admonition by Adolf Meyer, M.D. Both strongly advised the writer never to refuse to consult with a patient. A single interview graciously granted during which the patient's story was listened to attentively, while not especially remunerative, had often permitted them to encounter many unusual instances of psychopathology and to achieve, in many cases, astonishingly effective results. These results had sometimes proved to be far better than the doctors had considered possible at the time of the interview, even if long-term therapy could have been instituted. They likened such instances to the processes of behavior wherein "love at first sight" has drastically and positively altered the lives of various individuals. One such historical example was the schoolteacher who thought it wrong for an adult man making his living as a tailor (Andrew Johnson) to be so uneducated. The events that unfolded began with teaching and led to love, marriage, a law degree, a judgeship, and eventually the presidency of the United States.

Adolf Meyer particularly stressed the utility of hypnosis in eliciting the potentialities of these transient patients and urged this writer to see such patients for both the educational values of the experience and the possibility of effecting unexpected results. Throughout the passing years the writer has conducted many "one-shot" interviews and sometimes as much as 20 years later has received an appreciative letter or a personal visit confirming the therapeutic impact of the brief encounter.

One such case is as follows: In 1936 the author lectured to his first class of medical students at the Wayne State University College of Medicine. During one of the last two lectures of the year the subject of hypnosis was discussed. One of the students hostilely and aggressively interrupted the lecture to denounce hypnosis as a hoax and challenged the author to hypnotize him. He proceeded to berate the author; one of his classmates who was well known to the author rushed up and quietly explained that no notice should be given to the student's misconduct. He was a known sufferer of migraine headaches, which developed unexpectedly; the headaches were always preceded by an outburst, as had just occurred; this behavior was merely the prodomes of a migraine headache, which would last for one to three days; and finally, such outbursts would occur in the most unexpected of situations—on the street, in the classroom, at parties, football games, etc. After the outburst the student would slowly become flushed of face and neck, followed shortly by projectile vomiting, and culminating in a violent, incapacitating headache of perhaps several days' duration. He had been examined by many competent physicians and had almost been refused admission to the medical school. So far no medication or

treatment had been found for his malady. (Several of the rest of the class members confirmed this account of the student's history.)

Within 10 minutes the student apologized for his conduct, declared that he was in the process of developing a migraine headache for which nothing could be done, in that about 15 or 20 minutes he would begin vomiting; after that happened, could he and a friend be excused so that he could be taken home. He also explained that his emotional outburst was a part of the aura. He was still getting angrier within himself, but he wanted to stay at the lecture as long as possible, since past experience had taught him how to judge his condition. Consent was given, but a challenge was issued that he might try hypnosis, since nothing else had worked. He bristled at this suggestion, but suddenly said, "Well, I've got nothing to lose but my breakfast, so go ahead with your silly hypnosis."

He was asked to take a seat in front of the class, facing the author and with his back to the audience. Slowly it was explained that he was to rotate his chair (it was a four-legged chair) bit by bit until he had made a complete turn of 360 degrees. His hostile manner and attitude suggested the inadvisability of attempting any routine traditional technique. Additionally, such a technique as moving his chair in a circle as he sat in it would be utterly incomprehensible to him as well as a difficult task. Yet, by so doing, he would be caught in the situation of actually participating with the author in a joint undertaking. Thus, he would validate by his own actions the idea that he was going into a trance.

As he gradually rotated his chair, the author explained to the class that the subject would do this task slowly, that each little movement would become slower and more difficult, that there was no hurry, no rush, that the subject could take his time and ought to, that each time he moved his chair a little, he would feel increasing fatigue and sleepiness, that the chair would seem to get more and more difficult to move, that his efforts would increasingly become less and less effective, and that shortly his eyes would close, he would take a deep breath, he would give up trying to move the chair, and simply relax by going into a deep trance.

All of the above was said as if it were no more than an explanation to the rest of the class. Thus, the subject would hear these suggestions as an explanation to the class but not as commands personally addressed to him. He would develop no counterset to the suggestions and would thus tend to respond to them more readily, since he was already cooperating by slowly rotating his chair. Another important factor was the impending threat of a disabling migraine headache and the undoubtedly strong desire to escape from it in some way, even if that "way" appeared silly to him. Indeed, the entire situation favored the development of a trance state—the long history of migraine, the prodromes of hostility, aggressiveness, and belligerency, his own feeling of helplessness, his unwillingness to experience the projectile vomiting, and his dread of the utterly painful incapacitation that awaited him.

By the time he was facing the audience, he had developed a deep trance. He was peremptorily told that the author was now in charge of him and that all instructions were

to be carried out. To this he nodded his head affirmatively. He was instructed to awaken, to speak derogatorily about hypnosis and the author, and to declare that such nonsense as hypnosis made him sick to his stomach. He should then *try* to prove that statement by going to the window, opening it, and *trying* to vomit projectilely, *but that he would fail completely*.

He was aroused, appearing surprised to find himself facing his classmates, made several unpleasant remarks as instructed, and then opened a window overlooking a vacant lot. He apparently did his best to vomit but failed, stating, "By this time I should have lost the lining of my stomach, but I'm beginning to feel better. I always vomit when I am about to have a migraine and I sure had all the warning signs this morning. But if I can't vomit, perhaps I won't have it [the migraine]."

This utterance was seized upon by the author to expand the idea that maladies, whether psychogenic or organic, followed definite patterns of some sort, particularly in the field of psychogenic disorders; that a disruption of this pattern could be a most therapeutic measure; and that it often mattered little how small the disruption was, if introduced early enough. After some discussion of this for the class (and as disguised suggestions to him) he was challengingly asked if he thought there was such a thing as hypnosis, and did he dare to volunteer to be a subject.

His reply was most informative: "I just told you it was silly nonsense, but I'm beginning to believe in it and I almost feel that you could hypnotize me. But what I don't understand is that something has happened to my headache. I knew this morning when I woke up that I was going to have one, and when I came into this classroom I was in my usual, helpless, ugly mood. But now I feel fine."

The answer given was, "It's all very simple, and as I explain you will go into a trance, a deep trance, remember everything, and then awaken, knowing that you never need to have another migraine headache. So rouse up!" He awakened from the trance that developed as the above remarks were made and had a total recovery of all events.

Hypnosis in Painful Terminal Illness

Milton H. Erickson

Presented before the Eighty-Second Annual Session of the Arkansas Medical Society, May 6, 1958, at Hot Springs, Arkansas, and being published simultaneously by *The Journal of the Arkansas Medical Society*. Reprinted with permission from *The American Journal of Clinical Hypnosis*, January, 1959, 1, 117-121.

The use of psychological measures in the treatment of human illness, whether organic or psychological or a combination of both, is as old as human history. In fact, the psychological aspect of medicine constitutes the art of medicine and transforms the physician from a skillful mechanic or technician into a needed human source of faith, hope, assistance, and, most importantly, of motivation for the patient toward physical and mental health and well-being.

With this integral relationship between psychology and medicine it is not surprising that hypnosis as a psychological measure should be considered, seriously and rightly, in the treatment of painful terminal illness, particularly the last stages of malignant disease. However, as a preliminary statement, it must be emphasized that hypnosis is not an absolute answer and that it cannot replace other medical procedures. Rather, it is no more than one of the adjuvants or synergistic measures that can be employed to meet the patient's needs.

To present this topic to you, it might be well first to define both hypnosis and the rationale of its use. Essentially, hypnosis is a state of intensified attention and receptiveness and an increased responsiveness to an idea or to a set of ideas. There is nothing magical or mystical about it; it is attentiveness to, absorption in, and responsiveness to an idea or a whole group of ideas. We see this sort of thing repeatedly in everyday living where hypnosis is not involved—the automobile driver who forgets everything he should keep in mind because he is fascinated by the white line in the middle of the highway or by the scenery along the roadside, or the man unwisely and so intensely interested in a woman that he literally forgets everything that common sense has taught him.

In medicine as well as in dentistry this normal everyday capacity for intensely directed attention can be employed to concentrate and redirect a patient's attentiveness and responsiveness to selected stimuli. This constitutes the use of hypnosis in painful terminal disease.

In treating such patients, the question is not one of treating the illness itself, since the patient is both dying and suffering painfully. The primary problem is how to treat the patient so that his human needs may be met as much as possible. Thus, it becomes a

complex problem of what the physical body has to have and what the patient as a personality needs, since cultural and individual psychological patterns are of as much and perhaps greater importance than the physiological experience of pain.

Before this audience there is no need to offer suggestions concerning the proper medically oriented procedures to employ in meeting the physical needs of the body. However, a statement should be made about meeting the physical needs of the body: Such treatment is just as important as the treatment of the psychological needs of the patient as a personality and should never be discredited. In fact, it is a prerequisite for any psychological treatment. Therefore, the question becomes: What is the adequate but at the same time the minimal treatment of the body? That it be minimal though adequate is essential, because in painful terminal disease sedatives, analgesics, and narcotics are employed that may deprive the patients of the privilege of knowing that they are alive and of enjoying what pleasures yet remain; also, they deprive relatives of adequate contacts with the patient. Hence, medication should be administered only in those quantities that meet the physical requirements without obstructing or defeating those psychological needs vital to the total life situation and which also require satisfactions even more than the physical.

To illustrate this point and to clarify the foregoing discussion, three case reports will be cited:

REPORT 1

The first patient was a 37-year-old woman of grade-school education, mother of four children, dying of advanced metastatic carcinomatous disease originating in the uterus. For the three weeks preceding hypnosis she had been kept in a narcotic semistupor, since this was the only way to control her pain, to enable her to sleep, and to enable her to eat without extensive nausea and vomiting. The woman understood her condition and resented helplessly her inability to spend the remaining weeks of her life in contact with her family. The family physician finally decided to have hypnosis employed.

The situation was explained to the woman, and narcotics were omitted on the day she was to be hypnotized so that this could be done without excessive drug interference.

Approximately four continuous hours were spent with the woman, systematically teaching her how to go into a trance despite her attacks of pain, how to develop a numbness of her body, how to absorb herself in a state of profound fatigue so that she could have physiological sleep despite pain, and how to enjoy her food without gastric distress. No elaborate explanations were necessary, since her educational limitations and the desperateness of her situation motivated a ready acceptance of suggestions without questioning doubts. Additionally, she was trained hypnotically to respond to her husband, her oldest daughter, and to her family physician, so that hypnosis could be readily reinforced in the event of any new development.

This one time was the only occasion on which the patient was seen by the writer. Her motivation was so great that the one hypnotic training session was sufficient.

The previous medication, it was found, could actually be discontinued, except for one heavy hypodermic administration late Thursday evening. This gave her additional relief, and it allowed her to be in full contact with her family in a rested state on the weekends. Also she shared in the family evening activities during the week.

Six weeks after her first trance, while laughing and talking to her daughter, she suddenly lapsed into a coma and died two days later without recovering consciousness. Those six weeks had been decidedly happy and pain-free for her.

REPORT 2

This 35-year-old woman, the mother of four small children and the wife of a professional man, was seen five weeks before her death from lung cancer. For a month before hypnosis, she had been almost continuously in a narcotic stupor, since the pain she experienced was unbearable to her. She asked that hypnosis be employed and voluntarily went without medication that entire day in her own self-determined effort to ready herself for hypnosis.

She was seen at 6:00 P.M., bathed in perspiration, suffering acutely from constant pain and greatly exhausted. Nevertheless, approximately four hours of continuous effort were required before a light trance could be induced. This light stage of hypnosis was immediately utilized to induce her to permit three things to be accomplished, all of which she had consistently refused to allow in the very intensity of her desire to be hypnotized. The first of these was the hypodermic administration of 1/8 grain of morphine sulfate, a most inadequate dosage for her physical needs, but one considered adequate for the immediate situation. The next was the serving to her of a pint of rich soup, and the third was the successful insistence upon an hour's restful physiological sleep. By 6:00 A.M. the patient, who finally proved to be an excellent somnambulistic subject, had been taught successfully everything considered to be essential to meet the needs of her situation.

The procedure followed was probably unnecessarily comprehensive, but the situation did not warrant any approach less inclusive. The first step was to teach her positive and negative hallucinations in the modalities of vision, hearing, taste, and smell. Then she was taught positive and negative hallucinations in the areas of touch, deep sensation, and kinesthesia, and in relation to this latter type of sensation, she was taught body disorientation and dissociation. When these learnings were sufficiently well acquired, the patient was given suggestions for glove and stocking anesthesias, and these were extended over her entire body. Thereupon it became possible to teach her rapidly combined partial analgesias and anesthesias for both superficial and deep sensations of all types. To this was added a combination of both body disorientation and body dissociation, so that these latter could supplement the former.

The patient was not seen again, either professionally or socially, but her husband telephoned or gave reports in person daily concerning the patient's condition.

She died suddenly five weeks later, in the midst of a happy social conversation with a neighbor and a relative.

During that five-week period she had been instructed to feel free to accept whatever medication she needed. Now and then she would suffer pain, but this was almost always controlled by aspirin. Sometimes a second dose of aspirin with codeine was needed, and on half a dozen occasions 1/8 grain of morphine was needed. Otherwise, except for her gradual progressive physical deterioration, the patient continued decidedly comfortable and cheerfully adjusted to the end.

REPORT 3

The third patient was a professionally trained man of advanced years, who understood fully the nature of his carcinomatous illness. Because of his educational background it was both necessary and advantageous to develop the hypnotic suggestions with care in order to secure both his intellectual and his emotional cooperation. While resigned to his fate, he resented greatly the narcotic stupors he developed when given sufficient medication to control his pain. It was his earnest desire to spend his remaining days in the fullest possible contact with his family, but this he found difficult because of the severely agonizing recurrent pains he suffered. As a solution, he requested hypnosis, and he himself discontinued medication for 12 hours in order to avoid a possible narcotic interference with a trance development.

At the first hypnotic session all suggestions were directed to the induction of a state of profound physical fatigue, of overwhelming sleepiness, and of a need to enter physiological sleep and to rest sufficiently to permit the induction of a hypnotic trance. A light trance was induced that almost immediately lapsed into a physiological sleep of about 30 minutes' duration. He aroused from this definitely rested and most firmly convinced of the efficacy of hypnosis.

A second and, this time, medium trance was then induced. Systematically a series of suggestions was given in which a direct use was made of the patient's actual symptomatology. The rationale for this was to validate the hypnotic suggestions through utilization of the experiential validity of his symptoms.

Thus the patient was told that his body would feel tremendously heavy, that it would feel like a dull, leaden weight, so heavy that it would feel as if sodden with sleep and incapable of sensing anything else except heavy tiredness. These suggestions, repetitiously given and in varying phraseology to ensure comprehensive acceptance, were intended to utilize the patient's feeling of distressing weakness, previously unacceptable to him and to combine it with the complaint of "constant, heavy, dull, throbbing ache." In addition, suggestions were given that, again and again as he experienced the "dull, heavy tiredness" of his body, it would periodically go to sleep, while his mind remained awake.

Thus his distressing feeling of weakness and his dull, throbbing ache were utilized to secure a redirection and a reorientation of his attentiveness and responsiveness to his somatic sensations and to secure a new and acceptable perception of them. Also, by suggesting a sleeping of the body and wakefulness of the mind, a state of dissociation was induced. The next step was to reorient and redirect his attentiveness and responsiveness to the sharp, brief, constantly recurring, agonizing pains from which he suffered, usually less than 10 minutes apart. These pains, while brief, less than one minute in duration as timed by a watch, were experienced by the patient subjectively as "endless" and as essentially "continuous" in character.

The procedure followed included several steps.

First of all, he was oriented in relationship to subjective time values by asking him, at the expiration of a sharp pain, to fix his attention rigidly on the movement of the minute hand of a clock and to await the next sharp pain. The slightly more than seven minutes of waiting in anticipatory dread seemed hours long to the patient, and it was with definite relief from his feeling of wretched expectation that he suffered the next sharp pain. Thus anticipation and pain, as separate experiences, were differentiated for him. Also, he acquired in this way an understanding of time distortion (Cooper & Erickson, 1959), particularly that aspect of time distortion related to the lengthening or expansion of subjective time experience.

Next a careful explanation was given to him that freedom from the experience of pain could be accomplished in several ways—by anesthesia and by analgesia, both of which he understood, and by amnesia, which he did not understand. The explanation was offered that in amnesia for pain one could experience pain throughout its duration, but that one would immediately forget it and thus would not look back upon the experience with a feeling of horror and distress, nor look forward to another similar pain experience with anticipatory dread fear. In other words, each recurrent sharp pain could be and would become a totally unexpected and completely transient experience. Because it would be neither anticipated nor remembered, it would seem experientially to have no temporal duration. Hence, it would be experienced only as a momentary flash of sensation of such short duration that there would be no opportunity to recognize its character. In this fashion the patient was taught another aspect of time distortion—namely, a shortening, contraction, or condensation of subjective time. Thus, in addition to the possible hypnotic anesthesia, analgesia, or amnesia for the pains, there was also the hypnotic reduction of their subjective temporal duration which, in itself, would serve to diminish greatly the pain experience for the patient.

When these matters had been made clear to him, he was urged most insistently to employ all of the mechanisms that had been suggested—alteration of body sensations, body disorientation, dissociation, anesthesia, analgesia, amnesia, and subjective time condensation. In this way, it was argued, he could quite conceivably free himself from pain more readily than by employing a single psychological process. In addition, the suggestion was also offered emphatically that he employ subjective time expansion to lengthen experientially all periods of physical comfort, rest, or freedom from pain.

By this variety of differently directed suggestions, repetitiously given and in different phrasings to ensure adequate comprehension and acceptance, the patient's sharp recurring pains were abolished in large part insofar as observation of his objective behavior and his own subjective reports were concerned. However, it was noted that periodically he would lapse into a brief unresponsive stupor-like state of 10 to 50 seconds' duration, an item of behavior suggestive of a massive obscuring reaction to pain. It was noted that these were less frequent and shorter in duration than the original sharp pains had been. It was also observed that the patient appeared to have no realization whatsoever of his periodic lapses of awareness.

No systematic inquiry could be conducted into the actual efficacy of the suggestions. The patient simply reported that hypnosis had freed him almost completely of his pains, that he felt heavy, weak, and dull physically, and that not over twice a day did any pain "break through."

His general behavior with his family and friends validated his report. Some weeks after the beginning of hypnotic therapy the patient lapsed suddenly into coma and died without recovering consciousness.

SUMMARY AND GENERAL COMMENTS

A presentation has been offered of the utilization of hypnosis in terminal painful disease. Three case reports, not entirely typical, have been presented in order to illustrate more adequately the actual possibilities of therapeutic benefits.

An effort has been made to describe the therapeutic methodologies employed, but this effort is not fully possible. Hypnotherapeutic benefits, especially in such cases as reported here, are markedly contingent upon a varied and repetitious presentation of ideas and understandings to ensure an adequate acceptance and responsiveness by the patient. Also, the very nature of the situation precludes a determination of what elements in the therapeutic procedure are effective in the individual case.

These three case reports indicate definitely that hypnosis can be of value in treating painful terminal illness. However, it is not to be regarded as an absolute answer to all the medical problems involved. Rather it is .one of the possible approaches in the handling of the patient's problems that possesses special and highly significant values at both psychological and physiological levels.

While hypnosis can sometimes be used alone as a means of pain control in carcinomatous disease, more often it is properly used as an adjuvant. In that capacity it can serve to diminish significantly the actual drug dosage and to effect a much greater relief both mentally and physically. In all probability the more comprehensive psychologically the hypnotic approach, the greater is the possibility of therapeutic results.

Interspersal Hypnotic Technique for Symptom Correction and Pain Control

Milton H. Erickson

Reprinted with permission from The American Journal of Clinical Hypnosis, January, 1966, 8, 198-209.

Innumerable times this author has been asked to commit to print in detail the hypnotic technique he has employed to alleviate intolerable pain or to correct various other problems. The verbal replies made to these many requests have never seemed to be adequate since they were invariably prefaced by the earnest assertion that the technique in itself serves no other purpose than that of securing and fixating the attention of patients, creating then a receptive and responsive mental state, and thereby enabling them to benefit from unrealized or only partially realized potentials for behavior of various types. With this achieved by the hypnotic technique, there is then the opportunity to proffer suggestions and instructions serving to aid and to direct patients in achieving the desired goal or goals. In other words, the hypnotic technique serves only to induce a favorable setting in which to instruct patients in a more advantageous use of their own potentials of behavior.

Since the hypnotic technique is primarily a means to an end, while therapy derives from the guidance of the patient's behavioral capacities, it follows that, within limits, the same hypnotic technique can be utilized for patients with widely diverse problems. To illustrate, two instances will be cited in which the same technique was employed, once for a patient with a distressing neurotic problem and once for a patient suffering from intolerable pain from terminal malignant disease. The technique is one that the author has employed on the illiterate subject and upon the college graduate, in experimental situations and for clinical purposes. Often it has been used to secure, to fixate, and to hold the attention of difficult patients and to distract them from creating difficulties that would impede therapy. It is a technique employing ideas that are clear and comprehensible, but which by their patent irrelevance to the patient-physician relationship and situation distract the patient. Thereby the patients are prevented from intruding unhelpfully into a situation which they cannot understand and for which they are seeking help. At the same time a readiness to understand and to respond is created within the patient.

Thus, a favorable setting is evolved for the elicitation of needful and helpful behavioral potentialities not previously used, not fully used, or perhaps misused by the patient.

The first instance to be cited will be given without any account of the hypnotic technique employed. Instead, there will be given the helpful instructions, suggestions, and guiding ideas which enabled the patient to achieve his therapeutic goal and which were interspersed among the ideas constituting the hypnotic technique. These therapeutic ideas will not be cited as repetitiously as they were verbalized to the patient for the reason that

they are more easily comprehended in cold print than when uttered as a part of a stream of utterances. Yet, these few repeated suggestions in the hypnotic situation served to meet the patient's, needs adequately.

The patient was a 62-year-old retired farmer with only an eighth-grade education, but decidedly intelligent and well read. He actually possessed a delightful, charming, outgoing personality, but he was most unhappy, filled with resentment, bitterness, hostility, suspicion, and despair. Approximately two years previously, for some unknown or forgotten reason (regarded by the author as unimportant and as having no bearing upon the problem of therapy), he had developed a urinary frequency that was most distressing to him. Approximately every half-hour he felt a compelling urge to urinate, an urge that was painful, that he could not control, and that would result in a wetting of his trousers if he did not yield to it. This urge was constantly present day and night. It interfered with his sleep, his eating, and his social adjustments, and compelled him to keep within close reach of a lavatory and to carry a briefcase containing several pairs of trousers for use when he was "caught short." He explained that he had brought, into the office a briefcase containing three pairs of trousers, and he stated that he had visited a lavatory before leaving for the author's office, another on the way, and that he had visited the office lavatory before entering the office, and that he expected to interrupt the interview with the author by at least one other such visit.

He related that he had consulted more than 100 physicians and well-known clinics. He had been cystoscoped more than 40 times, had had innumerable X-ray pictures taken and countless tests, some of which were electroencephalograms and electrocardiograms. Always he was assured that his bladder was normal; many times he was offered the suggestion to return after a month or two for further study; and "too many times" he was told that "it's all in your head," that he had no problem at all, that he "should get busy doing something instead of being retired, and to stop pestering doctors and being an old crock." All of this had made him feel like committing suicide.

He had described his problem to a number of writers of syndicated medical columns in newspapers, several of whom offered him in his stamped self-addressed envelope a pontifical platitudinous dissertation innovative upon his problem, stressing it as one of obscure organic origin. In all of his searching not once had it been suggested that he seek psychiatric aid.

On his own initiative, after reading two of the misleading, misinforming, and essentially fraudulent books on "do-it-yourself hypnosis," he did seek the aid of stage hypnotists—in all, three in number. Each offered him the usual blandishments, reassurances, and promises common to that type of shady medical practice, and each failed completely in repeated attempts at inducing a hypnotic trance. Each charged an exorbitant fee (as judged by a standard medical fee, and especially in relation to the lack of benefit received).

As a result of all this mistreatment, the medical no better than that of the charlatans and actually less forgivable, he had become bitter, disillusioned, resentful, and openly hostile,

and he was seriously considering suicide. A gas station attendant suggested that he see a psychiatrist and recommended the author on the basis of a Sunday newspaper article. This accounted for his visit to the author.

Having completed his narrative, he leaned back in his chair, folded his arms, and challengingly said, "Now psychiatrize and hypnotize me and cure this—bladder of mine."

During the narration of the patient's story the author had listened with every appearance of rapt attention except for a minor idling with his hands, thereby shifting the position of objects on his desk. This idling included a turning of the face of the desk clock away from the patient. As he listened to the patient's bitter account of his experiences, the author was busy speculating upon possible therapeutic approaches to a patient so obviously unhappy, so resentful toward medical care and physicians, and so challenging in attitude. He certainly did not appear to be likely to be receptive and responsive to anything the author might do or say. As the author puzzled over this problem, there came to mind the problem of pain control for a patient suffering greatly in a terminal state of malignant disease. That patient had constituted a comparable instance where a hypnotherapeutic approach had been most difficult, yet success had been achieved. Both patients had in common the experience of growing plants for a livelihood, both were hostile and resentful, and both were contemptuous of hypnosis. Hence, when the patient issued his challenge of "psychiatrize and hypnotize me," the author, with no further ado, launched into the same technique employed with that other patient to achieve a hypnotherapeutic state in which helpful suggestions, instructions, and directions could be offered with reasonable expectation that they would be accepted and acted upon responsively in accord with the patient's actual needs and behavioral potentials. .

The only difference for the two patients was that the interwoven therapeutic material for the one patient pertained to bladder function and duration of time. For the other patient the interwoven therapeutic instructions pertained to body comfort, to sleep, to appetite, to the enjoyment of the family, to an absence of any need for medication, and to the continued enjoyment of time without concern about the morrow.

The actual verbal therapy offered, interspersed as it was in the ideation of the technique itself, was as follows, with the interspersing denoted by dots.

> You know, we could think of your bladder needing emptying every 15 minutes instead of every half . . . . hour . . . . Not difficult to think that . . . . A watch can run slow . . . . or fast . . . . be wrong even a minute . . . . even two, five minutes . . . . or think of bladder every half hour . . . . like you've been doing . . . . maybe it was 35, 40 minutes sometimes . . . . like to make it an hour . . . . what's the difference . . . . 35, 36 minutes, 41, 42, 45 minutes . . . . not much difference . . . . not important difference . . . . 45, 46, 47 minutes . . . . all the same . . . . lots of times you maybe had to wait a second or two . . . . felt like an hour or two . . . . you made it . . . . you can again . . . . 47 minutes, 50 minutes, what's the difference . . . . stop to think, no great difference, nothing important . . . . just like

> 50 minutes, 60 minutes, just minutes . . . . anybody that can wait half an hour can wait an hour . . . . I know it . . . . you are learning . . . . not bad to learn . . . . in fact, good . . . . come to think of it, you have had to wait when somebody got there ahead of you . . . . you made it too . . . . can again . . . . and again . . . . all you want to . . . . hour and 5 minutes . . . . hour and 5½ minutes . . . . what's the difference . . . . or even 6½ minutes . . . . make it 10½ hour and 10½ minutes . . . . one minute, 2 minutes, one hour, 2 hours, what's the difference . . . . you got half a century or better of practice in waiting behind you . . . . you can use all that . . . . why not use it . . . . you can do it . . . . probably surprise you a lot . . . . won't even think of it . . . . why not surprise yourself at home . . . . good idea . . . . nothing better than a surprise . . . . an unexpected surprise . . . . how long can you hold out . . . . that's the surprise . . . . longer than you even thought . . . . lots longer . . . . might as well begin . . . . nice feeling to begin . . . . to keep on . . . . Say, why don't you just forget what I've been talking about and just keep it in the back of your mind. Good place for it—can't lose it. Never mind the tomato plant—just what was important about your bladder—pretty good, feel fine, nice surprise—say, why don't you start feeling rested, refreshed right now, wider awake than you were earlier this morning [this last statement is, to the patient, an indirect, emphatic, definitive instruction to arouse from his trance]. Then [as a dismissal but not consciously recognizable as such by the patient], why don't you take a nice leisurely walk home, thinking about nothing? [an amnesia instruction for both the trance and his problem, and also a confusion measure to obscure the fact that he had already spent 1½ hours in the office]. I'll be able to see you at ten A.M. a week from today [furthering his conscious illusion, resulting from his amnesia, that nothing yet had been done except to give him an appointment].

A week later he appeared and launched into an excited account of arriving home and turning on the television with an immediate firm intention of delaying urination as long as possible. He watched a two-hour movie and drank two glasses of water during the commercials. He decided to extend the time another hour and suddenly discovered that he had so much bladder distension that he had to visit the lavatory. He looked at his watch and discovered that he had waited four hours. The patient leaned back in his chair and beamed happily at the author, obviously expecting praise. Almost immediately he leaned forward with a startled look and declared in amazement, "It all comes back to me now. I never give it a thought till just now. I plumb forgot the whole thing. Say, you must have hypnotized me. You were doing a lot of talking about growing a tomato plant and I was trying to get the point of it and the next thing I knew I was walking home. Come to think of it I must of been in your office over an hour and it took an hour to walk home. It wasn't no four hours I held back, it was over six hours at least. Come to think of it, that ain't all. That was a week ago that happened. Now I recollect I ain't had a bit of trouble all week—slept fine—no getting up. Funny how a man can get up in the morning, his mind all set on keeping an appointment to tell something, and forget a whole week has went by. Say, when I told you to psychiatrize and hypnotize me, you sure took it serious. I'm right grateful to you. How much do I owe you?"

Essentially, the case was completed, and the remainder of the hour was spent in social small talk with a view of detecting any possible doubts or uncertainties in the patient. There were none, nor, in the months that have passed, have there occurred any.

The above case report allows the reader to understand in part how, during a technique of suggestions for trance induction and trance maintenance, hypnotherapeutic suggestions can be interspersed for a specific goal. In the author's experience such an interspersing of therapeutic suggestions among the suggestions for trance maintenance may often render the therapeutic suggestions much more effective. The patients hear them and understand them, but before they can take issue with them or question them in any way, their attention is captured by the trance-maintenance suggestions. And these in turn are but a continuance of the trance-induction suggestions. Thus, there is given to the therapeutic suggestion an aura of significance and effectiveness deriving from the already effective induction and maintenance suggestions. Then again the same therapeutic suggestions can be repeated in this interspersed fashion, perhaps repeated many times, until the therapist feels confident that the patient has absorbed the therapeutic suggestions adequately. Then the therapist can progress to another aspect of therapy using the same interspersal technique.

The above report does not indicate the number of repetitions for each of the therapeutic suggestions for the reason that the number must vary with each set of ideas and understandings conveyed and with each patient and each therapeutic problem. Additionally, such interspersal of suggestions for amnesia and posthypnotic suggestions among the suggestions for trance maintenance can be done most effectively. To illustrate from everyday life: A double task assignment is usually more effective than the separate assignment of the same two tasks. For example, a mother may say, "Johnny, as you put away your bicycle, just step over and close the garage door." This has the sound of a single task, one aspect of which favors the execution of another aspect, and thus there is the effect of making the task seem easier. To ask that the bicycle be put away and then to ask that the garage door be closed has every sound of being two separate, not to be combined, tasks. To the separate tasks a refusal can be given easily to one or the other task or to both. But a refusal when the tasks are combined into a single task means what? That he will not put away the bicycle? That he will not step over to the garage? That he will not close the garage door?

The very extent of the effort needed to identify what one is refusing in itself is a deterrent to refusal. Nor can a refusal of the "whole thing" be offered comfortably. Hence Johnny may perform the combined task unwillingly but may prefer to do so rather than to analyze the situation. To the single tasks he can easily say "later" to each. But to the combined task he cannot say "Later" since, if he puts away the bicycle "later," he must "immediately" step over to the garage and "immediately" close the door. This is specious reasoning, but it is the "emotional reasoning" that is common in daily life, and daily living is not an exercise in logic. As a common practice the author says to a patient, "As you sit down in the chair, just go into a trance." The patient is surely going to sit down in the chair. But going into a trance is made contingent upon sitting down, hence a trance state develops from what the patient was most certainly going to do. By combining

psychotherapeutic, amnestic, and posthypnotic suggestions with those suggestions used first to induce a trance, and then to maintain that trance, constitutes an effective measure in securing desired results. Contingency values are decidedly effective. As a further illustration, more than once a patient who has developed a trance upon simply sitting down has said to the author, "I didn't intend to go into a trance today." In reply the author has stated, "Then perhaps you would like to awaken from the trance and hence, *as you understand that* you can go back into a trance when you need to, *you will awaken*. " Thus the "awakening" is made contingent upon "understanding," thereby ensuring further trances through association by contingency.

With this explanation of rationale the problem of the second patient will be presented after a few preliminary statements. These are that the author was reared on a farm, enjoyed and still enjoys growing plants, and has read with interest about the processes of seed germination and plant growth. The first patient was a retired farmer. The second, who will be called "Joe" for convenience, was a florist. He began his career as a boy by peddling flowers, saving his pennies, buying more flowers to peddle, etc. Soon he was able to buy a small parcel of land on which to grow more flowers with loving care while he enjoyed their beauty which he wanted to share with others, and in turn, to get more land and to grow more flowers, etc. Eventually he became the leading florist in a large city. Joe literally loved every aspect of his business and was intensely devoted to it but he was also a good husband, a good father, a good friend, and a highly respected and valued member of the community.

Then one fateful September a surgeon removed a growth from the side of Joe's face, being careful not to disfigure Joe's face too much. The pathologist reported the growth to be a malignancy. Radical therapy was then instituted, but it was promptly recognized as "too late."

Joe was informed that he had about a month left to live. Joe's reaction was, to say the least, unhappy and distressed. In addition he was experiencing much pain—in fact, extremely severe pain. .

At the end of the second week in October a relative of Joe's urgently requested the author to employ hypnosis on Joe for pain relief since narcotics were proving of little value. In view of the prognosis that had been given for Joe the author agreed reluctantly to see him, stipulating that all medication be discontinued at 4:00 A.M. of the day of the author's arrival. To this the physicians in charge of Joe at the hospital courteously agreed.

Shortly before the author was introduced to Joe, he was informed that Joe disliked even the mention of the word hypnosis. Also, one of Joe's children, a resident in psychiatry at a well-known clinic, did not believe in hypnosis and had apparently been confirmed in this disbelief by the psychiatric staff of the clinic, none of whom is known to have had any firsthand knowledge of hypnosis. This resident would be present, and the inference was that Joe knew of that disbelief.

The author was introduced to Joe, who acknowledged the introduction in a most courteous and friendly fashion. It is doubtful if Joe really knew why the author was there. Upon inspecting Joe, it was noted that much of the side of his face and neck was missing because of surgery, ulceration, maceration, and necrosis. A tracheotomy had been performed on Joe, and he could not talk. He communicated by pencil and paper, many pads of which were ready at hand. The information was given that every four hours Joe had been receiving narcotics (¼ grain of morphine or 100 milligrams of Demerol) and heavy sedation with barbiturates. He slept little. Special nurses were constantly at hand. Yet Joe was constantly hopping out of bed, writing innumerable notes, some pertaining to his business, some to his family, but many of them were expressive of complaints and demands for additional help. Severe pain distressed him continuously, and he could not understand why the doctors could not handle their business as efficiently and as competently as he did his floral business. His situation enraged him because it constituted failure in his eyes. Success worked for and fully merited had always been a governing principle in his life. When things went wrong with his business, he made certain to correct them. Why did not the doctors do the same? The doctors had medicine for pain, so why was he allowed to suffer such intolerable pain?

After the introduction Joe wrote, "What you want?" This constituted an excellent opening, and the author began his technique of trance induction and pain relief. This will not be given in its entirety since a large percentage of the statements made were repeated, not necessarily in succession but frequently by referring back to a previous remark and then repeating a paragraph or two. Another preliminary statement needed is that the author was most dubious about achieving any kind of success with Joe since, in addition to his physical condition, there were definite evidences of toxic reactions to excessive medication. Despite the author's unfavorable view of possibilities there was one thing of which he could be confident. He could keep his doubts to himself and he could let Joe know by manner, tone of voice, by everything said that the author was genuinely interested in him, was genuinely desirous of helping him. If even that little could be communicated to Joe, it should be of some comfort, however small, to Joe and to the family members and to the nurses within listening distance in the side room.

The author began:

> Joe, I would like to talk to you. I know you are a florist, that you grow flowers, and I grew up on a farm in Wisconsin and I liked growing flowers. I still do. So I would like to have you take a seat in that easy chair as I talk to you. I'm going to say a lot of things to you, but it won't be about flowers because you know more than I do about flowers. That isn't what you want. [The reader will note that italics will be used to denote interspersed hypnotic suggestions which may be syllables, words, phrases, or sentences uttered with a slightly different intonation.; Now as I talk, and I can do so *comfortably*, I wish that you will *listen to me comfortably* as I talk about a tomato plant. That is an odd thing to talk about. It makes one *curious*. *Why talk about a tomato plant*? One puts a tomato seed in the ground. One can *feel hope* that it will grow into a tomato plant that *will bring satisfaction* by the fruit it has. The seed soaks up water, *not very much difficulty* in

doing that because of the rains that *bring peace and comfort* and the joy of growing to flowers and tomatoes. That little seed, Joe, slowly swells, sends out a little rootlet with cilia on it. Now you may not know what cilia are, but cilia are *things that work* to help the tomato seed grow, to push up above the ground as a sprouting plant, and *you can listen to me*, Joe, so I will keep on talking and *you can keep on listening, wondering, just wondering what you can really learn*, and here is your pencil and your pad, but speaking of the tomato plant, it grows so slowly. *You cannot see* it grow, *you cannot hear* it grow, but grow it does—the first little leaf-like things on the stalk, the fine little hairs on the stem, those hairs are on the leaves, too, like the cilia on the roots, they must make the tomato plant *feel very good, very comfortable* if you can think of a plant as feeling, and then *you can't see* it growing, *you can't feel* it growing, but another leaf appears on that little tomato stalk and then another. Maybe, and this is talking like a child, maybe the tomato plant does feel comfortable and peaceful as it grows. Each day it grows and grows and grows, *it's so comfortable*, *Joe*, to watch a plant grow and *not see* its growth, not feel it, but just know that *all is getting better* for that little tomato plant that is adding yet another leaf and still another and a branch, and it is *growing comfortably* in all directions. [Much of the above by this time had been repeated many times, sometimes just phrases, sometimes sentences. Care was taken to vary the wording and also to repeat the hypnotic suggestions. Quite some time after the author had begun, Joe's wife came tiptoeing into the room carrying a sheet of paper on which was written the question, "When are you going to start the hypnosis?" The author failed to cooperate with her by looking at the paper and it was necessary for her to thrust the sheet of paper in front of the author and therefore in front of Joe. The author was continuing his description of the tomato plant uninterruptedly, and Joe's wife, as she looked at Joe, saw that he was not seeing her, did not know that she was there, that he was in a somnambulistic trance. She withdrew at once.] And soon the tomato plant will have a bud form somewhere, on one branch or another, but it makes no difference because all the branches, the whole tomato plant will soon have those nice little buds—I wonder if the tomato plant can, *Joe, feel really feel a kind of comfort*. You know, Joe, a plant is a wonderful thing, and *it is so nice*, so pleasing just to be able to think about a plant as if it were a man. Would such a plant *have nice feelings, a sense of comfort* as the tiny little tomatoes begin to form, so tiny, yet so *full of promise to give you the desire to eat* a luscious tomato, sun-ripened, it's so *nice to have food in one's stomach*, that wonderful feeling a child, a thirsty child, has and can *want a drink*, *Joe*, is that the way the tomato plant feels when the rain falls and washes everything so that *all feels well*. [Pause.] *You know, Joe*, a tomato plant just flourishes each day *just a day at a time*. I like to think the tomato plant can *know the fullness of comfort each day. You know, Joe, just one day at a time* for the tomato plant. That's the way for all tomato plants. [Joe suddenly came out of the trance, appeared disoriented, hopped upon the bed, and waved his arms; his behavior was highly suggestive of the sudden surges of toxicity one sees in patients who have reacted unfavorably to barbiturates. Joe did not seem to hear or see the author until he hopped off the bed and walked toward the author. A firm grip was taken on Joe's arm and then immediately loosened. The nurse was

summoned. She mopped perspiration from his forehead, changed his surgical dressings, and gave him, by tube, some ice water. Joe then let the author lead him back to his chair. After a pretense by the author of being curious about Joe's forearm, Joe seized his pencil and paper and wrote, "Talk, talk."] "Oh yes, Joe, I grew up on a farm, I think a tomato seed is a wonderful thing; *think, Joe, think* in that little seed there does *sleep so restfully, so comfortably* a beautiful plant yet to be grown that will bear such interesting leaves and branches. The leaves, the branches look so beautiful, that beautiful rich color, *you can really feel happy* looking at a tomato seed, thinking about the wonderful plant it contains *asleep, resting, comfortable, Joe*. I'm soon going to leave for lunch and I'll be back and I will talk some more."

The above is a summary to indicate the ease with which hypnotherapeutic suggestions can be included in the trance induction along with trance-maintenance suggestions, which are important additionally as a vehicle for the transmission of therapy. Of particular significance is Joe's own request that the author "talk." Despite his toxic state, spasmodically evident, Joe was definitely accessible. Moreover, he learned rapidly despite the absurdly amateurish rhapsody the author offered about a tomato seed and plant. Joe had no real interest in pointless, endless remarks about a tomato plant. Joe wanted freedom from pain, he wanted comfort, rest, sleep. This was what was uppermost in Joe's mind, foremost in his emotional desires, and he would have a compelling need to try to find something of value to him in the author's babbling. That desired value was there, so spoken that Joe could literally receive it without realizing it. Joe's arousal from the trance was only some minutes after the author had said so seemingly innocuously, "want a drink, Joe." Nor was the reinduction of the trance difficult, achieved by two brief phrases, "think, Joe, think" and "sleep so restfully, so comfortably" imbedded in a rather meaningless sequence of ideas. But what Joe wanted and needed was in that otherwise meaningless narration, and he promptly accepted it.

During lunchtime Joe was first restful and then slowly became restless; another toxic episode occurred, as reported by the nurse. By the time the author returned Joe was waiting impatiently for him. Joe wanted to communicate by writing notes. Some were illegible because of his extreme impatience in writing. He would irritatedly rewrite them. A relative helped the author to read these notes. They concerned things about Joe, his past history, his business, his family, and "last week terrible," "yesterday was terrible." There were no complaints, no demands, but there were some requests for information about the author. After a fashion a satisfying conversation was had with him as was judged by an increasing loss of his restlessness. When it was suggested that he cease walking around and sit in the chair used earlier, he did so readily and looked expectantly at the author.

"*You know, Joe, I could talk to you some more about the tomato plant and if I did you would probably go to sleep*, in fact, *a good sound sleep*. [This opening statement has every earmark of being no more than a casual commonplace utterance. If the patient responds hypnotically, as Joe promptly did, all is well. If the patient does not respond, all you have said was just a commonplace remark, not at all noteworthy. Had Joe not gone

into a trance immediately, there could have been a variation such as: “But instead, let’s talk about the tomato flower. You have seen movies of flowers *slowly, slowly* opening, giving one *a sense of peace*, *a sense of comfort* as you watch the unfolding. So beautiful, *so restful* to watch. One can *feel such infinite comfort* watching such a movie.”]

It does not seem to the author that more needs to be said about the technique of trance induction and maintenance and the interspersal of therapeutic suggestions. Another illustration will be given later in this paper.

Joe’s response that afternoon was excellent despite several intervening episodes of toxic behavior and several periods where the author deliberately interrupted his work to judge more adequately the degree and amount of Joe’s learning.

Upon departure that evening, the author was cordially shaken by hand by Joe, whose toxic state was much lessened. Joe had no complaints, he did not seem to have distressing pain, and he seemed to be pleased and happy.

Relatives were concerned about posthypnotic suggestions, but they were reassured that such had been given. This had been done most gently in describing so much in detail and repetition the growth of the tomato plant and then, with careful emphasis, “*You know Joe,” “Know the fullness of comfort each day,*” and “*You know, Joe, just one day at a time*.”

About a month later, around the middle of November, the author was requested to see Joe again. Upon arriving at Joe’s home, he was told a rather regrettable but not actually unhappy story. Joe had continued his excellent response after the author’s departure on that first occasion, but hospital gossip had spread the story of Joe’s hypnosis, and interns, residents, and staff men came in to take advantage of Joe’s capacity to be a good subject. They made all the errors possible for uninformed amateurs with superstitious misconceptions of hypnosis. Their behavior infuriated Joe, who knew that the author had done none of the offensive things they were doing. This was a fortunate realization since it permitted Joe to keep all the benefits acquired from the author without letting his hostilities toward hypnosis interfere. After several days of annoyance Joe left the hospital and went home, keeping one nurse in constant attendance, but her duties were relatively few.

During that month at home he had actually gained weight and strength. Rarely did a surge of pain occur, and when it did it could be controlled either with aspirin or with 25 milligrams of Demerol. Joe was very happy to be with his family, and there was considerable fruitful activity about which the author is not fully informed.

Joe’s greeting to the author on the second visit was one of obvious pleasure. However, the author noted that Joe was keeping a wary eye on him, hence great care was taken to be completely casual and to avoid any hand movement that could be remotely misconstrued as a “hypnotic pass” such as the hospital staff had employed.

Framed pictures painted by a highly talented member of his family were proudly displayed. There was much casual conversation about Joe's improvement and his weight gain, and the author was repeatedly hard pushed to find simple replies to conceal pertinent suggestions. Joe did volunteer to sit down and let the author talk to him. Although the author was wholly casual in manner, the situation was thought to be most difficult to handle without arousing Joe's suspicions. Perhaps this was an unfounded concern, but the author wished to be most careful. Finally the measure was employed of reminiscing about "our visit last October." Joe did not realize how easily this visit could be pleasantly vivified for him by such a simple statement as, "I talked about a tomato plant then, and it almost seems as if I could be *talking about a tomato plant right now. It is so enjoyable to talk about a seed, a plant*. " Thus there was, clinically speaking, a re-creation of all of the favorable aspects of that original interview.

Joe was most insistent on supervising the author's luncheon that day, which was a steak barbecued under Joe's watchful eye in the backyard beside the swimming pool. It was a happy gathering of four people thoroughly enjoying being together, Joe being obviously most happy.

After luncheon Joe proudly displayed the innumerable plants, many of them rare, that he had personally planted in the large backyard. Joe's wife furnished the Latin and common names for the plants, and Joe was particularly pleased when the author recognized and commented on some rare plant. Nor was this a pretense of interest, since the author is still interested in growing plants. Joe regarded this interest in common to be a bond of friendship.

During the afternoon Joe sat down voluntarily, his very manner making evident that the author was free to do whatever he wished. A long monologue by the author ensued in which were included psychotherapeutic suggestions of continued ease, comfort, freedom from pain, enjoyment of family, good appetite, and a continuing pleased interest in all surroundings. All of these and other similar suggestions were interspersed unnoticeably among the author's many remarks. These covered a multitude of topics to preclude Joe from analyzing or recognizing the interspersing of suggestions. Also, for adequate disguise, the author needed a variety of topics. Whether or not such care was needed in view of the good rapport is a debatable question, but the author preferred to take no risks.

Medically, the malignancy was continuing to progress, but despite this fact Joe was in much better physical condition than he had been a month previously. When the author took his departure, Joe invited him to return again.

Joe knew that the author was going on a lecture trip in late November and early December. Quite unexpected by the author, a long distance telephone call was received just before the author's departure on this trip. The call was from Joe's wife, who stated, "Joe is on the extension line and wants to say `hello' to you, so listen." Two brief puffs of air were heard. Joe had held the telephone mouthpiece over his tracheotomy tube and had exhaled forcibly twice to simulate "hello." His wife stated that both she and Joe extended

their best wishes for the trip, and a casual conversation among friends ensued with Joe's wife reading Joe's written notes.

A Christmas greeting card was received from Joe and his family. In a separate letter Joe's wife said that "the hypnosis is doing well, but Joe's condition is failing." Early in January Joe was weak but comfortable. Finally, in his wife's words, "Joe died quietly January 21."

The author is well aware that the prediction of the duration of life for any patient suffering from a fatal illness is most questionable. Joe's physical condition in October did not promise very much. The symptom amelioration, abatement, and actual abolishment effected by hypnosis, and the freedom of Joe's body from potent medications, conducive only of unawareness, unquestionably increased his span of life while at the same time permitting an actual brief physical betterment in general. This was attested clearly by his improved condition at home and his gain in weight. That Joe lived until the latter part of January despite the extensiveness of his malignant disease undoubtedly attests to the vigor with which Joe undertook to live the remainder of his life as enjoyably as possible, a vigor expressive of the manner in which he had lived his life and built his business.

To clarify still further this matter of the technique of the interspersal of therapeutic suggestions among trance induction and trance maintenance suggestions, it might be well to report the author's original experimental work done while he was on the Research Service of the Worcester State Hospital in Worcester, Massachusetts in the early 1930s.

The Research Service was concerned with the study of the numerous problems of schizophrenia and the possibilities of solving some of them. To the author the psychological manifestations were of paramount interest. For example, just what did a stream of disconnected, rapidly uttered incoherencies mean? Certainly, such a stream of utterances must be most meaningful to the patient in some way. Competent secretaries from time to time had recorded verbatim various examples of such disturbed utterances for the author's perusal and study. The author himself managed to record adequately similar such productions by patients who spoke slowly. Careful study of these verbal productions, it was thought, might lead to various speculative ideas that in turn might prove of value in understanding something about schizophrenia.

The question arose of whether or not much of the verbigeration might be a disguise for concealed meanings, fragmented and dispersed among the total utterances. This led to the question of how the author could himself produce a series of incoherencies in which he could conceal in a fragmented form a meaningful message. Or could he use the incoherencies of a patient and intersperse among them in a somewhat orderly fashion a fragmented, meaningful communication that would be difficult to recognize? This speculation gave rise to many hours of intense labor spent fitting into a patient's verbatim, apparently meaningless utterances a meaningful message that could not be detected by the author's colleagues when no clue of any sort was given to them. Previous efforts at producing original incoherencies by the author disclosed a definite and

recognizable personal pattern indicating that the author was not sufficiently disturbed mentally to produce a bonafide stream of incoherent verbigerations.

When a meaning was interspersed in a patient's productions successfully, the author discovered that his past hypnotic experimentation with hypnotic techniques greatly influenced the kind of a message he was likely to intersperse in a patient's verbigerations. Out of this labor came the following experimental and therapeutic work.
