Brief, scattered bits of information disclosed that each was an only child, highly protected by rigid, domineering parents, and that each was completely dependent on their parents for everything including even their opinions in general. They were genuinely in love and were expecting to be married with parental blessings upon being graduated from college. Among the planned wedding presents were a secure position in the firm of the father-in-law-to-be for the young man and a beautiful home from the young man's parents. Now all of this, their entire planned and desired future, was at stake unless they abided by parental commands and secured the abortion.

Two full hours of desperate endeavor failed to make the slightest impression upon their insistent, hysterical, highly obsessional, repetitional demands.

Finally the senior author decided to capitalize upon the obsessional fearful behavior they were both constantly manifesting by using that very behavior itself. As everybody knows, it is impossible to hold a stop watch to time oneself and to avoid thinking about an elephant for one whole minute. This simple, childish challenge seemed to present a method of dealing affectively with the problem they presented.

Accordingly, the author emphatically demanded, All right, all right, quiet now, quiet - if you want the help you ask. Quiet, and let me tell you how to ensure getting the abortion you are desperately trying to prove to me that you want. You have told me you want the abortion. You have told me that there is no other choice. You have told me that, regardless of everything, you are going to go ahead with the abortion. You declare most emphatically and resolutely that nothing can stop you. *Now let me warn you about one thing that can stop you, that will surely stop you, against which you will be totally helpless if you are not warned about it in advance. Quiet now! Listen attentively because you need to know this if you really want the abortion, if you really intend to get the abortion.*Now listen quietly and attentively. Are you listening?

Both nodded their heads silently, expectantly. The senior author continued, You do not know an important thing, a vitally important thing. That essential information is this: You do not know whether that baby is a boy or a girl. You do not see, cannot see, the vital connection between that question and the abortion you have told me that you want. *Yet that question will prevent you from getting the abortion since you don't know the answer.* Your personalities, your psychological makeups make that question important. You do not know why, but who expects you to know? Let me explain! If that baby were going to be kept by you, you, not knowing if it were a boy or a girl, would have to think of a name for it that would fit either sex, such as Pat, which could be either Patrick or Patricia, or Frances for a girl or Francis for a boy. *Now that is the very thing you must avoid at all costs.* Under no circumstances, not even once, *after you leave this office,* are you to think of a possible name for that baby, a name that would fit either sex. *To do so and to keep on doing so would compel you psychologically to keep the baby,* not to get an abortion. Hence, under no circumstances are you to dare to think of a name for that baby. Please, please

don't, because then you won't get an abortion. Every time you think of a name, that thinking will definitely deter you from getting an abortion. You will be forced into taking the money you have and seeing a justice of the peace and getting married. You want an abortion, and you can't have it if you think of a name, so don't, just don't, don't don't think of a name, any name for the baby *after you leave this office, because if you do you will keep it, so don't don't don't think of a name, any name.* Now without another word, *not one word, not a single word, especially not a baby's name,* leave this office at once." Thereupon the senior author took them by hand and led them quickly to the door to hasten their departure.

Several days later they returned smiling in an abashed fashion, stating, After we got married - *because we just couldn't help thinking of dozens of names, and every name made the baby more precious to us* - we realized that all you did was bring us to our senses before we did something awful foolish and awful wrong. We had just lost our heads, and our parents didn't help either - that's why we acted like such awful fools in your office.

Inquiry disclosed that both sets of parents accepted the elopement instead of an abortion with a profound sense of relief. The original plans for setting up the young couple were carried out when the husband was graduated.

The young mother had to delay her graduation for some time. Then the grandmothers alternately babysat so that the young mother could complete her college work. At the present time little Leslie has several young siblings.

From the very beginning of the interview with this distraught couple the extreme obsessional character of their behavior, thought, and emotions was most marked. They seemed, as persons, to be sound, yet caught in a situation they could not handle. Hypnosis was obviously not a suitable procedure, but it was realized, as observation of them continued, that hypnotic technique of suggestion, seemingly worded to favor undesirable results, could effect positive results and that a specious psychological contingency could be so emphatically suggested to them that their own hysterical, obsessional behavior would make it effective in securing a desirable end result. The presentation of the problem so emphatically of not thinking of a name befitting either sex *outside of the office* and only incidentally mentioning marriage by a justice of the peace, without actually suggesting that they resort to it, precluded any tendency for them to rebel because they had been told what to do. This created a favorable climate for their voluntary marriage by a justice of the peace, since they were not recognizably so instructed. Fundamental to this evolution of results was their own sense of guilt, their own desire for marriage, their need to do something, the unexpressed, unrecognized anger at their hitherto loving, permissive parents, their outraged feelings at the rage and demands that they obey their parents' commands, and the suggestion of the friend that they seek tranquilization. All this resulted in a disturbed emotional state that left them in an essentially irrational state. The author then simply, deliberately, *utilized* their own state of irrational thinking to effect a favorable outcome by the use of a hypnotic technique of the presentation of ideas in a fashion conducive to acceptance despite their overwrought emotional state. Additionally, that technique of suggestion subtly transformed the problem from we must get an abortion to we must not think of a name for the baby. This could only be a losing battle, and the very desperateness of their efforts not to think of a suitable name could only serve to bring them closer and closer to marriage, as indeed it did.

The use of *negativity*(they must *not* think of a baby's name) is of decisive significance in this case. Since their whole situation was permeated with negativity (their parents would *not* help them, they could *not* finish college, *not*have a baby, *not* get married, etc.), the senior author was utilizing a dominant mental set by phrasing his suggestion in a negative form. Since negativity was the dominant mental set, it was the most effective one to achieve the desired results.

Utilizing the patient's own patterns of obsessional thinking and affect; Questions initiating unconscious searches and processes; Negative suggestion; Posthypnotic suggestion tied to behavioral inevitabilities.

CHAPTER 9

Case 12 Facilitating Potentials: Transforming Identity

Utilizing Spontaneous Trance: An Exploration Integrating Left and Right Hemispheric Activity

SESSION 1: Spontaneous Trance and Its Utilization: Symbolic Healing

Jill was an attractive thirty-year-old mother who was college educated and highly talented as an artist. She visited the senior author to learn if her spontaneous states of reverie were actually a form of hypnosis. She reported that she would sometimes lapse into spontaneous periods of reverie when she was painting such that her body suddenly became completely immobile in the middle of a brush stroke and she experienced herself as being deeply absorbed in fantasies and visions that would cross her mind like a vivid dream. These periods might last anywhere from a few minutes to hours. She reported that she often experienced deeply meaningful insights during these periods, and at the present time many of her inner experiences served as inspirations for her art.

Immediately upon entering the office for the first time, before a word was spoken, Jill focused on a wooden dolphin that was one of many unusual carvings on top of a bookcase. As she sat with her attention still fixated on the dolphin, she began to speak in a soft, faraway voice about the dolphin who swam away to sea, the dolphin is lost. It was immediately obvious to both authors that Jill had lapsed into one of her spontaneous periods of reverie; from a clinical point of view she appeared delusional. After a few minutes of talk about the dolphin, Jill seemingly blinked and came back to the reality of the office situation with E watching her intently and R fumbling to get the tape recorder operating. Dr. X, a psychologist with academic training in experimental hypnosis, was also present. E first questioned Jill politely to determine if she had been taking any drugs, but she blushed smilingly and assured him that she had never taken any psychedelic drugs. Such behavior was normal for her.

Individual Differences in Trance Behavior

E: How far away were you?

J: As far away as the ocean.

E: All right. Was I there?

J: No.

E: You were alone, I thought so. [To R] She showed a lack of movement that we all show in the absence of others. The dissociation of her right arm was acute. The left arm somewhat. There was a failure of head movements. Her eyelids sank to a one-half level. As she is behaving right now, she is much more in contact.

R: So that was classical trance behavior.

E: She is evidencing here her own pattern of trance behavior. There is no such thing as pure trance behavior.

R: There is no such thing as pure or classical trance behavior: Everyone manifests their own individual pattern. Certain behaviors like body immobility and altered eyeball behavior are typical, however.

Spontaneous Trance Equivalent to REM Sleep?

J: Would a person in such a state - call it leaving or whatever you want to call it - can that take the place of sleep sometimes? Sometimes I'll be very tired and I'll want to go and paint something. I'm tired, but I'll make the decision to paint anyway. But what happens a lot is, that I'll be painting and I'll still think I'm painting but it's like, I'm not asleep exactly, but it's like I'm somewhere else. Totally. It's not just a thought, like thinking of something else.

Just the other night I realized I did this. I did not realize I did this until, oh, four days ago, when I saw my hand holding a brush in the same position for about at least twenty minutes or a half-hour. And I thought I was somewhere else in this kind of imaginative conversation. And I thought I had not slept for a long time and I had woken up from a dream. But I realized it wasn't [a dream], since the brush was there. And I did not feel tired anymore. I painted for a few hours longer, and then I was surprised to see it was even getting to be morning. I'm a little shy about talking about it since it is essentially such a private kind of thing that I do.

E: It is a very nice kind of thing. [Pause]

E: It is a state similar to the hypnotic, and you can rest, you can be comfortable. You can paint. You can trust your unconscious mind.

E: She does a remarkable job of explaining. How on earth do you get across to a person that you have experienced a totally different feeling? She knows that she has different feelings in trance, but she really doesn't know how to describe them, and neither do I.

R: The feelings are so private that she has no external references to develop a communication bridge. Her description of these spontaneous trances suggests that for her, at least, there is an equivalence between trance and the REM stage of dream sleep, since she comes out of trance

refreshed as if she had been asleep.

Negative Hallucination in Sequential Stages

[J now evidences minimal cues of entering a trance as she listens to E. Her eyes are in a fixed stare at him, and her body remains completely immobile.]

E: Now you have forgotten the presence of the others.

[Pause]

How completely have you forgotten the presence of others?

[Pause]

How much?

J: I don't know how to measure it.

E: But they were awful vague to you just now, right?

J: Yes, yes. Although I think I was just on the surface.

E: You lose a knowledge of the presence of others first by losing the number present, then losing which sex, and only then the positive identity of the person. When you lose your identity or recognition of who is present, then you finally can lose the totality of their presence. I don't know why that is, but it always follows that progression. Her remark about not knowing how to measure it is very revealing: Consciousness does not have available all the knowledge that is in the unconscious, which actually governs our perceptions and behavior.

R: Losing first the number present makes sense, since number is probably the most abstract left-hemispheric function. The loss then progresses by degrees until you finally lose recognition, or the most concrete perceptual right-hemispheric aspect of the situation.

Trance in Everyday Life: Right and Left Hemispheric Dissociation in Trance?

X: When you asked about her attending to the rest of us, she came out of it, her state.

E: And you saw her come out of it.

X: Immediately.

E: And you saw her recognize it. She came from somewhere to here. Now you can use that for very constructive purposes. Emotionally constructive, artistically constructive, and constructive as far as thought is concerned.

J: Can it be done on purpose? I mean can I will it? Can I use it that way? Because I know that I feel better when I am doing some painting and I, I don't know what words to use to label it, when I go into that, when that happens, when I experience that.

E: Yes, you can do it intentionally.

J: Is that the same as when you are listening to music and you have the feeling of actually entering the music? Or being inside of colors instead of just using them on the outside? It is very funny to talk about, because it is not just something to talk about, exactly. I feel a little shy.

R: This slight falling into trance or reverie is a normal aspect of everyday behavior. You and Dr. X are trained observers and can pick it up immediately. You can use this awareness of the spontaneous beginnings of trance to choose the most appropriate moment for inducing or encouraging further trance. Do you wait for such moments to induce trance?

E: They are going to be *interested* in what makes me think they can be put into a trance. So I merely make use of their interest and keep away from formal trance induction.

R: How do you make use of their interest? You direct it to the inner parts of their own world?

E: Yes. And there I stay with them.

R: Her continued emphasis on not knowing what words to use to label it, when I go into that. . . strongly suggests there is a dissociation between the verbal aspects of left-hemispheric functioning and the right-hemispheric experience of trance, wherein one has the feeling of entering the music and being inside of colors.

Indirect Induction of Trance by Focusing on Inner Experience

E: Don't be shy. A woman who thinks as an artist attended one of my lectures and told me she could not be hypnotized. I told her that was all right and asked her what type of music she liked. She said she liked orchestral music. I asked her if she could pick out the second violinist over there. And she picked him out. She described his clothes, she found a redheaded musician. Do you know that orchestra then played all her favorite pieces of music? I knew from the way she talked that she could do it, but she didn't know it. She went into that dissociated state and heard the music and could see the people very nicely. And that is a very excellent thing to do. Sarah Bernhardt in her acting was having a quarrel with her husband in a play. She unintentionally took off her wedding ring, and she *really*took it off.

You do get inside things, and there is nothing wrong or abnormal about it. Every person who has a lot of feeling has hangups about how other people feel about it. Now what pleasures do you like? Do you like swimming?

J: Yes, all the pleasures. All the pleasures! That's it! [She now begins to cry.] I try not to, I don't want to be that way, but I do feel guilty about enjoying all the things I enjoy. Whether it is doing my thing in art and really going into it. That's why I cry.

R: You can induce trance most subtly and easily by simply letting a person focus on what is of most interest to them. Trance is initiated when they become absorbed in something they are really interested in. This is the basis of all indirect induction of trance.

E: Yes. I did not ask that woman if she wanted to enter trance. I simply asked her if she could pick out the second violinist.

R: You find an interest area of the person. An area where there are strong programs built into the person, and you just focus on that to induce trance.

E: That's all!

R: But why do your subjects become so absorbed in their interest areas that trance behavior is evident? We all talk about what's intensely interesting to us in normal conversations every day without falling into trance.

E: *Because I stick to that one thing!*

R: The conversation does not jump to something else. You focus on one thing, you intensify that absorption, and that's what trance is.

E: I don't let the conversation jump to anything else. Yes, trance is a focusing on one thing. Watkins has written a paper describing a trance as dropping all the peripheral foci and narrowing it down to one focus. I agree with that.

A Rapid Age Regression and Therapeutic Reorientation

E: I think that is a very nice thing that you enjoy.

J: I do too. It is not the me now, it is probably the childhood thing. As a child it was always put down. That's it! That's where it conies from. It's as though the tears I feel coming now are not me here now crying. It is the child-feeling from long, long ago. It is an old, old feeling that is coming out now.

[E now questions Jill about her family background, number of siblings, and other details of her early life.]

E: How would you like to go for a swim in the ocean now?

[Pause]

J: [In a very soft, faraway voice] Immediately when you said that I was there.

E: Close your eyes and go for a long pleasant swim in the ocean all alone.
Swim a long way from three years.

[Pause]

A long way
from three years old
to your present age.
And enjoy every stroke of it.

[Long pause as Jill closes her eyes and very evidently follows internal imagery as her eyes shift rapidly under her closed eyelids.]

And my voice will be meaningful sounds in the water.

[Long pause]

And you'll see that little girl,

[Pause]

a bigger girl

[Pause]

a young lady.
Look at her carefully,

[Long pause]

and you'll learn a surprising number of nice things about her you didn't know.

R: She describes so well how it's the child side of her who is crying now. Did you choose this method of induction because she had already demonstrated that the theme of swimming in the ocean had spontaneously induced a trance in the beginning of this session in her association to the dolphin? In other words, you were again simply *utilizing* a subject's own inner programs to induce trance?

E: No. I was primarily interested here in getting her as far away from her family as possible, since it was becoming too emotionally involving for this situation. I wanted to help her with her tears by distracting her from her emotional distress. I was creating a situation where she would be free from stress and free to enjoy. A patient has to be talented to be able to make such quick jumps as she, but the therapist has to be able to recognize the situation and know where the patient should jump.

I picked three years because it's reasonable to assume that she had siblings by the age of three - problems with them. Since she is showing early-childhood emotions, and early memories usually begin around three years, I assume that is the age from which her emotions are actually coming. I ask her to swim away from them to get the relief she needs at this point. She was regressing too much in her emotions, and I wanted to yank her back to her present age. I ask her to become a bigger girl and finally a young lady.

R: You use a very short period of age regression to simply touch the source of emotional distress and then have her quickly leave it. You permit a momentary catharsis and a very rapid resolution of the problem for the time being. You then introduce a therapeutic reevaluation of her early childhood by suggesting she learn the nice things about herself, since she earlier told you about her deprivations and guilts. You are thus *utilizing* her need for positive self-affirmation to deepen trance and at the same time effect therapy.

Validating Inner Trance Work

[Long pause after which J spontaneously smiles, stretches, and awakens]

E: Hi!

J: Hi. My dolphins are swimming also.

E: Now share only the things you can share with total strangers. Tell us the nice thing you were able to discover, something you had forgotten.

E: The Hi is informal. This is tremendously important in therapy, that you keep things informal so you give the patient the privilege of concealing just how important some of these things are.

R: Because if the material becomes too important, the conscious mind will start blocking it out. She apparently came out of trance spontaneously, but actually she was probably following the implications of your remarks to awaken before doing a certain amount of learning.

E: By implication I'm asking her to work at all the things and to communicate only what she can share. That now by implication *confirms* all the others! She has to select only one bit of trance behavior out of many. When she does that, she is also confirming or validating the others, and that's what you want your patient to do. It also is implying that there may be bad things.

Symbolic Language: Linguistic Cues of a Shift in Hemispheric Experience?

J: The beautiful way the light was showing through these bushes that need to be trimmed but shouldn't be trimmed at all. I saw them this morning, the way the light shimmered through the leaves, and these shoots were making designs. It was so beautiful, and I hoped that the gardener wouldn't trim them. It was very pretty. I wish I could have gotten through to people to tell them how beautiful these bushes were in their natural state.

E: How old were you then?

J: It's now. This morning.

E: Now!? How many shades of green were on the leaves of the bushes?

J: At first I saw so many shades, but I didn't want to see all of the different shades. I just wanted to go into one. When I finally stared at it long enough, it turned into more like chartreuse.

E: But you can see different shades.

J: Yes, I see them. It's a good feeling, too.

E: Society says, Trim those bushes.

R: Trim down your behavior; get in line. But she is saying here that she does not want to be trimmed, she wants to be free to grow in her own natural way.

E: That's right! And she does not know on a conscious level what she is saying. She is not talking about bushes, she just thinks she is. I then get away from that in a hurry and distract her with talk about shades of color because I don't want to put any emotional pressure on her. That was a therapeutic opening, but she did not come here for therapy.

R: In saying I just wanted to get into one [shade of color] she is repeating her earlier theme of actually *entering* the music ... or being *inside* the colors. I wonder if such language implies that her ego identity (associated with left-hemispheric functioning) is allowing itself to be surrounded by, or under the dominance of, the more artistic experience of the right hemisphere?

E: Yes, I think that could well be. You frequently find that patients say being in trance is being in a different part of themselves: You know you are you, but you are in a different you.

R: That different you is the more intense, experiential functioning of the right hemisphere. Sperry (1964) has said we all exist in at least two worlds of experience (the right and left hemisphere). Hypnosis can be a way of more clearly differentiating these worlds of existence. When she speaks of going into trance, she actually means going into the world of right-hemispheric experience. According to this view artistic talent consists in the ability to give in to right-hemispheric experience (Rossi, 1977). Artistic development would involve the discipline of the left hemisphere's learning to submit itself to right-hemispheric experience and then forging some expression of it in a consensually valid art form.

Life Review in Trance: Time Distortion

E: What about the swimming? Anything you can share with strangers?

J: Yes, I was swimming. At first I was alone, and then the dolphins came. But I did not feel awkward at all because they have no destination anymore. And when I started swimming back, I came into a net of dolls and old toys, childhood things. And my immediate thing was to swim through it. But I knew I could not do it because my fist got stuck in the net. So I put my fist out and I could still swim and I felt my legs being very strong kicking the water. And I gently moved the net of childhood things over and pushed it out to sea, so it was free again, and I swam some more. Whatever obstacles there were, different things from my family, etc., I just swam gently through them after that.

As I was swimming, my body changed; it became older. I was swimming in a plaid dress from when I was ten, and then I was swimming in this long cape I bought when I was an adolescent, and then the suit I got when I was married. It's really weird! And then when I had my children, I remember the things I wore and I was also swimming in that. And the various things I had on until now. Until suddenly I was in a lovely form watching the ocean.

E: Here again by emphasizing that she should reveal only what she can share with strangers, I'm keeping her on the surface. I'm protecting her. She then outlines the course of therapy she wants to discuss.

R: How to cope with these childhood things. She actually goes through a life review with so many details in so short a time that she probably experienced considerable time distortion (Cooper and Erickson, 1959).

E: She comes up to the present and is ready to deal with the present situation.

Facilitating Creativity

E: All right. Close your eyes.

[Pause]

And go for another swim in something
you've never worn before. Something very happy.

R: Is this an example of facilitating creativity? You may be asking her to synthesize some new psychic structures when you ask her to wear something she has never worn before.

E: Yes. It's a break from the past when she becomes aware that there are other things she can wear, that she has never seen or experienced before. You're also giving her permission to do something she has never done before. Also, symbolically, something you've never worn before can be an experience! It isn't necessarily clothes that we are talking about.

Validating Trance Behavior

E: And have a long and tiring swim, but enjoyable.

At the end you will feel rested. [Long pause]

E: Why tiring? You're tired when you really have done a good day's work, a fruitful day's work.

R: So by suggesting she be tired, you are introducing an element that is associated with doing work and thereby validating that she is to do or has done important work in trance.

E: Yes. Today's tool has earned tonight's repose. Longfellow. But enjoy it and feel rested.

Utilizing Time Distortion

E: A lot of time will pass.
But pass very rapidly.

[Pause]

It will be a delightful surprise
to find out how rested you are after being so tired.

[Long pause]

And only tell the part that you can share with strangers.

[Long pause]

And just a bit more fatigue before you go into that nice restful state.

[Long pause]

And there is a surprise for you
at the end.

[Pause]

The destination becomes clearer.

[Pause]

Almost there.

[Pause]

And you may continue to enjoy

the rested feeling
after you arouse.

[Pause]

E: First you let the patients know they have a wealth of time so they will do all their work. Then you distort the time so it can all be done in a short time.

R: That's your approach to utilizing time distortion: Give a lot of time, then let it pass quickly so the work is quickly done.

E: Implying there was a lot, of which she should share only a bit. You then validate further by confirming her fatigue. You keep validating your suggestions as you go along.

R: You're validating that she has done important work. When you imply she has done important work, that reinforces any tentative steps she has made in that direction. And however little she may have done, that is immediately reinforced so she is more likely to work even better in the next trance.

Surprise and the Creative Moment: Secrets in Facilitative Psychological Development

E: And be greatly surprised by the new and pleasant understanding you have reached.

[Long pause until J begins to awaken, to reorient her body, and open her eyes]

Only tell us what you wish to share with strangers.

R: Is this emphasis on *surprise a* way of facilitating the development of the new? Since surprise is usually associated with *new insight,* suggesting surprise would tend to facilitate an ambience where creativity and new mental structure could be synthesized.

E: Yes, that's right. What pleases a little child? A surprise and a secret. All children like them! [Here E tells a charming story of how he cured one of his daughters of bed-wetting before it became a real problem. The daughter began bed-wetting when her younger brother was born. After a week of this bed-wetting, E told his wife to tell his daughter that after she had a dry bed for a week, she could go to E's office and say he had to give her a quarter but he could not know why. It was a secret. Daddy could not know why he had to pay her a quarter because it was her secret. After a week of dry beds she came in and demanded her quarter. She got it with no questions asked, so her secret remained intact. She came in the next week for another quarter. The third week she forgot to ask, and she has had a dry bed ever since. She had accomplished her own secret wishes since she didn't like a wet bed either.]

R: So secrets and surprises motivate children!

E: A secret for the child so they can surprise the adult.

R: When you are surprised, I would speculate that a creative moment is taking place wherein new protein structures are being synthesized in the brain that then serve as the organic substrate of new phenomenological experience. The experience of surprise is the reaction of consciousness, the old frame of reference or set that has been governing consciousness, reacting with a startle to the new that has just been synthesized and now appears on a phenomenological level for the first time. The surprise implies that the old frame of reference must now be expanded or changed to accommodate the new (Rossi, 1972, a, b c; 1973a b).

E: Yes, every time you surprise a small child, you widen its range of responses.

R: Every time adults do a double-take, you widen their range of responses. So we are always trying to facilitate surprise as creative moments in therapy.

E: Yes. And when you keep a secret, you widen your understanding of how things work.

R: Wait a minute! How does that work?

E: One must widen a whole lot of receptors to uncover a secret. Every time you try to keep a secret, you have to find ways of hiding it. That is an important learning process, too! Just keeping a secret makes you learn how to erect guards, defenses. It broadens all of your understanding to keep a secret.

R: When you increase your defenses, you also increase your understanding?! That's the opposite of the classical psychoanalytic view! Of course there is a difference between the use of unconscious defenses, which would limit your understanding, and conscious defenses, of which you speak, that actually can increase understanding. You could actually, under certain circumstances, facilitate a person's psychological development by asking them to keep a secret. By telling a child to keep a secret, for example, you are telling that child to put certain defenses under conscious ego control, to develop creative tact, etc.

Symbolic Language: Fantasy to Work Through Traumatic Material

J: All of it! I was swimming alone this time. No animals, nothing, just me in the water. The water was very intensely colored. I did not want to swim on the surface, so I went almost the whole way underwater. And when I got under there, the colors were like nothing the sun could make on top. I was so happy. The whole way I felt happy! And I could really swim underwater. It is hard for me to keep that up in a real pool. As I went deeper and deeper and deeper, there were shells like you've never seen. And then I even found some that looked like stones and gems and could even breathe underwater. And I took them and I just threw them up so hard they went on top of the water and they changed colors outside because I could see through the water. And I did this all the time. I'd just swim underwater and find these beautiful shells and even these discarded, uh, like dishes, I don't know what they were, but they were beautiful and when I tossed them, they changed. And I did that

all the way to shore.|

As I got to shore I could sense that, I could see it underwater - you know - you can sense how the shore is building up when you are way down there and the rocks change after so many feet. Like geographical.

E: When she says it's just me in the water, she is saying she is nude. She is not covering up anything. There is no need to cover up. I did not want to swim just on the surface means she is going deeply. The shells are the empty things of the past, shells that once had something, problems, agonies in them. She can see them as empty, but she doesn't know she is looking at her past and its problems here.

R: She sees this symbolically without consciousness understanding its significance, as we are now.

E: She is detoxifying the situation.

R: She is detoxifying the situation for her conscious mind right now because it would be too traumatic to burst out in tears and depression, looking back again at these old problems. When you say the shells are empty now, you mean that she has already dealt successfully with the problems they once contained? If the shells were full, that would mean she was still carrying all those old problems.

E: Yes. There is a willingness to let the bitterness, frustrations, and disappointments of the past remain in the past. She's taking the first step toward the recognition that she is no longer carrying them.

R: So this was a good psychotherapeutic movement that she took in this fantasy. Fantasy can be a way of detoxifying or working through emotionally traumatic material.

E: She is describing therapy here with these gems and stones that she throws up to the surface of the water! She is describing therapy in symbolic terms, but she is only recognizing the words and not the meaning behind them.

R: Therapy is like taking the gems from underneath the surface and throwing them up to consciousness. The gems would be the valid insights.

E: And the stones would be the not-so-good things. In successful living you can always afford to throw away a lot of gems because there are always a lot more available to you. Those gemlike friendships of childhood can be given up because there are other things for the adult. Now the beating a playmate gave you - that is a stone you toss aside.

R: So she is describing a good therapeutic movement.

E: Her unconscious is doing it in symbolic terms. Her conscious mind does not yet understand it fully. But there is an understanding present that allows her to say these things that way.

E: The shore is society. The closer you get to it, the more complicated it is.

Psychological Healing Through Symbols: Right-Versus Left-Hemispheric Healing?

J: I knew I was coming to shore and it was OK. But I wanted to take some of them with me. I did not want to leave them all there. So, I wasn't wearing anything but paint. That's what I wanted to wear. It wasn't ordinary clothes. I was painted from toe to my earlobes. My face was just plain. All kinds of designs, and I realized the designs on my body mirrored the designs underwater. It was like one.

And so I got out of the water, and the designs were still there. But I took off the designs; it sounds weird, but all the designs kind of came off, and I wrapped all the shells in them and I pulled them to shore like in a net. And they made a round circle, and when I saw that, I did take one of these gems with me. I hadn't meant to but I did anyway. And when I noticed it, it got very bright! And the more I looked at it, the brighter it got! Until it seemed to burst into flames, but it wasn't a hot flame, it was just a flame flame. And I lay down in it and it was so bright! So light! It was beautiful, you really should have been there. And I lay down in it, and it wrapped me over, and I didn't need any paint, I didn't need any clothes. I didn't need any makeup, I didn't need anything. I just lay down in it, and it wrapped me up and closed me in. And it sort of elongated and filled out the shore, and I just looked at it. It was very beautiful and very bright!

I don't think you could look at it if you saw it out here. I feel very intensely good, like in every cell in my body!

E: From toe to my earlobes, a rather peculiar way of speaking. Toes are very physical, and earlobes are where you hear: Touch and hearing are involved, and paint says vision.

R: So you are saying she has many of the senses in there close together: She is a sensual person.

E: Yes. When she takes off the designs and pulls them to shore like a net, she is describing what she is doing with a past trauma.

R: The designs are symbols of a trauma of the past that she is successfully coping with.

E: It could be the loss of a childhood friendship, a childhood injury, anything.

R: It could be anything, but this design and gem image is the way her mind is dealing with it on an unconscious level.

E: Yes, on an unconscious level. She is dealing with it very intelligently and very comprehensibly. She's putting everything down for the conscious mind to understand later.

R: Would you say then this was a healing on a symbolic level?

E: It is a healing on a symbolic level.

R: So while she was going through this symbolic experience, a process of healing was taking place. She tells you about this symbolic experience, but her conscious mind still does not know that a healing has taken place.

E: She shared it with me, a stranger. She told me, and she can't take away any more what she has told me. There is no longer any way for her to deny it.

R: She has validated the healing process by telling it to you even in these symbolic terms. She has confirmed it, she has stamped it in. So she can heal herself on a deeply symbolic level, and once she tells it, she can't undo it. You feel a healing process took place while she was in trance, and this is one of the ways hypnotherapy can heal people.

E: Yes.

R: She is walking out of your office after this experience healed in some way. You do not know in what way or to what degree, but you do know some trauma has been dealt with. The whole problem may not be resolved, but some increment of resolution has occurred in this fantasy that has a successful tone to it and is associated with such happy feelings at its conclusion: the symbolism of light and good body feelings.

E: With a sudden burst of light comes Oh, that is what it is! The light of day dawns.

R: Light is associated with new insight and learning. She is saying that the light, the insight was so beautiful.

E: Yes.

R: That is exciting to think that that is the actual moment when a curative process is taking place. I'd hypothesize that this was the creative moment when new proteins were being synthesized in the brain and new phenomenological structures could come into consciousness.

E: Yes, therapy is like reading. First you read the alphabet, then different combinations of letters. First short ones and then longer ones - words. Then combinations that are connected - sentences. Then a theme and a plot. She's recognizing and describing the essential steps in therapy in this section.

R: She is symbolically describing increments in the therapy process: Her experience here was but one step, one letter, word, or sentence in the total process of a redevelopment of her life.

E: You let the patients use their own words to describe the process.

R: You let them utilize the structures that are already present to express the new. For Jill, ***flames*** and ***gems*** and ***stones*** and ***shells*** were the currency of her mind for expressing the therapeutic process of change and growth. Therapy on a symbolic level uses the language of the patient. A

growth process can be talked about in any terms. Whatever terms you use can facilitate its progress merely by being experienced and expressed. Since these are all highly imagistic terms, it's tempting to speculate that this form of symbolic healing is characteristic of the right hemisphere, whereas the more classical type of Freudian therapy that analyzes problems back to real-life events is more characteristic of left-hemispheric healing. Patients who are strongly dominated by left-hemispheric functioning would do well in the classical forms of insight therapy, but those dominated by their right hemisphere could do better with symbolic therapy. This could also account for the undercurrent of antagonism that has always been present between the classical forms of insight therapy and people with artistic temperaments. Artists have always been suspicious of Freudian analysis with good reason! The Freudian tends to translate everything into terms understandable by the reality-oriented, ego consciousness of the left hemisphere, while the artists' natural proclivities incline them to the symbolic approaches of the right hemisphere. Religiously inclined people who find healing through evangelical or miraculous experience would also be utilizing their right-hemispheric capacities for symbolic healing.

E: A good author can outline a story or plot line but then finds that his characters run away with him. The characters seem to have a will of their own, and the story turns out differently than the author had planned. There again you may have the right hemisphere intruding upon the plans of the left. In the introspective accounts of such authors they will say, I never intended so-and-so to be married, but he did. Then I thought he should have two children, but more turned up.

R: What fascinates me is that whatever the language of the patient is, when you talk in that language you can effect a therapeutic change. When she has a hypnotic experience utilizing that language in a positive and constructive fantasy that leaves her feeling good, then an increment of healing or growth has taken place. Whenever something good happens in a fantasy, on whatever symbolic level, then healing has taken place. Would you agree with that?

E: Yes. We can reinforce the value of that experience by speaking well of it to the patient even though we do not know exactly what it is referring to. You don't know how long the patient will need to digest the new material. It could be a day or a week or whatever. So you need not see patients on a rigid schedule. It is best to let them call when they need to. A therapist should have flexibility in his schedule to accommodate the patients' needs.

R: So they should come to therapy when their particular healing process needs to be reinforced or extended.

Facilitating Self-Healing: Integrating Left- and Right-Hemispheric Functioning

E: And you can feel good anytime you want.

R: You can utilize these states.

J: I'd really like to learn how to do it.

E: I'm going to let you discover that you can. In the other room is an Indian portrait painted by a young woman who had absolutely no art training at all. You go out and look at it and pick out all the good things in it and come back.

[J goes out to examine the portrait and returns in a few minutes.]

E: Did you like it?

J: Yes. I like the mouth, the eyes, the muscle right here. It was beautiful.

[E now tells something about the background of the picture. A casual conversation takes place for about five minutes about one of E's successful cases.]

E: Here I'm putting the good feeling, the healing process, under her own control. She is an artist, so I want her to pass judgment on another artist and thus reinforce the artist in her.

R: You are helping her validate herself. You elevated her by giving her this task without her knowing that you were giving her a boost. By having her judge an artistic production, you are utilizing and facilitating or reinforcing her natural right-hemispheric tendencies and integrating them with the left. Judgment is probably a left-hemispheric function, which you are joining to her right-hemispheric sensitivity to art.

E: By discussing and giving reality to the other artist, I'm giving more reality to her judgment.

R: You are probably fostering a whole new phenomenological world here in which she can integrate left- and right-hemispheric functioning.

Rhetorical Questions Engineering Responses

E: Now I'm going to ask you what I've not yet asked you: What do you have to do?

J: There is nothing to do. Nothing. I've just fully enjoyed talking to you.
Your eyes are incredible!
May I look at them more closely?

[J bends closer to E and studies his eyes.]

E: You don't want your patients to feel as if they are under a great burden, so I carefully gave her a chance to give this answer.

R: How did you set her up to give that answer?

E: The question I asked seems so damn precise, and yet it is not the least bit precise. It is just vague. What can you do with a question that is so vague it has no meaning? I thus engineered that I've got nothing to do answer.

R: You engineered her into saying in effect, I've got nothing to do; I'm satisfied now, doctor. I can hardly believe you really did that with premeditation! That is fantastic!

E: I've been practicing this sort of engineering for some time!

Self-Hypnosis Training: Further Symbolic Healing

E: I'm going to tell you to go in the other room and return in five minutes and tell me where you have been.

[Jill leaves for five minutes after E explains that he wants her to have some practice in developing her altered state by herself. Up to the present her altered state came upon her spontaneously and unwilled. Now she is to learn to bring it on when she wants to and thereby learn to control and constructively utilize her gift for achieving altered states. When she returns, she continues as follows.]

J: I'm interested in my attitudes toward people and things. I suppose it is basically a conflict between attitudes I have and those I should have. When I was in there, I sat down and went someplace. I was on a desert, and all of a sudden I noticed a peacock come from this cactus. Suddenly it got very big, and I jumped on its back and pulled out a feather, and suddenly it became night. I got the feeling somehow that on the peacock, it raises its tail feathers - that is where its beauty is. I know it is weird, but somehow I would here discover my attitudes to things.

As we rode through the night, I pushed the feathers apart, I wanted to see what was underneath. And there were other colors - every color, even more than you could imagine, so I knew this was my peacock, so to speak.

Then, as we arrived, suddenly these fingers began pointing, and I laughed because I knew they were old, wrong attitudes in me. And all of a sudden we had to stop because the mailman was there with a letter.

E: So you've made a few trips. Now you've got to go out there and make your own.

J: I am! I am! But as you make it out there, there is a lot that changes inside, too. On my last trip in there I was lighting a few lanterns. I think that's my attitude toward things now. I felt good about that.

R: She obviously succeeds in going into a self-induced hypnotic state where she experiences this visionary state with the peacock, her body getting big, and so on.

E: Two words - night and tail. Slang terms for sexual ideation. She is saying that sex is beautiful. She is exploring her attitudes toward sexual things. The colors are facets of emotions.

R: Is this another process of symbolic right-hemispheric healing taking place, when she laughs at

the pointing fingers? She has solved the guilt problem implied by all the pointing fingers and can now laugh at them. She might have been overcome with guilt with all these sexual feelings coming out, but here she has gained an increment of therapeutic change by not falling into guilt. These symbolic fantasy trips are actually solving inner problems on an unconscious level. As long as a person is going on these fantasy trips with a good outcome, they are solving little increments of an inner problem.

E: Yes, they are solving them for the purpose of reaching a consciously recognizable goal.

SESSION 2:

Part One: Facilitating Self-Exploration

This session begins the next day with a casual conversation about hypnosis. E then gives an extensive example of one of his wife's hypnotic experiences of recalling early memories. J gradually grows quiet, closes her eyes, and apparently goes into a trance in response to the gentle cadence of E's voice.

Hypnotic Induction by Indirect Associative Focusing

E: Now my daughter investigated through hypnosis a great many things, seeing them as she actually saw them at the time and later seeing them for their significances. In other words an infant has a fragmentary memory: A hand lifting is only a hand that is lifting. There is no arm involved. It takes some time to connect the hand to the forearm, the upper arm, the shoulder, the self. And to discover that the hipbone is connected to the kneebone and so on. Some time to discover it. Adults seldom realize the learning process that is involved. As an artist you should be interested in those memories.
You've got to be creative.
Colors for a child are bright and stimulating. Just what does a brightness stimulus mean?

[Pause]

And the thrill of lifting something heavy. That counts.

[E tells a story to illustrate individual and cultural difference for about five minutes - how his son-in-law brought a Vietnamese child home to the U.S. and the trials of teaching the child to eat solid food like an American.]

And you've got so many memories and so many understandings you don't realize you have that can enrich your understanding in so many ways.

[E now tells a brief story about a heroin addict who was an artist and his patient. E asked him to sit on the lawn and discover something. The patient discovered new ways of seeing the sheen on the grass, the direction of the trees, and so on.]

E: I use personal examples frequently because they are best known and carry a greater sense of conviction.

R: You're beginning this session with many examples of self-exploration and early learning. All these examples are together indicating a direction for her own inner efforts. You do not tell her specifically what to do; you simply lay down a suggestive network and allow her own unconscious to respond by picking up and elaborating this or that aspect of your network. In Chapter Two we called this the process of indirect associative focusing.

E: You depend upon the patient's natural associative process to put things together. If I want you to talk about your family, the easiest approach and the one least likely to arouse your resistance is for me to first talk about my family.

R: If you have a target area, X, you want a patient to talk about, you first talk of the associated topics A, B, C, D, etc. that all converge upon X. Gradually the area X is stimulated to the point where it is expressed by the patient. You're beginning this session by giving her associative process many possibilities of response by talking about many things. Your target area does seem to be associations about *childhood, individual differences,* and *creativity.*We will soon see how effective you've been when we learn what her responses to your introduction are.

E: It is desirable to do it indirectly, so that the patient does not feel under attack. It is a way of obviating defenses.

Spontaneous Movements Funneled into a Therapeutic Framework: Contingent Suggestions

[J begins to make small movements with her hand, and then her entire arm begins to move gracefully and easily, as if floating. Her entire body gradually takes on a rhythm as if it were swimming or flying. Even her legs lift in slow motion, with delicate flowing motions in coordination with the rest of her body. She remains seated, but flows easily around in her seat.]

E: Now of course I don't know what you are doing. There is a possibility that you are exploring - infantile learnings subsequent learnings and reaching understandings. You are making realignments of understanding, realignments of words.

[Pause]

One of the things my daughter put to me was: Daddy, how old was I when I first had tears? Because I know I did not have tears when I cried when I was very young?
I told her that's right. The month at which one gets tears varies from one individual to another.

[Pause]

Her discovery that she had not had tears till a certain age, but not when, gave her a new understanding of tears.

[E now outlines for a few minutes the stages in the development and expression of anger from infancy to adulthood.]

What I want you to do is to begin being yourself.

[Pause]

Accepting yourself.
And knowing that you can control yourself.

[E tells one of his favorite stories about one of his baby daughters, who screamed for days because people walked and she knew she was a people. She finally got up and walked her first hundred steps with no hesitation.]

You want to do something. You control yourself. You focus your efforts.

[Another story about one of his daughter's persistent and finally successful efforts to enter medical school.]

R: She is obviously in a state of deep inner involement with all these apparently spontaneous movements. It's nice to know that even you, with all your fifty years of experience, really don't know just what she is doing. You do, however, utilize these moments to suggest that she is making therapeutic progress by realigning her understanding. Whatever the original significance of her movements, you are funneling them into a therapeutic framework. This is a form of contingent suggestion in which you tie your therapeutic suggestion to her ongoing behavior.

Facilitating Self-Exploration

And it is a wonderful thing to explore,
to discover,
the self.

[Pause]

Now there are discoveries you make.
Some are personal
and belong only to you,
and some can be shared with certain others,
and some can be shared with others in general.
And one of the nice things about it is this:
You don't know what you are going to discover,
but you are going to have a delightful time discovering it.

[J's motions are now fuller and more luxuriant. She is smiling broadly at times. There is a happy atmosphere in the room.]

Just like the small child who says,
I'm building something,
and when I get it done
I know what I really began.
The same things applies to the infant in a crib.

[Long pause]

And for anybody to watch you
and interpret your behavior
can be looked upon as futile
as that
of looking at an infant in a crib
who really doesn't know what
she is doing.
But she is doing something.

[Pause]

You can find out what
you are doing.
Because you have the background of understanding,
and it has to be your background
to understand it.

[Long pause]

[E describes how an infant can repeatedly reach for its own hand and each time not understand what is happening as the hand moves. The adult watching the infant is puzzled that the infant is making this continuous reaching movement.]

Now I have talked,
trying to give you
a general
background
from which
you can start
your own self-exploration.

[E gives many clinical examples of the source of psychopathology in the inhibition of self-exploration due to parental and societal structures.]

R: So, in general, one of your first steps with a new patient is to initiate some self-exploratory

programs. When you introduce trance with these self-exploratory programs, you are actually laying down a foundation for future deep absorption in trance.

E: Yes. You encourage patients to do all those simple little things that are their own right as growing creatures. You see, we don't know what our goals are. We learn our goals only in the process of getting there, I don't know what I'm building, but I'm going to enjoy building it, and when I get through building it, I'll know what it is . In doing psychotherapy you impress this upon patients. You don't know what a baby is going to become. Therefore, you wait and take good care of it until it becomes what it will.

R: The very fact that you don't know makes you take extra good care.

E: Life isn't something you can give an answer to today. You should enjoy the process of waiting, the process of becoming what you are. There is nothing more delightful than planting flower seeds and not knowing what kind of flowers are going to come up.

R: So you were setting Jill on a self-discovery program without knowing what she was going to discover. That is very characteristic of you and your work. You can carefully engineer things, but you also enjoy blind exploration.

E: That's right.

Facilitating Individuality: Indirect Ideodynamic Focusing for Hallucinatory Experience

I'm suggesting
a comfortable examination.
An examination
which will show you
how your understanding grew and changed.

[Long pause]

Now I'm going to add one new
dimension
to what you are doing.
And that is this:

[E describes how once when he demonstrated hand levitation, all the observers thought the subject failed until he proved that the subject hallucinated his hand levitating.]

That hallucination was just as effective as a real hand movement because it
was the inner experience that was important.
You can at any time you
wish

make use
of the engrams.
I think you know that word.
Imprints for various learnings and experiences.
But you don't need muscles
and bone and flesh.

[Pause as J moves gracefully as ever]

And you can see colors
with your eyes closed.

[Pause]

And you can feel heat and cold
while your body remains comfortable.

[E gives further examples of hallucinated feelings and sensations under hypnosis. At one point he has J open her eyes and, finding that she knows nothing about a tapestry hanging on his office wall, E proceeds to give her a little lecture about the pre-Columbian origin of its symbols, etc.]

E: This also gets the person into their own individuality. In psychotherapy we are looking for the individualities. A patient, all too often, does not have much.

R: This is a way of facilitating their individuality with self-exploration leading to more self-recognition. As you then talk about the hallucinated hand movement, you are touching indirectly upon whatever her own hand movements may mean while also indirectly facilitating the possibility of hallucinatory experience by ideodynamic focusing.

E: Yes, but I'm especially focusing on the inner experience that was important. What are her really important inner experiences?

R: Yes, the common denominator of most of your suggestions finally comes through very clearly here when you say she can make use of the engrams . . . imprints for various learnings and experiences. This is very characteristic of your approach. You first tell stories and give many interesting examples of what you later more directly suggest the patient can now do. Your initial patterns of indirect associative and ideodynamic focusing initiate many autonomous search processes within the patient, so that when the more direct suggestion comes, the unconscious is ready in terms of its own mechanisms and the conscious mind is eager to receive whatever it can.

Criteria for Genuine Creativity: Psychosynthesis

E: Now I'm going to speak to Dr. Rossi.
There is no way whatsoever to interpret any of these movements correctly.

Any meaning we give them is our meaning.
They may be completely infantile movements manifested by adult muscles.

R: And a different time orientation, perhaps.

E: And a different mental orientation. A different emotional orientation.

R: This is a general exploration program you've put her on.

E: And she can remember at any level that she wishes.
I know that I can remember what happened at three weeks old.
If I can so can others.

[J continues her movement, seemingly oblivious to the conversation between E and R.]

R: What is of interest to me is that she may be going through an emotionally corrective experience. Is there any way we can find out? Is her mind actually synthesizing new psychic structures? Is she at this moment synthesizing new proteins as the organic substrate of new phenomenologi-cal experiences? How could we ever find that out? As Dr. X said the other day, he liked the hand-levitation induction because it gave him continuous feedback as to what was happening in a subject. I'd like to get more feedback and yet not disturb her experience.

E: You permit the patients to find out that they can solve a problem that previously was insolvable. So you do know there was something added.

R: Yes, something is synthesized. Something is being put together. [E tells a detailed example of how an apparently spontaneous naming of a street by an adult was actually a response coming from the adult's childhood. What may appear spontaneous or newly synthesized may thus simply have roots in past experience that we are unaware of.]

R: There is no way of knowing exactly what is going on, but you sense something good is happening, so you just let it continue.

E: I don't know if it is important or not. She is obviously having a good time.

R: Yes, I expect a very creative time. It must be pleasing for her to know she can do this on her own for any constructive purpose.

E: You never know, her slow motion could be subjectively perceived as rapid motion.

[E gives a clinical example of this.]

E: You know there is something synthesized, to use your favorite word, because when patients find something new, never again can they function in the old incomplete way. Their world is permanently changed.

R: The most self-evident criterion for genuine creativity or psychosynthesis is that the patient's world view, attitudes, and behavior do change. Anything less than this simply means the patient is only paying lip service to the therapist for whatever insights are purportedly developed.

E: When do patients have a good time? When something has been cured!

R: So having a good time, positive affect in a patient under these circumstances, means something is being healed.

E: That something desirable is occurring no matter how unpleasant it may be.

R: So positive affect is another important criterion of satisfactory work.

Three Types of Trance: Self-Absorption, Rapport, and Somnambulism

R: Would you say J is in a somnambulistic state now? How would you describe her trance?

E: Call it deep ; it is self-oriented. Somnambulistic means you have a certain relationship outside. She may be achieving certain purposes, but they are all inside herself.

R: There seem to be at least three basic types of therapeutically useful trance: (1) *The self-absorption type* like this, where the patients are so absorbed in self-exploration that they are seemingly oblivious to the therapist; (2) the more popular conception of trance, when the patients are very much in *rapport*with therapists and responding to suggestions and (3) *somnambulism,* where the patients' eyes may be open and they may talk and act as if awake, yet respond hypnotically to the therapist's suggestions.

E: In practice you have all kinds of admixtures between them, but those would be the extremes between which useful trance work can be done.

Spontaneous Awakening and an Unexpected Reinduction

[With a slight startle J. awakens, apparently spontaneously at this point.]

R: How would you compare your spontaneous trance experiences with your hypnotic work with Dr. Erickson today?

J: This is longer, for one thing. But also . . .

[At this point J's eyes close and her arms again take on their spontaneous trance movements.]

R: During the first few moments after awakening one is still in a light trance state (Erickson and Erickson, 1941). This together with my question about trance was apparently enough to reinduce her into another deep trance.

SESSION 2:

Part Two: Automatic Handwriting and Dissociation

Utilizing Spontaneous Trance for New Learning

[While J is in trance the senior author continues.]

E: Now there is something else I'd like to have you learn.

[Pause]

I'd like to give you the opportunity to learn a totally new thing.

[Pause]

And are you willing to learn something totally new?
Without much effort?

[Pause; J finally nods her head very slowly. The senior author arranges four sheets of paper and a pencil on the desk between them, so both he and J could have easy access to them.]

E: Notice my pauses in this section. To ask someone to learn something new is a threat, so I pause and then I slowly say without much effort to make it less threatening.

Converting Self-Absorption to Rapport

E: Now whatever you are doing
can be discontinued temporarily.
And you can come back to the office and join me.
And can move your chair closer?

J: Umm?

E: Move your chair closer to the desk and writing materials.

[J's eyes remain open after she adjusts her chair, but the staring quality of her eyes and slow body motions indicate she is still in trance.]

R: Here you are asking her to come back into close rapport with you. In the first part of this session you let her indulge in the *self-absorption type trance.* Now your remarks are beginning to convert her over to the type of trance were she is in close rapport with you so she can experience new hypnotic learnings by following your directions closely and exactly.

Automatic Writing, Age Regression, and Dissociation

E: Now I'm going to treat you like a child. Is that all right?

J: Sure.

E: There is paper there and pencils.

J: Can I act like a child? And treat me like one?

E: No, you are going to stop acting like -

I'm going to stop treating like a child.

[Pause]

But you can lean forward.
Now while looking at me, what do you suppose your hand might do?

J: Clap! [With a happy childlike laugh] I don't know what it would do.

E: Touch the pencil to the paper.

J: It's hard to control [as she picks up the pencil awkwardly].

E: You can control, you can write.

[Pause]

And you could write something you didn't know you were writing.

J: Not know I was writing?

E: And you could write a question to which you do not know the answer consciously.
And only know it unconsciously.

[Pause]

R: You introduce the possibility of automatic writing by first establishing a childhood or early learning set. Just as she first learned to write as a child, you hope a more childlike set will help her automatic writing. But she seized too eagerly onto the child role, so you had to correct it. Actually she was responding too literally to your earlier statement that you were going to treat her as a child.

E: Yes. She is responding as a child out of desire. I had to get her away from that because children can be pretty irresponsible.

R: The awkwardness she experienced in holding the pencil is a revealing cue about her state of age regression. You then give your first direct suggestion regarding automatic handwriting: She can write without knowing what she is writing. This not knowing, of course, facilitates further dissociation from her V adult consciousness.

Indirect Ideodynamic Focusing to Facilitate Automatic Writing

I'll give you an example of that.

[The senior author here describes an example of automatic handwriting. A patient who felt troubled about something requested that she be allowed to write a question and then an answer. Erickson distracted her with conversation as she spontaneously wrote her question and answer on different parts of a sheet of paper. He folded up the paper and put it in her purse. Three months later she reported that she found the answer to her question and requested permission to look at the paper that was still folded. She now unfolded the paper and saw she had actually written two questions. The first was, Will I marry Bill? The answer was, No. The second question was, Am I in love with Howard? The answer was, Yes. She was now actually engaged to Howard. Thus the automatic writing three months earlier had reflected her major conflict at the time and indicated feelings about Bill and Howard that would later become manifest in breaking up with the former and getting engaged to the latter.]

E: Now all of us have such questions.
That patient knew from my behavior that I would not read the question she wrote or the answer she wrote.
Let your hand wander as it takes hold of that pencil.

[Pause. J picks up the pencil.]

Now suppose you talk to me about something other than what your hand will write.

R: This is very typical of your approach when a subject seems to need help in trance. When a new hypnotic learning is still in the process of being formulated or expressed for the first time, you begin quietly and casually to give many examples of the desired hypnotic behavior. This seems to motivate subjects and give them unconscious clues as to how to proceed. It also gives time to make the necessary inner connections that will make the behavior possible; time for the subjects to realize that you really mean it, and you are willing to wait for them. It's the basic process of indirect ideodynamic focusing again. Your mentioning Now all of us have such questions tends to facilitate unconscious processes of search within her for some meaningful material to express itself in the writing. You attempt another dissociative approach by asking her to talk to you about something other than what she is writing.

Amnesia and Protecting the Patient in Trance

[Pause. J stares unblinkingly into Erickson's eyes, and as he stares back into her eyes, her hand with surprising quickness and firmness writes a clear sentence. When her hand

finishes the sentence and it is apparent no more writing is forthcoming immediately, he quickly and subtly turns the four sheets of paper over so the writing is now covered and a blank sheet is on top. J continues to stare into his eyes and apparently does not notice his paper shuffling.]

J: Was it a question?

E: Humm?

J: Was it a question? I wrote some questions?

E: Where?

[J now sees the blank sheet of paper, and a look of puzzlement comes to her face.]

You wrote a question?

J: Did I write a question?

E: Where?

J: Down here. [Much obvious puzzlement]

[Pause]

I thought the pencil moved somewhere, I think.

[Pause]

I guess I didn't. I'm holding a pencil. Why am I holding a pencil?

[Pause]

Did I dream something? Did I fall asleep? No, I didn't fall asleep because I have vivid memories of things.

R: Why do you cover up the writing she has just done?

E: You cover it up so she will feel safer: You are not trying to pry. You are also teaching her a sustained amnesia.

R: Even while in trance you are protecting her from seeing too much of that material.

E: Yes. That gives her an opportunity to write more. She knows then that you are not going to take advantage of her. I don't pry, I don't read it at that point myself.

R: All this puzzlement and doubtful self-questioning are indications of her developing amnesia as well as dissociation. So precarious is her ego consciousness that she's not sure if she's been dreaming or asleep.

Classical Description of Dissociation

E: Vivid memories you can share?

J: Yes, I had a very important one for me. You really want to hear it all?

E: Was the presumed question important?

J: I don't know. I just had a feeling of importance, of something important. I was holding a pencil, my hand felt as if it didn't move. I felt very stiff. When you hold a pencil and you are writing, you pinch your fingers together. But the pencil wasn't pinched in my fingers. That's why I felt like something was odd.
I was holding a pencil, and the only reason I can think of that I'd be holding a pencil is to write.
But I didn't feel like I was holding a pencil. It doesn't make sense. I don't feel like I was actually holding a pencil. But I see the pencil hi my hand so I assume I'm holding it, right? But my hand still feels kind of stiff. Not stiff like a board. But it is not - I don't know how to describe it - it's kind of numb almost. It has a different kind of feeling in there, right now.

E: Does this question seem to make sense? Does your hand want to write again?

J: Again? It feels like it wants to write but it can't because it doesn't want to hold the pencil to write. Do you know what I'm talking about?

E: I do.

J: You hold a pencil, you have to hold the pencil with the tips of your fingers so that you can control it and let it go the way you want it to.

E: What she is describing is the dissociation of her writing and that part of her conscious awareness. This is a classical description of dissociation from a subjective point of view. Her unconscious wants to hold the pencil differently than she holds it in the normal state.

R: Why?

E: Because its unconscious material! Just like when you are on vacation you dress differently. How different? Just different!

R: The fact that the pencil is held differently is a sign of the genuineness of the phenomenon of automatic writing.

E: Yes.

Body Dissociation and Depersonalized Language

J: My hand holds the pencil and *it* feels as *if it is* going to write, but it is not, it doesn't hold the pencil to write. It doesn't hold the pencil in the accepted manner to write.

E: Maybe it's automatic writing. [Pause]

J: That's possible. I never thought about that before.
But how can it be? Your hand still has to - all right, wait a minute. The muscles still have to hold the object to make it work.
Don't they? I don't feel like I'm even holding the pencil!

[She has in fact been holding the pencil throughout this discussion.]

But I *see* I'm holding a pencil! I don't feel the pressure.

E: Ordinarily a person knows he is holding a pencil, he doesn't have to see he's holding a pencil.

J: Right, that's how I feel, but I don't feel I'm like really holding a pencil, but I see that I'm holding a pencil.

E: Yes, that's right. Maybe it's because your hand wants to do some more automatic writing.

[Pause]

It is possible to put your hand in a position where *it* has an opportunity.

[Pause]

Maybe you'd like to watch it and see what it is writing, only, of course, you won't *know* what it is writing.

[Long pause. J's hand finally begins to move with decisive firmness and quickly writes a few sentences.]

J: Could I read it? There is writing there, is that my handwriting?
My hand feels very strange, like it's my hand but it didn't write anything.

E: Notice her language when referring to her own hand: *it* feels as *if it*is going to write . . . *It* is no longer herself.

R: Her dissociation is leading to a depersonalization of the dissociated body part and its activity.

E: She has to actually see the pencil to know it's being held. This again is evidence for a separation of conscious and unconscious.

E: Notice how I accept and reinforce the depersonalization by using it and contrasting it with the part of her that I address as you. She can *see* what she is writing, but this in itself implies she will not *know* what she is writing. You can see without knowing. I can just see those books, for example. Her questions and the strange feeling are all characteristic of the dissociative process.

A Dissociation Between Thinking and Feeling

E: Look in this place.

[The senior author thus distracts her vision for a moment and then deftly turns the paper over so J is again confronted with a blank sheet of paper.]

You look puzzled by something. Now do you want to read it?

[Pause as J looks in vain for her writing on the blank sheet of paper.]

J: Did I dream it? (In a very soft, faraway voice)

[Pause]

Did I dream it?

[The senior author now reveals one of the sheets of J's writing to her.]

E: Is this the writing?

J: What about this writing? It doesn't look quite like my handwriting, does it? Is that my own? First of all you have to tell me, did I write that? I *think* I must have, but I *don't feel* I did.
I found myself holding a pencil and therefore I put it back together: I must have written something because usually I don't hold pencils unless I do something with them. But I don't feel as if I wrote anything. This hand is my hand. [Referring to her left hand that did not write] This hand [her right that did the writing] feels more separate than this one [her left]. But they don't know, they don't feel as if they actually wrote.

E: Now just express here your intellectual impression: Did you write the writing on the other sheet?

J: I don't feel like I did.

R: Her remark, I *think I* must have, but I *don't feel* I did, indicates a clear dissociation between *thinking and feeling.* It's interesting to note that her ego consciousness associated with the *thinking* of her left hemisphere is retained as a part of her identity, *while feeling* that may be more associated with right-hemispheric experience is dissociated off.

E: All these questions and attempts at logic and rationalizing are highly characteristic of a genuine dissociative state.

R: It is as if her left hemisphere with its logic is trying to rationalize an act that may be outside its range of experience, just as patients with right-hemisphere lesions and deficits use their intact left-hemispheric logic to rationalize their behavior without ever recognizing its incongruities (Luria, 1973).

Furthering Dissociation: A Conflict Between Thinking and Feeling

E: All right, let's see what your hand thinks. Let your hand point to the writing that you did. Now just watch your hand start pointing.

[J's hand lifts.]

It might pick up the pencil and write, yes.

[J's hand does write yes.]

J: How can it know if I don't know? I feel that it can know, but my mind thinks I feel that, I feel that it knows that it wrote something. Something, somewhere! But I

[Pause]

I wrote something, but it's very

[Pause as J seems to fall deep into thought]

E: Very what?

J: My thinking isn't very clear right now [faraway voice].

E: Why?

J: I'm very relaxed. My thinking - it's like my feelings don't want my mind to think, particularly.

E: Let your hand point... to automatic handwriting. J: But it's going to point to nothing.

E: Perhaps it will write yes or no. [J's hand lifts the pencil.]

E: I thrust upon her a yes when I said the hand might write yes. This furthers the dissociation because it shows her she can write automatically, but she can also do responsive writing (response to Erickson's suggestion to write yes). At this point she does not want to think that she obediently wrote yes, so her feelings do not want her mind to think, particularly.

R: You have precipitated a conflict between her thinking and feeling.

The Subjective Experience of Dissociation

E: That's what we mean by automatic. Would you like to try to guess what it is going to write?

J: No. I don't want to try anything. I just want to let it go by itself.

E: Yet you can guess. The hand will write the correct answer.

J: I would think yes and no - because it doesn't feel like I wrote when I thought about how it felt when I was holding the pencil.

E: My question is: Did it write? [Her hand begins to write.]

J: It's moving by itself. It's moving by itself. Strange, I'm so aware of it.
[Whispered very softly] It is going.

[Pause]

It's holding a pencil. It feels, I don't know, it feels like my hand is a cosmic hand. I see it as a part of my body, but it's like a cosmic hand coming out of the clouds.

E: Do you think you might like to try more?

J: Not my forehead, but the rest of my being feels as if it's going to write more. But just not my forehead. It's like my forehead is pulling against the

rest of my body right now.

E: Let your hand pull over on top of the paper. J: Humm? [Faraway voice] E: Write.

J: Should I start it writing or just wait? I don't know how to do it. I mean I] don't know how to.

E: Is it enough? Is there any writing undone that you would like to do?

J: Yeah, I think so.

E: Let your hand start writing.

[Her hand begins to write several sentences as she looks at Erickson's face. As usual with automatic writing, the hand picks up speed till it's writing at a furious speed, seemingly much faster than normal. When she has finished, she shuffles the papers without any apparent awareness on her part so a blank sheet is again on top.]

E: By asking her the first question of trying to guess what it is going to write, I facilitate the dissociation and I let her affirm that she herself wants to do the automatic writing. She then gives many beautiful subjective expressions of the dissociation between mind and body by a person relatively naive about hypnosis.

A Question Structuring an Amnesia

E: Now we can ask: Do you think you can do automatic handwriting? [As if no writing had taken place]

J: Pardon?

E: Tell me honestly: Do you think you can do automatic handwriting.

J: I think I can. Anything is possible in the world. I think anything is possible.

E: I'm just talking about you.

J: I don't know too much about it. How *do* you begin? I mean my hand feels like - it's just a little bit mine, you know. Because it looks like it's mine but it doesn't - and the only way I've written is to hold the pencil between the pads of my fingers. I tried it with my toes once. Also my mouth and teeth. [Her automatic writing was sometimes done holding the pencil awkwardly between her second and third fingers with a closed fist, like a child's first efforts.] But right now, to be perfectly honest, my hand does not feel like it is holding the pencil to write with. You know what I'm talking about? I feel like I'm babbling.

E: You're talking and making sense only you don't know it. And Dr. Rossi's finding that out. Would this paper be all right to try automatic handwriting on?

J: Well, sure, I'll try it, but I mean, still tell me how to begin, exactly. I let my hand feel it, right? It feels like I'm not using my hands. So how do I know if it felt that it wrote, exactly? It felt like a hand coming out of a cloud that I could watch and see move maybe if I looked at it.

R: This question at this point tends to give her an amnesia for the writing she has just done. You are actually reorienting the conversation to a point in time before the handwriting was done so the writing activity tends to fall into an amnesic lacuna. This is what we have called a structured amnesia (Erickson, Rossi, and Rossi, 1976).

E: Yes, it sets the act of writing in its own cubicle of time. She then gives many classical expressions of the dissociative process: It looks like it's mine but it doesn't.

R: Her feeling that she is only babbling is another sign of the dissociation within her. Her words make perfect sense to us because we understand both sides - conscious and unconscious . But she cannot put the picture together with understanding even though she is trying, and thus her own efforts sound like babbling to her.

The Economy of Automatic Handwriting: The Variable Language of Yes and No

E: All right, now I'm going to do something. I would like to have you be interested and pleased.

[The senior author now reveals the first sheet of her automatic handwriting - Figure 1.]

J: I did that? Oh, my God!

E: You're amazed that you did automatic handwriting?

J: I wrote that? Can I read it?

E: You don't know what is written, you haven't read it, to my knowledge. You may want to read it or you may not want to read it, that's up to you.

J: I want to!

E: This is the second part. [Reveals the second sheet as well - Figure 2]

J: I don't know how to spell too well, do I?

E: Automatic writing is characterized by misspellings.

J: Oh, really.

R: You've done very well!

R: She writes her words with unusual clarity for automatic writing.

E: Yes, usually there is more economy of effort. A yes answer can be condensed into a vertical line and a no into a horizontal line.

R: So a vertical line is actually an abstraction of yes and a horizontal line is an abstraction of no.

E: That's right. And an I don't know can be a horizontal with varying degrees of angle to mean it is more like yes (toward the vertical) or more like no (toward the horizontal). Thus:

A yes line written on the opposite side of the paper could mean a no. A yes line on top of the paper is yes, but if it is written on the bottom of the paper, that could signify the reverse, a no.

Multiple Meanings in Automatic Writing: Caution in Interpretation

J: Can I read it out loud? [She reads.]
To rest and be at one with the sun is okay.
To get down again just slide down on a moon beam.
Gee, that means you have to wait till night time and the sun cools down toget down.

[The senior author now reveals the third sheet of her automatic writing - Figure 3.]

Figure 1: The first sheet of Jill's automatic writing. The larger top line script is automatic writing. Underneath each line is Jill's normal adult writing of the same words done for later comparison.

I wrote?
Gee, what strange writing!
It doesn't look like mine, that I know! [She reads.]
The sun is not too hot to splash in.
I love the sun and I am at one with the sun's center.
We are the same and I leave the fire whole again, not burnt.
And love is like the sun.

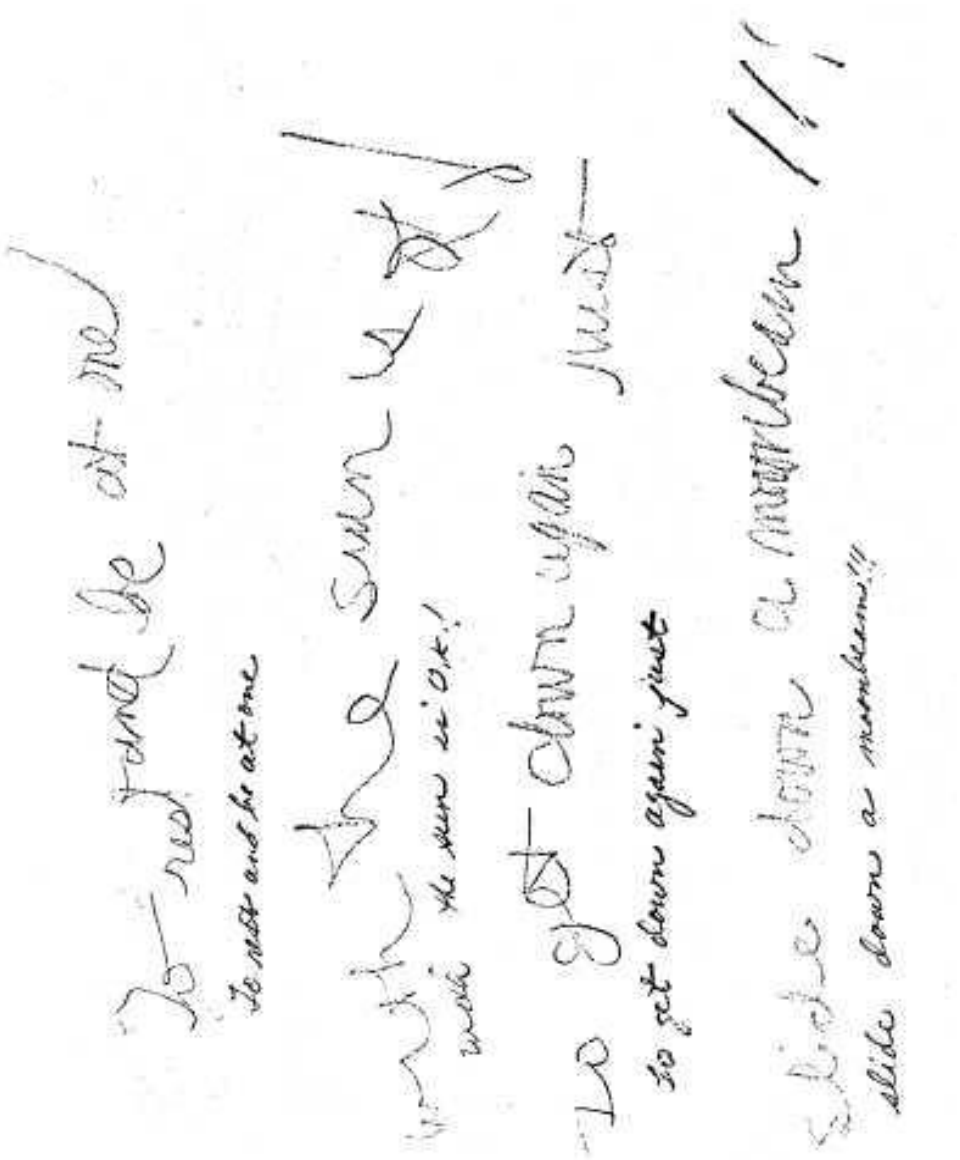

Figure 2: The second sheet of Jill's automatic writing. The large script is the automatic writing and beneath each line is Jill's adult writing of each word done later for comparison.

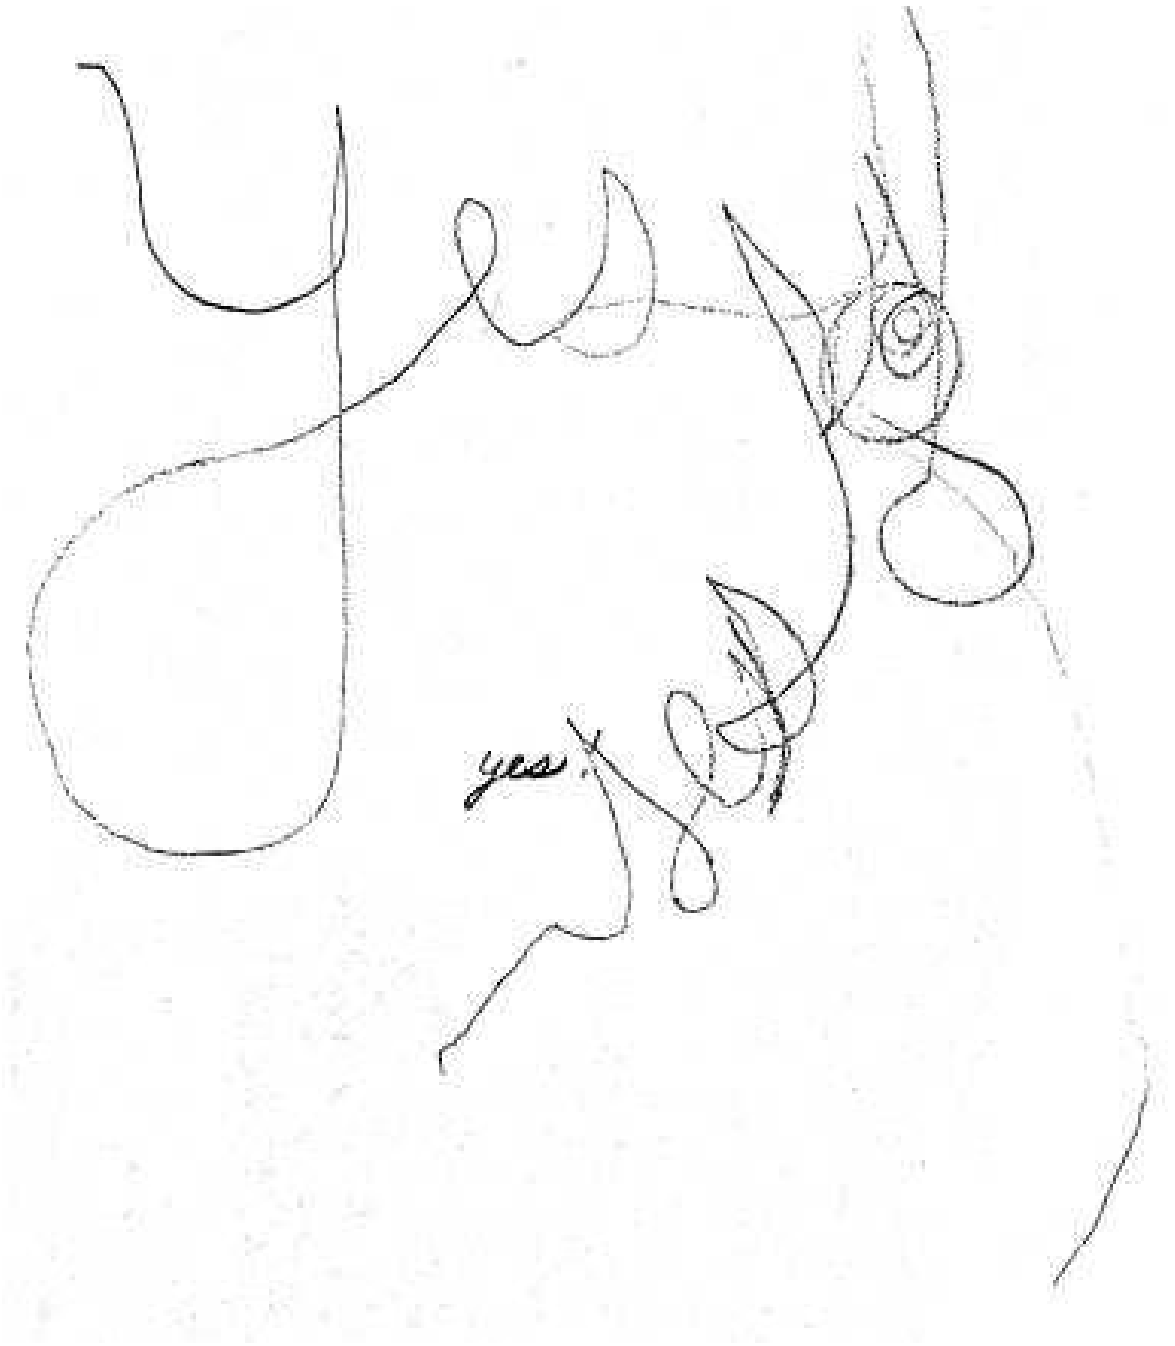

Figure 3: The third sheet of Jill's automatic writing, where she writes yes several times in large, sometimes overlapping script. The small clean yes toward the bottom is her normal adult writing, done later.

Figure 4: The fourth sheet of Jill's automatic writing. The larger script is automatic, the smaller, repeating the same words, is her normal adult writing done for later comparison,

[The senior author reveals the fourth sheet of paper with her automatic writing - Figure 4.]

I wrote that too?

[She reads with deep feelings and some tears.]

Will the unfulfilled love of the new destroy my life?
Is there a way to leave the center of the sun without jumping down deep into the fire and falling?

E: Does it mean something to you?

J: In a deep way, but not in a lollipop way.

E: I have a very ridiculous question to ask you: What color is your hair?

J: Blond. Rinsed Blond. My natural color has some blond in it.

E: Because my daughter was asking me about a blond-haired girl and I did not know a blond-haired girl! [Referring jokingly to the fact that Erickson is color blind] And Pete Thompson, who I've know for many years . . . [The senior author goes on for a few minutes about blond hair thus starting a casual conversation distracting from the psychological work at hand.]

E: Reading aloud is different than reading silently so she had to ask for specific permission to read aloud. It's another aspect of her dissociation. Now I made no effort to find out what she meant. When she said this was strange writing, that means it is foreign to her consciousness. You have to be aware of the possible double-meaning words like sun that could be son. You always look for those possibilities. I may have my ideas about what it means but I'm not going to ask her to betray it.

R: The fact that she speaks of the possibility of her life being destroyed suggests that you are right in believing that the issues are delicate and so your caution is justified.

E: Yet she *is* trying to betray something to me even though I don't feel I'm entitled to it at this early stage of the game. So I let her betray something to me but I choose what it will be: her blond hair.

R: You utilized her premature impulse to betray by sidetracking the betrayal to the relatively innocent issue of her artificial blond hair.

E: Then from betrayal I further deflect the conversation to my daughter, my life, and finally my friend Peter which takes her far away from the hot material indeed. For psychotherapy you take learnings out of context and use them in new ways.

Source Amnesia

E: By the way, what do you know about that? [Referring to the tapestry on the office wall]

J: Is it something pre-Columbian? I don't?

E: What makes you think it is pre-Columbian?

J: I saw the design on there. The design? The design looks like a, I don't know? I really don't know. The faces though look like it somewhat. I could be wrong but I don't know - it's attractive - but I don't know too much about it.

E: Was it I who told you that was pre-Columbian?

J: Who, you?

E: Yes.

J: Well, I never asked you about it, that I know of. Why? Were you supposed to have?

[Pause]

Were you supposed to have told me something about it?

E: Not supposed to - I did!

J: You did, really!

R: Here J is demonstrating a source amnesia: She knows about the pre-Columbian symbols you spoke to her of earlier while she was in trance, but she does not know the source of this knowledge.

Age Regression via Visual Hallucination of Many Self-images

Indirect Associative Focusing to Facilitate Certain, Direction in Trance Induction

After hearing an interesting case history for a half an hour about the adoption history of two little girls, their struggle for acceptance, and the many lives they lived in different homes, Jill becomes fixated in her attention and her eyes blink as if she were going into trance. Her eyes finally close. A few minutes later her hand begins to levitate and float about spontaneously. She is evidently in close rapport because she smiles and sobs at appropriate places.

E: And J
in your lifetime

you really have been
many different little girls.
And one of the things you can do, Jill, you can do it with your eyes open,
you can do it with your eyes closed. Line up
a whole line
of girls. Have each of them in some significantly meaningful state.

R: You are again using indirect associative focusing when you tell this interesting case about little girls to begin the process of activating her own personal associations and memories of her own childhood. She is entirely absorbed in your story; her attention is focused and fixated so she naturally begins to manifest the initial signs of trance.

Here you make a smooth transition from your case history to your first overt directive to facilitate J's current trance experience.

E: Yes, and if she has any doubt within her about being able to see these little girls, you depotentiate it by giving her the choice of having her eyes open or closed. I then use the words significantly meaningful to help her reach personally meaningful material.

The Objective Observer

E: As for you, Jill, you can be an objective intelligence off to one side, delighted to look at those little girls, that long line of little girls. And you can describe them as freely as you wish.

R: Here you give her consciousness the task of being an objective observer. Perhaps this is the best place for consciousness in this initial, uncovering stage of therapy. You allow the unconscious to do the uncovering via a series of images of girls that consciousness can simply receive. Consciousness is thus placed in a receptive mode (the ideal mode for trance), where it is not likely to direct or interfere with images emerging automatically from the unconscious. The phrase freely as you wish then gives a positive and reinforcing orientation to your permissive suggestion to describe her experience.

Catharsis Balanced with Positive Affect and the Objective Observer: Implication

E: You can be pleased, amused. You can empathize
with the little girls, but you will be a detached intelligence.

R: Telling her she can be pleased and amused facilitates the experience with a positive affect. Allowing her to empathize permits emotional flow and a possible catharsis while still protecting her with the objective observer. E: Pleased and amused evoke different aspects of the spectrum of her inner life. You can be amused by a bad girl and pleased with a good girl. So she has a tremendous amount of freedom to explore all these possibilities in her past - and all this by implication.

Now being that detached intelligence you need not know that you are Jill. You are something separate. But a knowing something. You need not know that those little girls are a succession of Jills. And I would like to have you enjoy that experience tremendously.

Covering Many Possibilities of Response to Depotentiate Doubts

E: You see those girls as if they were tangible hallucinations or you can see them in your mind's eye or you can see them not knowing that they are mental images. You see them and think that they are flesh and blood.

R: You now cover a number of possible ways she can see the images: as hallucinations, as images in the mind's eye, or a total belief in their reality out there as flesh and blood.

E: Yes, you also depotentiate her doubts by giving her many possible modes of response.

Not Knowing to Depotentiate Left-Hemispheric Functioning?

E: And you need not know that each is related to the other. But I would like to have you perform this task very completely, and you can do it while in a trance state or you can be fully awake and recall the experience as an extremely vivid dream that you can relate to me and to Dr. Rossi. And you can feel free to discuss that little girl or that slightly bigger girl or that much bigger girl. That is something that you can do in a manner far better than you know. In a manner that will be a pleasure for you to learn that you can do it so well. Now let your hands come to rest on your thighs and just rest comfortably.

R: I wonder if not needing to know the images are related together is a way of dismissing or depotentiating left-hemispheric functioning?

E: That could well be. As I read this transcript I'm amazed how long experience has taught me to cover many possibilities of reponse whenever I'm exploring a patient's inner life.

R: Yes, you enumerate many possibilities of response, from constructing the images while in trance to recalling them later as a dream.

Voice Locus as a Cue for Visual Hallucinations

E: And feel very, very comfortable, and whenever you want to start, you line those girls up [At this point the senior author shifts his body 45 degrees away from J so he is now oriented to an imaginary wall in that direction] against that nice white wall. [J opens her eyes and blinks with a blank look] And you are looking, is there enough wall there for you to see all of them? [J looks up in the new direction Erickson has oriented himself to. She now stares with dilated pupils with her eye focus shifting about. She is apparently hallucinating with her eyes open.]

J: It isn't just a wall.

R: This is an interesting use of voice locus and body reorientation as a cue for the direction where she may experience a visual hallucination.

Dangling Phrases to Facilitate Self-Expression

E: I know.
I can say it's a wall, but you can say it's a -

J: Porch, it's a gate. But it is white and some of the paint is splintering. There is a little girl standing behind it, but it is like a gate porch fence kind of. And there is a big tree with gray bark that crumbles off when you put your fingernail on it, and she is doing it. She is watching it fall down and the sun feels very warm. She is wearing a dress that is patched from old sheets, or new sheets. It has patches on it. She likes the design of the patches better than her dress because it feels fuzzy under her finger and it has a red flower on it. And she is thinking, she is thinking the tree is her backyard tree. It is a Sunday and her father is coming with ice cream, but she knows it really isn't true.

E: But it is nice to think so.

J: She has a little calico cotton dog, a red background with little white flowers and its nose part is orange. It is like a patch dog made of more patches. She loves it. And she feels that now she is feeling it and she is hugging it.

R: You use an incomplete dangling phrase here for her to finish.

E: Yes, dangling phrases give her an opportunity to express herself.

R: You always let the patient fill in the blanks whenever possible. In this way the therapist is always seeking out the patient's frames of reference and association rather than intruding his ideas on the patient.

E: Yes, therapy should always be designed to fit the patient and not the patient fit the therapy. Her vivid description of how as a child she crumbles the gray bark when you put your fingernail on it is one of those ingenuously personal details that tends to ratify trance.

Body, Head, and Eye Orientation as Cues to Visual Hallucinations

J: And she is watching someone walk up the dirt way. It is not paved. It's got stones, and he kicked one stone and she liked it. And because he kicked the stone she liked him. And she is waving to him now. And she knows that she wants to push the fence, but she is going to have to walk around, more than push it right there, to where there is an opening. And she is going up to him. She wants to hug him.

R: As she spoke these words her body, head, and wide-open eyes oriented in the direction where she was apparently hallucinating someone kicking stones. As she talks about the fence, she looks

up as if it's taller than herself.

Evoking a Complex

J: She feels she doesn't have a father. She would like the man to be her father. I can feel that she does.

E: She doesn't know that there are other little girls standing there a little bit older.

J: And she has a father, but she is not sure of him because she is walking down the sidewalk and there is a man coming along supposed to be her father. She feels like she is pretending, really, but she wants that pretending to be real. So she is going to pretend real hard and she is going to go over to him though she doesn't know him, and she feels like she is brave, you know.

R: Jill is obviously incorporating elements of your case about the adopted girls here. It's almost as if your preinduction case history is now functioning as an implanted complex (Huston, Shakow, and Erickson, 1934).

E: She is using some material I offered, and what she uses is a function of her personality, not mine. Her using this detail indicates how, like most children, she has had fantasies about being adopted. My preinduction story evokes that complex within her.

Many Levels of Simultaneous Functioning in Trance

J: I can feel it what she is feeling, I can see it in her face, but she is also very happy and waving-like. And she goes and says I have a new house. She is not at the fence anymore. She is not in the same place at all. She is in a neighborhood where there are regular homes. There are some fences and a gate, but it is different, she is just different.

And she goes up to him and she says, Can I walk with you and hold your hand? Then she knows that, that he is going to be, he is really going to be her father. And they walk into a house and it has some steps in the front, reddish-colored steps.

E: When she says, I can feel it, what she is feeling, it indicates that she is functioning on many levels simultaneously here.

R: The detached observer facilitates these multiple levels of functioning.

Two-State Dissociative Regression to Facilitate Objective Perception and Left-Hemispheric Functioning

E: Does she know about the first little girl? [Pause]

J: No, I don't think so. No.

E: Well, you have seen the first little girl, the second little girl.

J: Yeah, but -

E: There are a lot of them.

J: But she doesn't I don't think she realizes that there was another little girl standing near fences, but they were different, they feel different.
Now she is in school.
She really does live in that house.
And she goes to school, there is also another little girl that was at a party.
They are both somehow. One is at school, one is at a party.

R: You are now reinforcing the dissociation between the images of the two girls when you ask if the second knows about the first little girl.

E: Yes. This is another example of what I called a two-state dissociative regression (Erickson, 1965a). You can see things better in such a dissociative state. Dissociation helps you realize different experiential states. If these different experiential states do not know each other, the observation of them can be all the more objective.

R: The objective observer and such two-state dissociative regressions could thus be means of facilitating the left hemisphere's objective perception of the many dimensions of the total personality. Since Jill falls so easily into right-hemispheric experience, her psychological problems may stem from a relative weakness of her left-hemispheric functioning; her ego identity and stability may be too fluid. The objective perception you are facilitating here may be a means of strengthening her left-hemispheric functioning.

Facilitating the Objective Observer: Resolving Childhood Problems

E: I want to make clear to your intelligence that you will become those little girls and that they really are all the same little girl at different times. But you can see any other girl that you wish.

J: There is a little little girl, she looks like someone I know. She is going up to these high school girls. She is very little. She is only about two or three, wearing a diaper.
She lives right near the high school and there are lots of steps because shelives above a store, but she goes, she likes to go out the door and walk
down these steps. Sometimes she has to crawl down, and she likes to go over and see what is going on.
She has chubby little legs and one curl across the top of her head. She ispulling a little dog. Not a real dog. And she smiles at this big high schoolgirl, really pretty girl who is with her boyfriend. And they seem to be talking about dancing or something like that. She knows what dancing is, though she is little.

R: The objective intelligence can recognize that all the images are of the same person even though each image (or ego state related to a specific age) remains dissociated from all others.

E: The objective observer that sees and describes current realities can also alter and change earlier childhood realities.

R: This is really amazing! The mind is a self-improving system that can change past distortions and traumatic experiences from the more adult point view. I have described a class of healing dreams wherein this appears to be one of the constructive functions of dream experience. (Rossi 1972a).

Facilitating the Objective Observer: Language Cues of Interacting Age Levels

E: Find all those girls named Jill and look at little Jill and little bigger Jill and a little bit bigger Jill and a bigger Jill. Because they really don't know each other. Of course there will be other boys and other girls. But little Jill …

[Pause]

And each little Jill has her own tune, and each of them, they won't really see each other. They won't even know that they are all there. Your intelligence can see them and understand them.

[Pause]

J: There is another girl. She is just four. No, she is not even four, she is almost four. She loves the boulevard because there is so much going on. The girl that takes care of her is looking all over for her. She is delighted to get down those stairs and down the street, and there is a big movie show. She is walking by it. Then there is another boy. She turns the corner and there is a huge park, it looks so big with grass in the middle, and this lady that everyone calls Crazy Mama is picking up papers. She has a white scarf on a huge behind and a big big arm and a white apron and a brown blouse. And she has a stick that she picks up papers with. This little girl is watching her, fascinated, because they say she ate her father and put him in a pot and cooked him. Could it be true? Then there is another girl who lives in that building, but she is older. She is five and a half. And she is very sad because she is moving away and she doesn't know where except that it is far, it is very far.

[J now gives a long and detailed account of moving from one part of the country to another and her perception of a few more age levels. Throughout this period her eyes are alternately opened and closed. When they are open, she is apparently hallucinating visually as she looks about describing the scene as she sees it. She concludes with the following.]

J: She is about ten and she is in the fourth grade and she knows all her work so well that they are skipping her into the next grade. She is very proud. She doesn't have pretty dresses like the other ones. The shoes have patches on them, but she doesn't mind it. She likes the designs on the patch. It doesn't matter. But she is doing very well. She has two

spelling books because she is doing the next grade work and her work, and they are skipping her. She is proud when she gets up and knows all the right answers. And they are moving again. [Pause]

R: You're again suggesting that each girl will not recognize the others even though the objective intelligence can relate them as one. Why?

E: There can be a freer recognition and recovery of many self-images if they do not have to recognize each other. The adult does not like to recall the experience of wet diapers of the infant or the running nose of the child.

R: So the objective observer that relates them is detached even from her adult self.

E: In this section we also witness the shifting levels of her vocabulary and perceptions. Words like boulevard, delighted, huge, and fascinated belong to the adult. Yet they are used to describe childhood images in a childlike way, as when she speaks of Crazy Mama's huge behind and her question could it be true? that she put her father in a pot and ate him. The detached, objective observer can recover childhood perceptions with an adult's understanding. This is a valid characteristic of trance. The detached observer is a center pole and fixed reality about which the patient can explore many childhood experiences in adult words. Memory is not all of one piece; it's always fragments of adult and child interacting.

Posthypnotic Suggestion for Time Distortion Yielding Long Rest and Recovery

E: Would you like to rest?

J: I am very tired.

E: All right.

Just close your eyes and rest.

Very comfortably.

Rest.
And have a long rest.
A rest that seems hours long.
Hours long with hours of comfort.

[Pause]

And as the comfort builds up in your body that supports that intelligence, and looks at that larger number of little girls each named Jill, but a different Jill each time, feeling different, doing different, thinking different, and really different, yet always Jill. And soon this

intelligence will renew its curious, fascinating looking at that long line of girls all Jill. None of which can see the other, all of which have only faint memories, partial memories of smaller Jills, and only partial ideas of what the bigger Jill is like that this intelligence can look in curiosity and interest and enjoy describing each one of those Jills. A feeling so rested now, as if you had eight hours of sound and restful sleep.

[Long pause]

It is going to be a pleasure to open your eyes and start talking about those girls.

E: I use time distortion here to allow her to adjust to the awake state, yet allowing her to retain all the memories of the different Jill states.

R: You are giving her a posthypnotic suggestion for hours of time distortion. We will see after she awakens just how effective the suggestion has been.

Confusion of Trance and Dream

J: I felt like I fell asleep. But up here, I think I know different. Is there a Kleenex? Thank you.

[She yawns deeply]

I felt like I fell asleep and had some dreams. Did I really fall asleep? Did I? I don't think - I feel like I fell asleep, really fell asleep.
I was dreaming about when I was much younger.

E: It was a nice restful sleep.

J: I know. That was not polite.
I didn't come here to fall asleep in a chair. My body feels like it was sleeping. I was dreaming about -

R: She begins by describing a dissociation between *feeling* and *thinking* in her evaluation of her trance. She then confuses the trance with dream experience.

Trance Reinduction via Suggestion of Dream: Language Cues to Visual Hallucinations

E: But the dream is continuing.

[J closes her eyes momentarily and appears to lapse back into trance. She then opens her eyes and continues.]

J: I was dreaming about when I was much younger. It seems so vivid. It *almost* seems like I

can see myself standing over there.

E: Sitting there and growing.

J: When I was a little girl. Of course exactly this one plaid dress that I wore I *can* see myself right over there. I wore it until no one could wear it. I *really* can see myself standing over there and going home. We lived on a street called X Avenue. The best part of the place was my father had put like a gate with a fence and a trellis with flowers all over it. I loved that. The house was OK, but it was small. But that part when you walked into the house through the trellis, you felt like you were entering somewhere.

E: And you can see yourself.

J: That's the strange thing. I can see myself right over there. Standing doing that. I can almost reach over there and touch that trellis.

R: You reinduce trance by simply suggesting the dream continue.

E: Yes, we witness the rapid transition from the more awake state, when she uses the past tense to say I was dreaming, to the trance state, when she next uses the present tense, It seems so vivid.

R: The rapid development of visual hallucinations with her eyes open is also indicated by her linguistic transition from It *almost* seems like I can see myself standing over there to *I can* see myself right over there. to I *really*can see myself standing over there ... She then admits her perplexity when she says it's a strange thing that she can see herself over there and almost reach over and touch the trellis she obviously is hallucinating.

Two-State Dissociative Regression

E: And I'd like to have you discover something missing. There are two of you there, one taller than the other. Only the taller one doesn't know that the smaller one is there, but you can see it.

J: The taller one is - there is one in this plaid dress, me in the plaid dress going in from school. And there is another girl wearing an older outfit, she is in high school coming back to see this house because she lived there once. But she is wearing a pongee pink plaid skirt, in fact she made it herself. She learned to sew so she could make them. Very pretty and she washes them and takes care of them herself so they are always very fresh. She is going to see that house. She is not sad, just nostalgic because she is looking to see if there are still marigolds growing there because she lived there once. And she loved these flowers that grew there. That is what she is coming to look for. This other girl that is walking from school, she feels like stopping here and asking her if the flowers are still growing there. She would even like to ask if she could come in that house again and look around.

R: In the first sentence she begins with a phrase describing the taller and older girl and then shifts

to the younger in the plaid dress. In the second sentence she returns to the older girl in high school coming back to see her former house where she will see her younger self. Within a moment she thus creates a situation wherein her younger and older self-images could be plausibly interacting. You suggested that the taller girl not know the smaller one is there, but by the end of this section it's apparent that the taller is seeing the smaller. So you must now try to reinforce the two-state dissociative regression.

Reinforcing Two-State Dissociative Regression: Creative Rationalizing in Trance

E: The smaller girl doesn't know the larger girl is there.

J: She doesn't see anyone else. She is just walking right into the house. But the taller girl thinks that she is having a dream or something because she thought she saw this girl to talk to. But she was looking at the trellis, and she looked and there was really nobody there. She had a strange feeling, as though it were a memory. Or, could someone run in that fast? I think she feels like she - I don't know, like she is dreaming. [The senior author continues suggesting older self-images until Jill has received significant periods of childhood, adolescence, and adulthood, into her current marriage. Particularly prominent are a series of memories about moving from the eastern seaboard of the U.S. **where she was born, to the west, where she now lives.]**

R: You now reverse your earlier suggestion and have the smaller girl not know the larger girl is there. Jill responds immediately to this reversal by rationalizing but the taller thinks that she is having a dream or something because she thought she saw this girl. . . there was really nobody there.

Awakening with Distraction to Facilitate Amnesia

E: And now let's draw a curtain and leave all that's happened behind the curtain. You shut your eyes. And everything that happened will be behind the curtain of yesterday, and today you will open your eyes into today, ready to begin a new work. And so sleep for what seems like a few hours of very restful sleep. And by the time your left hand gets down to your thigh, it will seem as if hours of restful sleep had passed and you can then awaken.

J: Excuse me. Oh, what a yawn [J stretches and obviously awakens].

E: Now there are some things I would like to introduce here.

[Erickson now distracts J with some interesting anecdotes about his family and the process of memory in psychological development, how different personality types remember via intellectual versus emotional associations, body associations, etc.]

Testing for Amnesia: Open-Ended Questions and Implications

E: Now, what work shall we do today?

J: Um?

E: What work shall we do today?

J: Whatever you would like. I guess I feel a little sleepy.

R: Plane trip make you sleepy?

J: But actually I am not tired. I don't feel like I would go to sleep.

R: After distracting her with your stories for about five minutes, you test for amnesia with an open-ended question, Now what work shall we do today? - with a certain tone and manner that actually implies no trance work has been done yet today. When she says she feels a little sleepy with possible reference to trance, you dismiss it by questioning whether it was the plane trip here that made her sleepy. This question tends to reorient her to the earlier part of the day, when she came to Phoenix by plane, and implies that she just arrived and has not yet done any trance work.

A Successful Posthypnotic Suggestion: Ratifying Trance by Time Distortion

E: Carefully, without looking, what time is it?

J: About five?

E: Five what?

J: I mean, probably about five o'clock. I woke up.

J: My body feels morningish. But I know it's not because I wouldn't be here at five in the morning.

E: What time did you arrive in Phoenix?

J: I think I woke up at five this morning. Anyway. I forgot. What time did I arrive? About eleven-thirty? Eleven-twenty?

E: How long did it take you to get here?

J: About twenty minutes.

E: Now it is five o'clock? What have you been doing?

J: I don't know exactly. We were talking.

E: About what?

J: Well, just now you mentioned something about personality types, right?

E: Yes.

J: Genetic structure.

E: Do you want to look at your watch?

J: I have been somewhere else. I really have been somewhere else, haven't I?

R: It is only two o'clock. How come you estimated five?

J: It's not like five in the morning, but it seems like five in the evening. But it was only two? I really must have been somewhere else.

R: Your questions about time established that she has experienced a form of lengthening or expanding subjective time that is very characteristic of trance (Cooper and Erickson, 1959.) Three hours of time distortion is more than usual, however, and indicates that she is successfully experiencing your earlier posthypnotic suggestion to have a rest that seems hours long."

Indirectly Assessing Amnesia

E: This time data is very important.

R: Yes, really!

E: And she had no idea that this would occur, nor did you.

R: That's right. It was a spontaneous thing.

J: What does that mean?

E: It happened that I personally knew it would happen.

J: Really?

E: Yes. It feels like five A.M., you think it was five P.M.

E: Many of my remarks in this section are beginning to lay out opportunities for her to break through her amnesia. But none of these hints helps. Rather than telling the patient outright about the time distortion, as is frequently done in experimental procedures, I prefer the indirect approach of assessing just how strong it is.

Confusion of Time and Place Ratifying Trance

J: Confusion.

E: You are really not tired. But you feel you have been away.

J: A lot of confusion.

R: This sort of confusion she experiences on awakening is another criterion of deep trance involvement.

Questions Indirectly Assessing Hypnotic Amnesia: Rationalizing Trance Associations to Maintain Amnesia

E: Now, where is the place you think you must have been some other place, east? west? south? north?

J: How's that?

E: You say that you feel as if you have been some other place.

J: Yes.

E: Was that east, west, south, or north?

J: East and west both. I don't know why. Why east and west?

E: That's right.

J: I don't feel like east and west. Why was I east and west?

R: Does it make any kind of sense?

J: No, it just feels in my shoulders like I was east and west. Figure that one out, I can't.

E: Now let's make mention of something else. How high is a fence?

J: Depends.

E: How high is a fence? How high do you feel a fence is?

J: First I feel it is high. Really high. Yeah. Why would I feel that way? When I sit down, maybe it is that high. Because I am sitting it must feel high.

E: Trees have bark. How does it feel?

J: Dusty and crumbly. Do you ever like to do that? Do you?

R: Oh, yeah, I love that. Especially in a big redwood forest. Is redwood bark dusty and crumbly? I thought grayish bark is dusty and crumbly. [The senior author provides further trance associations, to no avail. J remains amnesic for her trance experience.]

R: You ask her a series of questions to indirectly assess her amnesia and give her an opportunity to break it down?

E: Yes. Since her trance memories were concerned with the moves from the east to the west coast, my question about directions might have enabled her to build an associative bridge to her trance experience.

R: She acknowledges the relevance of east and west, but she does not know why. She is thus sensing something about the relevance of your question, but the trance experience remains amnesic.

E: Since that did not break down her amnesia, I hint about the fence that was so high in her hallucinations that she had to look up.

R: Her response that it is really high again indicates that some trance associations must be leaking through, but still the basic amnesia is not broken. In fact she goes astray when she tries to rationalize that a fence is high when she sits down! Although she acknowledges the trance associations you supply, she rationalizes them away. I wonder if the same process takes place in everyday life, when we may have current intentions about some matter that our right hemisphere knows about but our left hemisphere tends to rationalize away.

E: I make yet another effort by mentioning trees have bark as a way of building an associative bridge to her trance memories of the gray bark she crumbled in her fingernails as a child.

R: I join in with more associations about grayish bark, but she cannot use them. Her amnesia remains intact.

[This session now ends. J was seen for a few more sessions during which she learned to utilize her spontaneous trances for artistic work and self development.]

Case 13 Hypnotherapy in Organic Spinal Cord Damage: New Identity Resolving Suicidal Depression

[*Previously unpublished paper by the senior author and reedited for this volume by the junior author.*]

Some years ago a young woman in a wheelchair approached the senior author and declared that she was profoundly distressed - in fact, suicidally depressed. Her reason was that an accidental injury in her early twenties had left her with a transverse myelitis: she was lacking in all sensations from the waist down, and she was incontinent of bladder and bowel. Her purpose in seeing the senior author was that she wanted to secure a philosophy of life by which to live; the incontinence of bladder and bowel and confinement to a wheelchair were more than she felt she could endure. She had heard the senior author lecture on hypnosis and had reached the conclusion that perhaps

by hypnosis some miraculous change in her personal attitudes could be affected. She explained further that as a small child she had been extremely interested in cooking, baking, sewing, playing with dolls, and fantasizing about the home, husband, and children she would have when she grew up. At the age of twenty she had fallen in love and made plans to marry upon completion of college. She had set to work filling a hope chest with hand-sewn linens and designing her own wedding dress. All she had ever wanted was a husband, a home, children, and grandchildren. Her love for her own grandmothers was a strong factor in her life, and she shared much emotional identification with them.

The unfortunate accident resulting in the transverse myelitis put an end to all her dreams and expectations. After some ten years of stormy difficulties and complications, she became able to use a wheelchair and to return to her university studies. Even with this improvement in her situation she saw no future for herself in the academic world, and became progressively depressed with increasing suicidal ideation. She had finally reached a point at which she felt some definite decision had to be made. Therefore she wished the author to induce a very deep hypnotic trance and discuss possibilities and potentialities for me. Don't speak too softly or gently of encouragement because I will listen with all my intelligence, and if you try to soft-pedal my situation or mislead or misinform me, I will take it that you see no genuine hope for my happiness in the future. I want to be fair with you. I have given you an enormous problem, that of deciding whether I shall live with some philosophy which will make life worthwhile, or whether I had better call it quits and cease to be a dependent, incontinent, ill-smelling wheelchair occupant for life.

I would like to return next Saturday for your answer, because I know you will need time to think about the problem.

But now you can hypnotize me. I have read just enough about hypnosis to know that you can't give me posthypnotic suggestions to prevent my suicidal intentions if there is no hope for me. Hence I shall attend carefully to you for the exact meaning or implications of what you say. So please, just train me to be a good subject.

Initial Trance Training: Two Simultaneous Trains of Thought

Her request was abided by and, probably because of her deep motivation, a very deep somnambulistic trance state was elicited. She was tested with great care for her ability to manifest the phenomena of deep hypnosis. Depersonalization, dissociation, time distortion, and hypermnesia of the happy past were either avoided or the suggestions were worded so carefully that there could not be even a seeming attempt to change her views and attitudes.

One suggestion of a therapeutic character that did come to mind was a well-known song of the old variety, which she was asked to hallucinate, visually and auditorily, with an orchestra and singer. The song was the one about the toebone being connected with the footbone, the footbone with the heelbone, the heelbone with the anklebone, and so on. To mislead and confuse her in any speculations that she might spontaneously make, she was asked to be annoyed by hallucinating at the same time another orchestra and singer interfering with the first singer and orchestra. This second group was performing the song Doing What Comes Naturally. My rationalization to her

for this apparently involved maneuver was that I wanted her to be able to entertain simultaneously two different trains of thought, and I could think of no less objectionable way of teaching her that she could entertain mentally and evaluatively compare different sets of thought. The harmless popular songs were as innocuous a way of accomplishing this and of giving such instruction as I could think of.

Unsuspectingly the patient accepted my explanation and became interested rather than annoyed at listening to two different orchestras and two different and rather silly songs at the same time. In reply I commented that it would be quite a problem to discover if she were listening to me with one ear and to the songs with the other ear. (This was another distraction.)

She proved to be a most unusually capable hypnotic subject and fortunately manifested complete trust in me upon arousing. She was particularly adept in experiencing hypnotic amnesia. Apparently her intention to carefully scrutinize my statements with extreme care while she was in trance had the effect of relegating any understandings and memories achieved during trance to the unconscious mind.

Facilitating a Yes Set with Personal Truisms

During the next few days an informative history was obtained from an intimate friend of the patient. From such information came various items of fact that could be utilized to help the patient give attention and credence to the author's statements. By this means a validity could be attached to the therapist's statements attested by the patient's own personal knowledge, rather than a validity achieved by the taking of a formal history. This is a much more effective method and may be used to elicit unwitting but helpful cooperation from the patient.

R: Since this was a particularly difficult patient who placed many restrictions on you, it was particularly important to achieve a yes set by gathering and expressing information that had a particular force of truth for her (personal truisms). What were some of the items of information you gathered, and how did you use them?

Formulating the Therapeutic Plan

The next Saturday afternoon, beginning at 1:00 P.M. and ending at 5:00 P.M., was spent with this patient. At first she was watchful and wary, but she soon concluded that the author was fully honest in his intentions of direct, open, and straightforward handling of her problem and his task.

An outline and analysis of her problem was made into a typewritten account. She was shown a separate copy of this material with certain phrases and sentences omitted, and a carbon copy of the account she held in her hands was left lying carelessly on top of the desk. The full copy of all the proposed procedures I planned without omissions was carefully locked up in the desk drawer. The edited material had been worded to omit any use of such words as suggestions of a therapeutic character, rationalization, and unsuspecting as parts of the general analysis of her character. In other words the purpose was to convince her that her wishes were being met exactly as she demanded and that I was seeking only her ratification of my understanding of her wishes.

She read the typewritten material carefully, agreed that the material I had attributed to her in my quotations adequately summarized her thoughts and desires, and agreed that if I wished, I could proceed. Then she interrupted, however, to ask what I intended to do with my typewritten account, to which the reply was given that if she decided the philosophy of life I offered was worthwhile, I might like to publish an account of my work with her, but that if she found it unsatisfactory, I would most certainly want to discard it - what else! This, she stated, seemed most reasonable (she did not realize that the flippancy of the what else was an effective stop to that line of inquiry).

Two-Level Communication

While she was still in the waking state, the explanation was then given that she could and should awaken from the trance state any time that was necessary. Deliberately the words as considered by her were not added. The implication was there for her unconscious mind; for her conscious mind the instruction implied any time that was *considered by her* to be necessary. If I had verbalized as considered by her, it would be accepted by her unconscious mind also, and a careful process of unconscious evaluation would be required. I wished, however, to limit her unconscious only to the words used. The unconscious is literal and tends to accept only what is said. This the patient could not appreciate, and hence she accepted in good faith exactly what was said uncritically, at both conscious and unconscious levels.

A Double Bind Utilizing the Patient's Inquisitiveness

Then she was told that she would be given - perhaps systematically, perhaps randomly - a whole series of odds and ends of valid, curious, and interesting information, and that her task would be to take out of all this the meaning most satisfactory to her. (Thus there was no hint that the order of presentation of ideas might be deliberate in significance and arranged in an order to effect certain results.) Again she agreed thoughtfully but without being given much time for reflection.

Then she was told that these same explanations would be repeated to her in the deep trance state, perhaps not in the full totality of the words said but in their essence, and that her unconscious mind could check her unconscious understandings against her conscious ones. Thus, by an incomplete wording of the instructions and by the request that she check her unconscious understandings against her conscious understandings, she was given again and intentionally the illusion of understanding totally and fully at both levels of awareness. She could not recognize the double bind placed upon her to make her conscious understandings about the procedure also her unconscious understandings.

R: This is an ingenious use of the double bind between the conscious and unconscious. It is particularly effective for her precisely because she was so interested in knowing at all levels what you were doing. You thus utilized this inquisitiveness to effect the double bind. The procedure might not function as a double bind for someone less inquisitive, because the inner dynamic or energy for carrying it out would be lacking. This is an excellent example of how double binds are dependent upon a patient's individual characteristics for their effectiveness.

A Listening Without Interruption Set

A deep, somnambulistic trance state was then elicited, and she was asked to be patient and considerate of any ambiguity or fumbling in meaning of what the author said. (This was a delaying technique to ensure full consideration.)

The first step of the procedure was to ask her to hallucinate as before the two orchestras and singers, thus setting the stage for the systematic evaluation of ideas and understandings. Once the stage was set, the orchestras and singers were to be removed, and then she was to let nothing interfere with her task. What the patient did not realize was that her task was the evaluation of the *total communication to be offered to her* and that there could be no hasty interruption or coming to a halt. She was thus unwittingly, and deliberately commited in an unrecognizable fashion to a prolonged state of receptiveness to a great variety of ideas.

R: The preparatory work of listening to orchestras and singers established a set to receive total, complete communication without interruption, because when we listen to music we usually do follow it to the end. You thus indirectly established a listening without interruption set. This approach might not work at all with a music critic, however, who was used to interrupting the music within his own mind to appraise it critically. Here again you are being careful to utilize the individual characteristics of your patient rather than use the same blanket approach for everyone.

Accepting the Patient's Frame of Reference: Utilizing Negativity to Open a Yes Set for an Exchange of Values

Thus, with brutal frankness but with utter simple casualness, she was told that not only was she handicapped by her accident, but unfortunately she could not really be called either a pretty girl or even just fairly good-looking. The simple fact, it was stated, was that she was definitely plain-featured, that as a rule men are attracted by looks primarily, but that it was fortunate that she did have good intelligence and a charming personality even though she was confined to a wheelchair.

E: Such a brutal beginning, with such negative statements only partially balanced by a final qualified favorable statement, could have no other effect than to convince her of my utter sincerity of purpose. Whether I was right or wrong, I could not be accused of trying to win her over to my views, to secure her compliance by favorable and pleasing words. Her evaluation of what I said was much more important than the content of what I actually said. Such brutal frankness also showed my fearlessness in confronting desperate issues. This was the first step in the orientation of her hopes for a fearless, nonsuicidal solution of her problems.

R: You were careful to take cognizance of and then utilize her own negativity so that she could accept your words. I'm sure that she came to you at least in part because you too are confined to a wheelchair, and you too must have experienced some of her bitter emotions. She is desperately looking for an identification with you that will enable her to find a nonsuicidal resolution of her problems. Your brutal fearlessness meets her conscious needs and opens a yes set for further therapeutic identification with you. In openly accepting her mental frames of reference you are

making it possible for her to eventually accept yours. This establishes the I-thou interaction that permits a genuine rapport and exchange of values.

Poetry, Parables, Puns, and Metaphor: Evoking Transformative Ideodynamic Processes

The senior author continued: But men are such curious creatures that they will be attracted to and marry just anything so long as it is female. Imagine any man in his right mind marrying an Ubangi duckbilled woman, *but they do it.* And can you imagine even necking with a Burmese giraffe-necked woman, but their husbands love them. And think of that historically happy, contented bean-pole Jack Sprat and his lard-tub wife. What she ever saw in him or he in her heaven only knows, but *love is blind, so all authorities say.* [An important communication, not recognizable as such.] And please don't ever tell Mr. Hippopotamus that Miss Hippopotamus does not have a lovely smile. [There was no way to ensure, only to hope that the patient in the deep trance might grasp the triple pun so pertinent to her in her condition hip-pot-mus (mess). On other occasions even more obscure puns have been readily picked up in the trance state by other patients. This patient resented her hips bitterly, she spoke of the commode as the pot and of the area of her hips as being a mess. Calling a spade a spade, especially in the patient's own language, however unrecognized at the time, often expedites therapy by convincing the patient that the therapist is unafraid of his task and recognizes it clearly.] And of course, could there ever be a love more divine than that of the starry-eyed Hottentot youth fantasizing in erotic reverie the beauty of the steatopygous, the hideous, fattytumored buttocks of the maiden of his dreams? Thank goodness, the Gaussian Curve, *the curve of natural distribution exists* [somewhere in that curve she has to fit], and that 'for every Rachel there is a Reuben, and for every Reuben, there is a Rachel' [an old childish song paraphrased] . 'East is East and West is West and never the twain shall meet' was not spoken of male and female.

E: From the hideous and negative beginning of the last section a markedly positive ending comes in this section. There is admixture of a happy childhood game, of the poetry of youth, the aim of adulthood, all combined by poetic nuances that could not be disputed. She could not find any single thing to dispute. She was caught in a flowing stream of ideas journeying a rough emotional passage but ending pleasantly.

R: Poetry, parables, puns, and metaphor (love is blind) all flow together in a way that actually utilizes her negative views about herself. The puns tend to evoke unconscious processes of search, and the poetry, parables, and metaphor open dimensions of mind that point to something beyond the limited views of her conscious mind. She is a highly gifted person seeking a philosophy of life, and you meet this need by first grounding your words in her negative realities and then point beyond them with your poetic metaphors and parables. Your rich use of the words curious, imagine, love, heaven, lovely, hope, divine, starry-eyed, fantasy, erotice reverie, beauty, dreams all tend to evoke nonrational ideodynamic processes (of the right hemisphere) that can be potent transformers of the fixed and limited negative views she has of her life situation.

More Poetry, Parables, Puns, and Metaphor: Evoking Inner Search and Unconscious Processes of Therapeutic Transformation

Then quickly, making a sudden change in tone of voice and of ideas before the patient could possibly assess the values of the individual ideas presented, I told the patient with a warning intonation, And don't ever forget the little child standing tiptoe, with bated breath, with shining expectancy in its eyes, its every movement and *lack of movement* [how could the patient from this type of phrasing consciously apprehend the hidden thought 'paralyzed from the waist down?] showing delight, confidence, surety, and certainty that the gift being offered to him is the *long-wanted*['long-wanted' is a pertinent and potent word] present from Santa Claus [a mythical figure, a source that one believes in with unlimited and hopeful faith; recognizing that the patient is asking for a miraculous gift from a hoped-for Santa Claus].

Eyes of expectancy, confidence of manner, security of being and knowing, just waiting to receive, and thus it goes on, year after year, generation after generation after generation. [What did the patient want but 'generation after generation after generation?' How else could all this be said except in the language of a child, remembering the belief in a Santa Claus, and with the firm convictions, memories, and understandings of childhood tied to adult words? There was no other way for the patient to understand except in terms of intense childish beliefs and emotions with all their attitudes of acceptance. Remember how she liked her grandmothers!]

Also, consider the foolish businessman with a profitable business and worries, worries, worries until the worry in his head has dug a hole right inside his stomach. He takes his upstairs worries downstairs, and wishes vainly that he could get rid of his downstairs pain that is down in his stomach. Poor fool! He does not remember how at the fraternity house he watched some poor fraternity brother eat apple sauce, putting it 'downstairs in his belly,' and then how he, with 'sweet' innocence, asked 'Was that a worm in the apple sauce you just ate?' laughing at the poor fellow leaping up to go elsewhere to put 'upstairs in his mouth' from 'downstairs in his belly' and hence to put outside of him the imaginary worm from downstairs in his stomach. Whatever it is that is downstairs in that poor fellow [the patient, too, is a'poor fellow'], he can always get it from downstairs to upstairs.

Why, I can even take this piece of typewritten paper and turn it toward you or toward me [demonstrating], and since I can read upside-down, we can both be pleased. [A male and a female in juxtaposition, and both pleased. The basic elements being mentioned, apparently irrelevantly, become more challenging in the need to understand them. I was a man, she was a woman, we were in juxtaposition; and we could both be pleased reading the same thing, doing something together, I in my way, she in hers. What was it that she wanted? A husband in juxtaposition, both of them pleased. Yet in no way could the patient become alarmed. Rather, she followed along with only curiosity, the symbolic values escaping from her full realization but becoming a part of a consistent series of partially received symbolisms.]

Oh, yes, 'doing what comes naturally'! [Back to the first session, back to the beginning of the second session - but why?]

Among all peoples, from the most primitive to the most civilized, there is a metaphoric language, all the way from 'and when thyself . . . shall pass among the guests star-scattered on the grass, and . . . reach the spot . . . turn down an empty glass' to 'He doesn't know his head from a hole in the ground.' [Both the glass and the hole are empty, but what a difference in the emptiness! The

patient is to make comparisons and contrasts and do what comes naturally ; all with a somehow related meaningfulness. All this was certainly not appealing to a conscious mind, but for its inescapable unconscious connotations it was bearing upon things known and unknown, consciously and unconsciously.] For example, I can ask you right now in the deep trance, Which is your dominant thumb - that is, are you right-thumbed or left-thumbed? - and you don't know, and what's more, you don't know how to find out. [Years of inquiry discloses a few naive students who actually comprehend the question.] Your body knows, but you don't know either consciously or unconsciously, do you? [She shook her head, frowned in perplexity thereby indicating that she did not.] All right, clasp your hands together over your head and, keeping them together, bring them down to your lap. Which thumb is on top? That is your dominant thumb. You have known for years that you were right-handed, but you have never noticed that you are not right-thumbed. You didn't even think of it. It is 'not natural' for your right thumb to be on top.

I noticed that you were left-thumbed, left-eyed, and left-eared last week, and I made up my mind that you should have free access to what your conscious mind knows about your body but does not know that it knows, and what your body knows freely but that neither your conscious nor your unconscious mind openly knows. *You might as well use well all knowledge that you have, body or mind knowledge, and use all of it well.* What does your body know and know full well, which you know and know full well consciously and unconsciously? Just this little thing! You think that erectile tissue is in the genitals *Just the genitals.* But what does your body know? Just take your finger and thumb and snap your soft nipple and watch it stand right out in protest. It knows that it has erectile tissue. You have had that knowledge without knowing it for a long time. And where else do you have erectile tissue? In New York State you stepped out of doors in thirty degrees below zero and felt your nose harden. Naturally! It has erectile tissue! Why else would it harden? And watch that hot baby slobbering for a kiss from the man she loves and see her upper lip get thick and warm? Erectile tissue in the upper lip! [The use of crude adjectives is deliberate and intentional. The patient needs to accept the ideas. Therefore, to ensure acceptance, she is given something to reject, namely the crude adjectives. In presenting therapeutic understandings a little roughage, as in the diet, is essential. Therapists who insist that everything they present is good and acceptable - and must be accepted because it is always tendered in courteous language and manner - are in error. There is a need to give the patient an earnest, compelling desire to protect and to respect that which is accepted. Therefore, let patients reword the presented ideas to please themselves. Then they become the patient's own ideas!]

And now we come to that toebone connected to the footbone and all the rest of the *connections.*[A word of more than one meaning, particularly in view of the foregoing material.] Let me word them! The external genitals are connected to the internal genitals, and the internal genitals are connected to the ovaries, and the ovaries are connected with adrenals, and the adrenals are connected with the chromaffin system, and the chromaffin system is connected with the mammaries, and the mammaries are connected with the parathyroids, and the thyroid is connected with the carotid body, and the carotid body is connected with the pituitary body, and the system of all these endocrine glands is connected with all sexual feelings, and all your sexual feelings are connected with all your other feelings, and if you don't believe it, let some man you like touch your bare breasts and you feel the hot, embarrassed feeling in your face and your sexual feelings. Then you'll know that every word I've said is true, and if you don't so believe, try it out, but the deep red flush on your face right now says you know it's so.

" So continue sleeping deeply, review carefully every word I have said to you, try to dispute it, to argue against it. Try your level best to disagree, but the harder you try the more you will realize that I am right.

And what good will it do for you? You! I mean you? Just stop and think! You enter a house! There stands a baby, dirty efface, tousled of hair, runny-nosed, wet, smelly, dirty, and its face lights up and it toddles to you so happily because it *knows* it's a nice baby and *that you will be glad to like it and that you will want to pick it up.* You know what you will do! So does the baby! *You can't help yourself.* [A negative statement with a positive meaning.] And then you enter another house and there stands a beautiful little child, hair combed, clean, neat, in a state of perfection, but its face says, 'Who, just who on earth would *ever* want to pick me up?' Certainly you don't, you agree with the child, and you want to find the parents and slap them around for mistreating that child, because you don't ever want to be greeted again, ever again, by that child in that manner.

Now put a look of starry-eyed expectation on your face, clothe yourself in an air of happy confidence. Romance for you is just around the corner [a crucial statement], I don't know which corner [a statement that leaves the question undecidable and hence requiring further consideration], *but it's just around the* corner! Don't ever forget there's a Rachel for every Reuben and a Reuben for every Rachel, and every Jean has her Jock and every Jock has his Jean, *and around the corner is your 'John Anderson, my Jo.'*

One doubt you will have, but naturally you are wrong! Your body knows, so does your conscious mind, so does your unconscious mind. Only you, the person, don't know. *So I'll answer the ninny that you are!* [She can defend only against the accusation that she is a 'ninny,' but to do so she has to admit that she knows the verity of what the author is about to say.]

Is there anything more ecstatic than the maiden's first sweet kiss of true love? Could there be a better orgasm? Or the first grasping of the little lips of the baby on your nipple! Or the cupping of your bare breasts by the hand of your love? Have you ever felt the chills run up and down your spine when kissed on the back of your neck?

Man has but one place to have an orgasm - a woman has many.

Continue your trance, evaluate these ideas, make no error about their validity.

At five o'clock I shall roll you down to the car that's picking you up. You will see me the same time next Saturday. Rouse up in the car.

Thus was the interview terminated abruptly. She was wheeled to the waiting car, and the senior author admonished silence to the driver by a finger on his lips.

R: You continue your poetic approach with an incredibly rich flight of ideas, with particular emphasis on evoking ideodynamic processes of attitude transformation that reach into the childhood of personality (Santa Claus) and extend into her adulthood (husband, home, and children) and beyond (generation after generation). You use a blend of just about every approach

to indirect suggestion and the unconscious that you have ever developed, including confusion, interspersed suggestions, and the apposition of opposites (male and female; brutal language with the poetic). You completely overwhelm her so that there is so much cognitive overload that her conscious mind cannot possibly cope with it. She is therefore sent on a furious inner search for meanings and frames of reference that could cope with your barrage. This inner search will naturally evoke unconscious processes of transformation in a therapeutic direction. You then abruptly stop and send her home in silence, lest her conscious mind be given an opportunity to limit and dismiss the process you have set in motion.

The Alternation of Hypnotherapy and Counseling: Termination of Therapy

The next Saturday was one of unusual interest. Advice and discussion was wanted by the patient in relation to advanced graduate work. There was no request for therapy and none was offered. The author was obviously in the role of a qualified professional academic advisor. A postgraduate career was outlined, and her visits were discontinued. (An amnesia, comprehensive in character, seemed present, but no effort was made to check it. Clinical results were the goal, no experimental checkings.)

R: I've noticed the same phenomena where patients will return after a particularly intense hypnotherapeutic session with an apparent amnesia and a need to simply discuss their life situation and plans with a counselor rather than a depth therapist. There seems to be an actual aversion to discussing the results of the previous hypnotherapeutic session. Rather, the patients seem to integrate it on an unconscious level, and the conscious mind now wants to go on to the next thing. Much of my work has this seesaw rhythm, where deep hypnotic work alternates with light counseling on alternate sessions.

A Ten-Year Followup

Within two years she was married. Her husband was a dedicated research man, and his field of interest was the biology and chemistry of the human colon. They have been married happily for over ten years, and there are now four children, all by Caesarian operations.

Ten years after the marriage the author happened to be lecturing in the state of her residence. She noted a news story on the author and called him on the telephone, asking him to lunch with her the next day. Before meeting her, three duplicate sets of questions were typed out. The answers were filled in on one set, which was sealed in an envelope. The other two sets were placed in separate envelopes.

Upon meeting her, two questions were introductorily asked: Why did you invite me to lunch? Her startled reply was, I know it's an odd thing to do, but you lectured to our class at the university several times, and I thought I would like to take you to lunch.

Is there any other reason?

Embarrassedly she replied, No, I realize that I am presumptuous, since I didn't really know you,

or you me, but I hope you don't mind.

The author replied, Here is a sealed envelope. Put it in your handbag. Then you sit at this table, read the questions in this unsealed envelope (handing her one), and answer them, please, on the paper with a pencil. Use 'yes' or 'no' as much as possible.

She looked bewilderedly at the author, read the questions, flushed very deeply, and said, If it were anybody except you, I would either slap your face or ask the waiter to call a policeman. But for some reason deep down in me, I don't know what it is, I'll be glad to do it.

The author said, While you are doing so, I will sit at another table with my back toward you and write what I think your answers are going to be. Then I will want to know how well our answers agree." Again she flushed deeply, saying, I just don't understand, but it is all right.

Accordingly, the two sets of questions were answered and the questions and answers are in the following summarizing table.

Question	Her answer	Author's answer	Sealed envelope answer
How often do you and your husband make love a week?	3-4	3-4?	3-4?
Do you have orgasms - yes or no?	yes	yes	yes
Right side 1 , or 1 and 2, or both *	yes, all	1 1 and 1 2	1 1 and 1 2 yes, all
Left side 1 , or 1 and 2, or both	yes	1 1 and 1 2	1 1 and 1 2
Sometimes left 1, right 2, and vice versa	yes	yes	yes

Sometimes right 1, left 2	yes	yes ,	yes
Explain above two answers in three words as closely as possible	nipple, and nipple and breast, or one or both depending	either and both of nipples and both breasts or singly of each or combinations	either and both of nipples and both of breasts or singly of each or combinations
Neck	sometimes, base	perhaps	perhaps
Lips	upper	upper?	upper?
Earlobes	no	?	?
Nose	no	?	?
Top of head	no	?	?
Back of neck	seldom	?	?
Others	between breasts	between scapulae	between scapulae
Are their other sensory sexual pleasures	yes	none of my business	none of my business
Do you realize that you are always at liberty to have any desired degree of amnesia for this interrogation, the past, and any possible role by me - if	yes	none of my business	none of my business

I had a role			
Do you know that I am most grateful to you even if it is no more than gratitude for the pleasure of knowing you?	I am grateful to you, but I don't see why you are grateful to me	I just hope	I just hope
Will you treat me merely as a friend with interests in common in scientific research if you so desire?	yes	I hope so	I hope so

*One (1) refers to the nipple and two (2) refers to the breast as a whole. This code was established when the original hypnotic work was done years previously.

(In the author's understanding of human nature it was considered best to terminate the questionnaire at this point. Much more information was wanted, but one cannot risk a clinical success for the possibility of a partial academic clarification.)

She was asked to take the sealed envelope out of her handbag and compare the answers there with those she had written.

She did so with many astonished glances at the author. Finally the author said, The answers I just wrote down agree with the sealed envelope sheet, which is marked three and which I marked last night. I have envelope number two. Yours is number one.

After a long pause she asked, What does this mean? I know you are not psychic. But I have obviously an amnesia or you could not have such reliable information about me of such intimate and detailed character. Was I your patient at one time?

What do you think?

Obviously! Let me see if I can remember. I have a feeling that you gave me something very nice, and then stepped out of the picture so I couldn't thank you. If I remember, do I have to keep on remembering?

No, you don't have to remember. I have now learned that some ideas I had were right, and I'm so very glad they were.

Will you publish it? And if I read it, will I remember?

I will try to write into it hidden instructions for you to forget all identities involved, if indeed you are involved. You know and I know there are others like you, and you don't know how many I know. But I will say this. I check to some extent on each one I have treated. I check when possible on those I haven't treated. Perhaps someone learned spontaneously and taught me how to teach others. Maybe others learned spontaneously and convinced me I should make inquiries whenever possible. You are a possibility. My account will be scientifically reliable, the disguise used will serve only to hide identities from anyone actually involved, and I am quite confident, adequately so.

R: This case history, the assumptions and presumptions, their validity and applicability, leave much to be desired. There is no doubt that the patient was truly benefitted. This is well established beyond all doubt and after the passage of many years. How much credit should be given the senior author is a serious question. That he at least deserves credit for initiating recovery is obvious, but did such recovery derive from the natural capacities of the body to heal itself when once oriented, or did the psychological processes themselves as employed serve to initiate new neural pathways of response and thus to awaken otherwise unrealizable potentialities? In brief, this report poses serious questions concerning the interplay of psycho-neuro-physiological relationships and the possible methodologies for their activation.

Case 14 Psychological Shock and Surprise to Transform Identity

[*Previously unpublished paper written by the senior author and edited for publication here by the junior author.*]

Meg was twenty-four years old. She had completed high school and secretarial training and had worked satisfactorily three years for a physician and one year for a business firm. She was the oldest child in a closely knit family consisting of her siblings, her long-widowed mother, and two spinster aunts. She contributed all her earnings unnecessarily to the family, and her personal expenditures were rigidly limited as well as rigidly supervised.

At the age of twenty-one she met a young Army private at church, and each felt a strong attraction for the other. Their meetings were confined to the church, the mother's home, or, if they went elsewhere, it was with the chaperonage of either one or both spinster aunts. Despite these difficulties a proposal of marriage was made and accepted with full family approval, all within six months, since the young man was completing his term of service and was returning to his home two thousand miles away. He wished to take Meg home as his bride, but she declared she needed until June, six months in the future, to get ready. As June approached, her letters contained more and more pleas for a December wedding, until the young man finally consented. But the December wedding was postponed until June, and this went on for three years.

During the third year Meg left her position with the physician and took one with a business firm, seeking out another physician to whom she offered vague, unrealistic complaints. He was

straightforward and kindly, but impatient with her complaints and frankly discredited them. Meg returned a few weeks later, complaining of hearing voices that talked to her during the day and awakened her at night. As she told her story, she would lapse into brief silences of a minute or two in which she would stare silently into space. The physician, a general practitioner, was alarmed and tried to refer her to a psychiatrist - the nearest one was more than 150 miles distant - but she refused to go. When he tried to interest her family, he was asked to care for her himself. He tried to do so but recognized his lack of competence. Finally, after months of laborious effort, he persuaded the family to bring Meg to the senior author. She was accompanied on the train by her mother, both aunts, and two grown siblings.

The interview with Meg was most informative. The auditory hallucinations she declared to have experienced for six months were psychiat-rically unconvincing. Her sudden lapses of staring into space seemed to be more a pose than a symptom.

Two hours were required to elicit the above history and the additional facts that she was afraid to leave home, that her fiance would not consent to live in Arizona, that she could not give up the hope of marriage, and that medical help would have to correct all these matters.

Additionally, she insisted on the validity of her auditory hallucinations and insisted that she could not travel by bus, train, airplane, or automobile except in the company of her family. She dropped the pose of staring into distance during the latter part of the interview. She also despairingly expressed an absolute conviction that she was past all medical help.

Trance Induction and Posthypnotic Suggestions

The next visit was made with the same entourage as the first visit. The senior author peremptorily refused to hear her complaints unless she went to sleep and talked with her unconscious mind but without telling anything she did not want to tell. By carefully worded, reassuring suggestions a medium-to-deep trance was induced in about thirty minutes. This trance was used to give her emphatic posthypnotic suggestions to the effect that, in return for the senior author's listening to all of her fears and her accounts of her hallucinations for the rest of the session, she would listen attentively to many things he would have to say on the occasion of her next visit; that until then she would be almost painfully curious about what he might have to say. Many repetitions were made of this instruction in slightly varying terms to ensure full understanding.

She aroused from the trance and launched into an extensive account of her auditory hallucinations and a brief account of the impossibility of leaving home, the even lesser possibility of leaving Arizona, and of her need to have four or five members of her family with her just to come for her interviews with the senior author. Again the senior author reached the conclusion that the psychiatric portrayal she offered of herself was no more than a symptomatic screen to conceal her actual problem.

Three weeks passed before she was seen again, this time with only four members of her family accompanying her. She was obviously eager, expectant, curious, yet fearful of what the senior author might have to say, and she tried to forestall him by declaring that she had some new worries.

R: You utilized her present behavior in a subtle and ingenious manner. Her major behavior was wanting to present her complaints about the difficulties of her life situation. During this second session you blocked her complaints just long enough to induce a trance. You then utilized her need for further complaint by making it a condition for listening attentively to what you would say on the next visit. She did complain to you for the rest of this session, so now she was bound to listen to you on the next. You heighten her *expecting* by telling her she would be almost painfully curious about what you would say and then let that expectancy build for three weeks!

E: Yes, I tied her up.

Direct Suggestions While Depotentiating Resistance

She was told firmly to close her eyes and to listen, even to go to sleep if she wished, but listen she must. As she closed her eyes the author began a series of instructions: (1) She must move out of the maternal home and room with some other girls, doing this within the week. This was to be explained to her family as medical orders. (The family physician had agreed to confirm this, and he was indeed consulted.) (2) She was to bank her paycheck and pay her own bills. (3) She was not to receive any member of her family as a visitor in her new quarters. (Her spinster aunts patrolled that street nightly for several hours at a time for several weeks.) (4) She was not to visit her home nor to make telephone calls to her family nor to receive them. (5) Her contact with her family was to be limited to brief greetings of not more than three minutes at church. (6) She was to attend the theater, eat at restaurants, go roller skating with her fellow roomers. (The family physician supplied much helpful information, including the actual possibility of two prospective roommates for her.) (7) She was to invite her roommates as a lark to go for a bus ride across town and back. (8) She was to come entirely alone on her next trip in two weeks to see the author. (9) One of the preceding instructions - one and only one - she could modify and thus violate it, but not too much, and this would comfort her and enable her to obey all other instructions completely and the modified one satisfactorily.

Over and over these instructions were repeated until she developed a trance state from which she was aroused at the end of the session. The instructions were then again repeated, and she was given another appointment in two weeks' time.

E: The purpose of the permission to violate and modify one of the instructions was psychologically to compel the acceptance of all the other instructions. Thus, by legitimately violating one, she could meet, at least in part, the author's authoritative instructions.

R: When you give direct suggestions, you are careful to provide her with some choices she can reject. You have spoken of this as the patient's right to success and failure (Erickson, 1965). Allowing the patient to reject some suggestions in effect depotentiates resistance so the others can be carried out.

E: When you allow the patient to violate some of your suggestions, they are now indebted to you to carry out the others.

She was definitely triumphant about her accomplishments and was promptly interrupted when she

tried to offer an explanation of her mother's presence. (It was better for her to feel guilt toward the senior author than toward her family.) A trance state was immediately induced.

She was instructed in a medium-to-deep trance to execute the following tasks: (1) To travel in a private automobile with friends across the state line (which she had never crossed, although it was but a few miles from her home) and to dine with those friends in some restaurant at least fifty miles from home. (2) To travel by automobile with friends to a specified city, making a round trip of over two hundred miles all in one day. (3) To consider seriously moving from her home town to Phoenix, securing a new job, and living on her savings until the new position was secured. (4) To spend the next half-hour crying, trembling, shivering, dreading, fearing all these tasks, at the same time realizing that one task a week would have to be done and that in the fourth week she would have to come to Phoenix alone, prepared to stay a week while she searched for employment and living quarters, and kept an appointment with the senior author.

During the previous visit and the present one no mention had been made of the voices. However, as this last series of suggestions was completed, she tremulously spoke: The voices------ only to be interrupted by the sharply voiced declaration, Neither of us have ever really believed in those voices. You made Dr. X believe in them, but I didn't. Now, you do everything I have told you to do or Dr. X and I will make you do right away what you are most afraid of. If you are obedient, we will let you build your strength.

E: What else could a girl completely dominated all her life do but yield obediently? This lifelong submission made possible the therapy employed.

R: I've noticed that when you do give direction suggestions, it's usually to a personality who has been trained by previous life experience to accept them. Thus you are again utilizing the patient's own personality needs to ensure the acceptance of your suggestions.

Breaking Family Dependence

A month later she entered the office to report that all tasks were completed. It had taken her one day to find living quarters and one additional day to secure employment beginning the next Monday. (She had wasted three days of the week forcing herself to come to Phoenix.) Then, with utter intensity, she asked when she could visit her home. Entirely casually she was informed, There is a bus leaving for your home town this afternoon. You will be able to make a surprise visit to your mother tonight in time for dinner. You can stay there overnight, go to church in the morning, and leave on the last bus in the afternoon, which will arrive in Phoenix at 10:00 P.M. Thus you will have a delightful weekend visit at home. This would be a good idea every week or two or three.

She sat silently, contemplatively staring at the author for the next fifteen minutes. Then in a subdued voice, asked," May I give my mother my new address? No injuction about this had been even offered her, and her request was interpreted as her own significant desire to begin the end of her family's domination and to cut the bonds of her dependency. She was answered, Your mother knows my address and telephone number. Just give me your address and telephone number, and in case of any emergency your mother can easily get in touch with you through me. She nodded

her head agreeably, stated the information, and departed without completing her allotted time, of which about one-half hour remained.

R: She was now living in your town in Phoenix and only visiting her mother and aunts. You were now functioning as a surrogate parent during this transition period while she was separating from her family.

Trance to Bypass Conscious Limitations

The following Monday noon, during her lunch hour, she appeared to report a lovely time, to ask for another appointment, and to make payment for the previous appointment.

She was informed that the next appointment would be a most unusual one for her. She was reminded that while she could swim, such activity had always occurred only with other girls and at the Y.W.C.A. A look of horrified dread appeared on her face. The senior author continued, You always wear clothes that are high-necked, the hems of your dresses are always below the knee, and you wear long sleeves even in summertime. Swimming suits can be very scanty and noticeable in mixed company at a swimming pool. An expression of agonized horror appeared on her face. But I am not going to ask any such thing of you. She sighed with intense relief. All I wish is merely that you keep your next appointment wearing the outfit called short shorts. Her gasp of horror was interrupted: Now close your eyes, sleep deeply, very deeply, now listen! Your next visit here will be kept by you wearing an outfit called short shorts. If it makes you feel more comfortable to do so, you may carry one of your regular dresses in a shopping bag to put on before leaving the office. Arouse now, knowing full well what you are going to do despite the most awful fears that you can manufacture. But bear in mind that this marriage that you want and yet have postponed two to six months at a time for four years is now coming closer and closer. It is now late June and I want a Christmas card from you and your husband this year. Such a Christmas card you are going to send. You will enjoy sending it and you will equally gladly show me the last few letters your fiance has written to you as soon as you arouse. Now awaken.

As she aroused, the play of emotional expression on her face was most varied, ranging from fear, dread, and deep embarrassment to a look of hopeful anticipation. She was told to let the senior author see a few of her most recent letters from her fiance. She hesitantly opened her handbag and hastily explained, I can tell you what he says in every letter - that if I don't marry him this summer, he will find another girl. So I have promised him I will marry him in September.

She was most startled by the senior author's statement, Yes, that's entirely right. You will be married to him in September, well married.

She appeared for the next interview wearing short shorts of the most extreme sort. She was most embarrassed but became bewildered by the author's apparent oversight of them, his discussion of her past deceptions of hearing voices, of staring into space, of telling her fiance that she would marry him in a certain month and then changing it, and a discussion, apparently without purpose or point, about the unpredictability of human history, human events, and the unpredictability of the acts and decisions of the individual human being, some of which would occur unexpectedly soon. She was finally given an appointment for the first of July and dismissed. She walked out too

bewildered to ask permission to change into her dress.

R: Your apparently irrelevant discussion of the unpredictability of human events is actually a preparation for the shock and surprise you will use in the next session, but she does not know that yet. This discussion serves as a foundation for what will follow. Her previous life had been too predictable. Your discussion of life's unpredictability is thus introducing a new therapeutic frame of reference and at the same time it probably sets many unconscious searches in motion for whatever relevances it can possibly have. Her unconscious knows by now that nothing you do is really irrelevant. A high degree of expectancy and desire is thus aroused for the crucial shock of the next session.

Shock and Surprise to Depotentiate the Old and Transform Identity

She entered the office on July 1 only to find it well-chaperoned. She was asked, This is July, isn't it, and didn't you promise to marry your fiance this month? Her reply was a hesitant Yes and then an urgent, But I promise you I will marry him in September.

Slowly, impressively, she was told, Since you are so unsure as you have conclusively shown over the past four years, you are today going to prove that you are competent to marry this month, and marry this month you will! I told you that in September you would be married, well married. Now we shall see if there is any reason that you should not be married; we shall learn if you are lacking in any way to justify your marriage postponements.

Now stand up and, one by one, take off your clothes, naming each article as you place it neatly on the chair.

She looked helplessly at the placid, composed face of the chaperone, then blushingly stood up, hesitated, then took off her shoes, more hesitantly her stockings, then, with many lingering movements, her dress and finally her slip.

Won't this be enough? she asked pleadingly, looking first at the author, then looking pleadingly at the chaperone, but no response was made.

Awkwardly, clumsily, she removed her bra, hesitated a moment, then removed her panties and stood in the nude facing the senior author defiantly. Thereupon he turned to the chaperone and remarked, She looks all right to me. Does she look all right to you? The chaperone nodded her head.

The author then turned to the patient and stated, I want to be sure you know and can name all parts of your body. I do not want to point to or touch any part of your body nor does the chaperone. If necessary I can do it, but please don't make it necessary. Just don't try to skip over anything with a name. As you name each part, touch it with one or the other hand, since you must use your right hand to touch your left elbow. Now start from the shoulders and work downward progressively, then turn your back to us and do the same as well as you can. Now go ahead, and no oversights.

With her face suffused with blushes, she did a creditable job. She was commended for this, whereupon her blushes disappeared, and in a most casual, matter-of-fact manner she proceeded to dress.

As she was doing so, she was asked if she thought she would be married by July 15. Her simple answer was, That would be too soon. I've got to quit my job. I hate to do that without notice, but my boss will understand, and then I've got to travel up north and meet Joe's family and bring him down home, and I've got to tell my family what kind of wedding I want. I saw the kind they gave my sister and I don't want anything like that. But they are going to do it my way or I'm coming to Phoenix and have nobody there except the witnesses. And I better send Joe a telegram right away.

Slightly over two weeks later she brought Joe into the office, explained that she wanted premarital counseling for each of them separately and then for both together. This was done to her satisfaction. A long-distance telephone call assured the senior author that after much struggling the mother and the spinster aunts capitulated and allowed her to have a wedding at which she alone chose the guests instead of the wedding being made a community affair.

E: The way she took over her own marriage plans indicates a radical transformation in her view of herself and reality.

R: Yes, the way her blushes disappeared after she had undressed and then in a matter-of-fact manner proceeded to dress indicate a creative movement of self-transformation. She then proceeds to discuss her immediate plans and forthcoming marriage in a most practical and appropriate fashion.

Followup: First, Second, Third, and Seventh Years

The specified Christmas card arrived, and the next year a birth announcement as well as a Christmas card was received. Three such birth announcements were received, and then no further word was received until about seven years after the wedding. The patient then again sought out the author. She brought her three children with her to display proudly, and then she explained about her marital discord because her husband, in moving with her to Arizona, was finding difficulty in his new occupational adjustment and blaming himself unreasonably. She asked for an appointment for her husband, and at that interview no serious difficulties were found.

Case 15 Experiential Life Review in the Transformation of Identity

[*Previously unpublished paper written by the senior author and reedited here for publication by the junior author.*]

This patient made a long-distance telephone call to state that she had been referred by a friend, that she would like an appointment in two weeks' time on a Thursday afternoon, that she would call the office the preceding Wednesday to ascertain the hour, that her name was Miss X. With this statement she terminated the conversation. On Wednesday she called the office, asked the hour of her appointment, and refused to speak to the senior author. The next day at the appointed time Miss X arrived, a woman who appeared to be in her early thirties, haggard and worn, her face tear-stained.

Her story in summary was that she was an adopted child in a family with four older children, the youngest of whom was twelve years her senior. For some unknown reason when she was still a small child her adoptive mother had become pathologically suspicious and inquisitive and had subjected her to interminable inquisitions to learn if the child had been a bad girl. The adoptive father was cold and undemonstrative, leaving all the children entirely to their mother's care. The four older children had graduated from college, and though they lived not too far away, made only infrequent calls at the parental home, these being extremely brief. Because of this the mother had many times interrogated her about what she had done or said that made the other children avoid the parental home.

The patient had tried to protect herself by absorption in her high school studies, always pleading homework to avoid her mother's repetitious interrogations concerning whether she was a good girl, whether she had done bad things, and whether she had bad thoughts. She won high school honors, but her only social life was rigidly chaperoned by her mother. She entered college but was forced to attend the college in her home town and to live at home. By absorbing erself in studies, going to summer school and taking special courses to fill in vacation and free time, she escaped much but not all of her mother's pathological questioning. She was forced to take an M.A. degree because you do not seem to be mature enough to be allowed to try to earn your living, and there is no knowing what bad thing will happen to you away from home.

With the awarding of her M.A. degree, in a state of utterly intense fear, the girl asserted that her age of twenty-two gave her the legal right to leave home. There followed an exceedingly traumatic emotional episode that the father terminated coldly and decisively with the statement, If you do not want to live with your mother and me in appreciation of all that we have done for you and all the protection we have given you, you may leave. But do not let it be said that we turned you away with no provision. Tomorrow in the bank I will place five thousand dollars to your credit. Take your clothes and leave, and whatever misfortune befalls you is upon your head. The mother's parting words were, I know you've done something bad. Be brave and tell me.

Weeping, the girl left. She went to another city, secured employment, and then tried to establish relationships with her foster siblings. They rejected her with the explanation, Mother will descend on us if we are with you, and we have enough trouble with her as it it. They also informed her that each of them had been treated in the same way. That their father had paid off each of them similarly, and only a sense of filial duty made them make their brief calls at the parental home. However, they had been bombarded with letters and telegrams from their mother demanding reports on my last erring child.

Reluctantly the girl cut all ties, moved to another city where she worked successfully as a secretary, but found herself unable to develop any social life. She became increasingly depressed, unsuccessfully sought happiness in expensive vacations, and finally sought psychiatric aid. The psychiatrist told her he was psychoanalytically trained in the Freudian school. Misunderstandings developed at once, since the question of sex arose in the therapeutic sessions. She desperately sought another and then another psychiatrist. Always the question of sex arose. She began to equate the words sex and psychiatry.

By a desperate effort she could present a good appearance in seeking employment. She applied

for a position as a civilian employee connected with the U.S. Army. At first she adjusted well, but as the months went by she became progressively depressed. She sought refuge in studying languages and became fluent in three foreign languages, but even more depressed.

An army psychiatrist recommended her return to the United States for psychiatric treatment. She asked instead for a transfer elsewhere in Europe to a new assignment where her linguistic ability would be of service. This was secured by her twice. The third request was tor a transfer somewhere to the Far East. There she was given a teaching position. She tried to learn another language and to lose herself in her work, but her depression became worse. Another army psychiatrist then became insistent that she return to the United States for therapy, and finally she reluctantly did so.

She began the rounds of the psychiatrists she had seen before and rejected them again for the same reason. She sought new psychiatrists but sooner or later the topic of sex arose. Then she learned of hypnosis. A former patient of the senior author's recommended him to her, and she hastily made the telephone call before she weakened.

What she wanted, she declared, was hypnosis, hypnosis that would blot forever from her mind all thought of questions and sex. And would the author without further delay please settle down to hypnotizing her and meeting her needs?

Since this was her opening request at the very first appointment, a laborious explanation was given to her to the effect that she was asking the author to work completely blindly, and that, considering her tearful appearance, he did not want to work blindly lest unintentionally he might say or do something harmful to her, or do something awkwardly or clumsily, and thus distress her emotionally. Her response was an outburst of uncontrollable sobbing that lasted some minutes.

Advantage was taken of this to explain, You see, even though I tried to speak gently and intelligently to you, I accidentally broke down your emotional control. So let us work in such fashion that you keep your emotional control; and whatever little you need to say to me, at least say that little, but try to point me in the right direction. In the first place, in order to speak intelligently I need to know the extent of your education - that's all, the extent, not where or how. It is possible that your employment experience, not where or for whom, just knowing the kind of employment experience would enable me to do my task better."

Bit by bit, with intermingled sobbing, the above history was obtained without specific dates, places, or names. Avoidance of asking for specific items of fact aided greatly in securing her cooperation.

She was instructed that the data given above were sufficient to begin work and that no questions would be asked her unless she so indicated a desire. Then she could give whatever additional information she desired. It was also explained that therapy would necessarily cover a number of hour-long periods, spaced in accord with her ability to learn since, as she knew, learning was a task requiring effort. Hypnotherapy would require earnest effort, not passive submission, even as it would require intelligent effort on the author's part. (This emphasis upon the word intelligent was to permit the author some freedom of action, and her own history of using her studies as an

escape suggested that continued use be made of it.) She agreed, and another long, laborious explanation was given of hypnosis as a learning process, something similar to acquiring the feel of a new language. This figure of speech was most appealing to her.

No effort will be made to report the separate interviews, since the procedure, rather than the events of specific hours, are of primary interest.

Indirect Induction with Early Learning Set

A wholly indirect hypnotic therapeutic approach was employed. She was asked to choose which of three paperweights looked the most interesting. She chose an agate geode. She was asked to sit comfortably, hands in her lap, to fix her gaze upon the polished surface, to enjoy the various colors, to sit entirely still, to hold her head still, to hold her ears still, and to give herself over to an enjoyment of the colors in the layers of agate, not really being obligated to pay attention to what the senior author was saying. After several varied repetitions of this instruction, her face took on a rather fixed, rigid expression. She was then asked to think through the problem of learning a language - not German, French, Italian, but a much more complex language, the English language as learned by a baby. In a slow, gentle, almost murmuring fashion the senior author described a baby lying in bed, hearing sounds, not knowing what they meant, the progressive articulation of sounds by the infant, its slow physical growth, the change in its features, its hands and feet, new movements, new sounds, bathing, eating, elimination, sleeping, its struggles in crying, its delight in cooing, reaching for things, and so on. Slowly a general comprehensive foundation was laid for extensive thinking by her about the physical growth of a child, its learning of phonetics, eating, elimination, activity, speech, locomotion, and all the rest during the first five years. Initially this was presented as a discussion apparently to illustrate some point to be made by the senior author, but unnoticeably the tenor of the comments shifted slightly. Then stronger and more direct suggestions were made that she lose herself in a wondering but intellectual appraisal of the multitudinous learnings she herself had experienced in the first five or six years of her life.

Evoking Early Repressions with Catharsis

Shortly, within ten minutes, it was obvious that she was in a profound trance and was now oblivious of the agate as well as the rest of her surroundings. Upon a request by the author she plunged into a systematic survey of the memories of her early childhood. This was governed and directed by the therapist by intruding such statements as: And in that first year what a wealth of fundamental learning, from diapers to pretty things and sounds and colors and noises; or, And then you come to the second year, creeping and walking and falling and using the toilet like a *good little baby* and saying little sentences ; and, Of course, there comes the third year and language is growing, words, so many, the parts of your body, the little hole in your tummy, and you even know the color of your hair.

For each of the first six years this was done, bringing in each year some reference to elimination, *stressing the ' 'goodness of toilet habits,* body curiosity, the goodness of food, of sleeping, washing, learning all manner of things, and of almost feeling herself doing all of these things. This was accomplished in about three hours of utterly concentrated work by the patient.

On the day that it was intended to progress to the next period, the patient entered the office jerkily, her face flushed, and her expression one of furious anger. Explosively she declared, I'm so mad at you I could slap your face. I just can't think of a name to call you that's bad enough.

Why not call me a stinking bastard of an S.O.B., since that is probably the best you can do, was the simple, direct reply.

I will, she shouted and did so, only to burst into a distressed, embarrassed laugh, saying apologetically, I don't know what made me say that, but in a funny way it makes me feel better.

She was asked, Since it made you feel better, do you want to repeat the statements, perhaps with improvement?

Oh, no, I want to tell you something I don't want to tell you. For two days now I've had a normal bowel movement and my stomach hasn't hurt when I eat, and I'm embarrassed to death to say this to you. I'd have died before rather than tell you. I don't know what you did to me, but something is happening and I don't want to cry either. And that damn psychiatrist in Europe who said that awful obsession I had about the bathtub being filled with bloody water when I shaved my legs showing suicidal tendencies was all wrong. Some day when I ask you, will you tell me what that silly nonsense was? But not right now! But now can we go ahead and let me look at the paperweight?

Two-Level Communication

In accord with her request, as she spontaneously developed a trance, she was softly instructed to make a comprehensive search of all her *real* childhood memories *and personal* experiences from six to ten. (Real and personal were words intended to restrict her to self-experiences rather than experiences with others - in particular, with her mother.) Very few suggestions were offered to her, usually, Did you leave out anything belonging to you at seven? Vague mention was made of big girls, you can see when they are big, and women are like big girls, only different. References to elimination were made more guardedly, One keeps in good regular body health, and speculations were offered about little learnings that grow up into the language of life.

It should be borne in mind that the patient was doing this survey as an adult, viewing in vivid, feeling detail a wealth of experiential learnings. Thus, even guarded general suggestions could be freely translated by the subject into more complete, adequate detail. As was later learned, the little learnings that grow up into the language of life was translated by her in one of her trance states to refer to genital explorations and stimulation. When first heard, it had only a poetic sound, and then slowly I gave it a sex meaning, but I don't remember when.

R: This is an unusually clear example of two-level communication. It took time to develop because an extensive unconscious search was required, and she does not remember when precisely because it was an unconscious elaboration that slowly filtered into her conscious mind.

Body Language as an Expression of Ideodynamic Processes

The tenth through the fourteenth years were covered with unexpected rapidity and ease. The senior author had expected tension and difficulty and was extremely guarded and cautious in his emphasis upon the *real,* the *actual,* the *personal*experience belonging to the self and not involving others - one learns a language not by one's hearing of it but by feeling it in one's own mouth and thoughts, and sensing its untranslatable nuances, and the beauty of a German guttural is a beauty that belongs to a German, however bad it sounds to the untutored ear, and the beauty of self-experience belongs to the self, and all others may vainly call it bad.

As she seemed to be reaching the fourteenth year, she was asked to take time out just to go back to the very beginning, to fill in overlooked self-learnings, to correct omissions, to note misunderstandings and partial realizations, and to view them well from the simple, rightful dignity of a fourteen-year-old, truly fourteen. That a risk was being taken in that she might not have begun menstruation until after the age of fourteen was fully appreciated, but the hope was entertained that such an error would be detected by observation and study of the emotional play on her face, which had increased progressively from the age of six. From the age of ten to fourteen the play of facial suggestions portrayed the change from a ten-year-old girl's face to that of a fourteen-year-old young adult.

The patient's initial history emphasized the importance of the avoidance of direct questions. However important a clinical and academic matter her thinking was to the senior author, it was serving a more important therapeutic purpose for the patient, which was the paramount purpose of the work.

Alternating Periods of Deep Hypnotherapy and Counseling

Following this review of the ages often to fourteen, she entered the office saying, Can we just talk a while without working? Upon assent she continued, Well, I've moved to a nice place, I've got a job, I'm not depressed. I actually am beginning to like me a lot. I'm not especially beautiful; I couldn't stop a clock if I tried. But I've got a nice figure. My mother would die if she had heard that wolf whistle I got the other day. That's the first one I really remember. And believe it or not I'm sorry for my mother. She is sick. It must be a painful sickness for her too, and my father is sick but not as sick as my mother. That five thousand dollars was really all he could give me. And they didn't try to make me sick. They just mistakenly did wrong things with good intentions. Well, mother wanted to keep me a virgin and she succeeded. But I'm going to take some credit for that myself. And that poor psychiatrist in Europe who thought I was suicidal because of my terrible obsession about a bathtub full of bloody water and a razor in my hand. What else could he think? I was taking a bath and I suddenly realized it was about time for my period and I was shaving my legs and I wondered what it would be like to shave my pubic hair, and then that horrible phrase my mother everlastingly dinned in my ears about being a good girl, and thoughts of masturbation, and then I couldn't think any more except of bloody water and the razor. It was awful then. I feel sorry for me then. Sounds funny to say it that way, but I do, I mean it. And I mean I feel sorry for my parents. I don't love them. They are just two people who tried to do me a kindness once, tried hard but failed. And it meant so much to them!

Another thing! I come to your office, I sit for awhile, I go away, I do nothing. You said hypnosis was learning. I haven't learned any hypnosis. All that's happened to me is I feel different, I think

different, I am different. I didn't mind telling you about my bowel movements. A couple of times before, I got up enough courage to go to a doctor, but I was too scared to let him do an examination. When I took the physical to go overseas, I got hold of sleeping pills so I could stand it. They quieted me down but didn't put me to sleep.

Do you suppose I need to see you? I know your answer is yes, and I agree. I wish I knew why the answer is yes.

You could ask, she was told.

Oh, I know that, but I' m not asking. I wonder why, but I certainly am not going to interfere with you, but I can't help feeling curious. Do you know what you are going to do next?

Oh, yes.

Well, that's good. I knew you did. Will it be all right to spend the rest of the time talking?

The rest of that interview was spent with a highly intelligent, widely read, well-traveled woman who was obviously starved for an opportunity for social expression.

At the next interview, as soon as she had developed a trance she was told, Well, let's complete the high school days and college years. This was done apparently easily, but frequently sudden manifestations of extreme physical tension would be present.

At the next meeting she remarked casually, The day we talked and that's all and I sort of reviewed things, do you have anything to say about that?

With slow, soft-voiced, forceful emphasis she was given the reply, Yes, I have, a great deal, more than you want to hear.

With an expression of utter fury she leaped from her chair and shouted, You stinking bastard, you are trying to tell me I was too glib, too smooth, too casual, too intellectual, you stinking bastard.

To this reply was made, Right, quite right. Sit down, look at the paperweight, then quietly, silently, with deadly hatred and bitterness and gall and venom, tear the hell out of 'a good girl' (these last words said mockingly).

There occurred a fascinating, almost silent display of emotions - grimacing, writhing, twisting, clenching of fists, spasmodic breathing, clenching of teeth, and moaning - in fact, every manifestation of violent distressing emotions. Toward the end of the hour she began to relax and was finally dismissed with instructions to return to her apartment, feeling tired and sleepy, and to go to bed and finish the task. In a self-absorbed manner she left the office, not noticing her perspiration-drenched dress.

Hyperamnesia in Reviewing Life History

At the next interview her facial expression and manner were one of bewildered respect. Instead of speaking casually her manner was alert and attentive. She addressed herself formally to the author and repeatedly said sir. She was asked how she felt.

Her reply was, Dr. Erickson, it is difficult to start. I have a vague, unclear memory of summarizing my feelings the other day, but, sir, I don't remember what I said. I only remember that what I said was partly right. But since then there have been changes in me. I feel as if I had been dreadfully sick, just dreadfully sick, but that now I am over it but in that weak stage when one is convalescing. Yet, I'm not physically weak, sir, it's just that I am well but haven't got all of my strength back. I began feeling this way when I awakened the afternoon of my last visit here. The bed was all torn to pieces. I had torn the pillowcases. I was drenched with perspiration. I was still in my dress and it was a mess. But before I got up and straightened up the bed and undressed and took a bath, I just lay back in bed and I literally reviewed my life history. I've never told you the real details. It's pretty horrible and painful, but all that is in the past. I almost felt like a stranger looking at all those things - the things I feel deeply that happened to me and that made me suffer so much. It was all real, it all belonged to me, but it all feels differently to me now, sir. It all belongs to the past.

As I lay there on the bed, I started with my childhood. It is hard to believe the detail in which I remembered things - even the little things I did as a baby creeping on the floor. They were terribly vivid to me. And I went right along, year by year. Things that I thought were forever forgotten stood out in detail, vivid startling detail. That little boy I kissed in the first grade - I could actually feel his lips on mine. A child's feelings are so different, so warm, so wonderful, so innocent. Each year of my life I felt, one by one. I don't know how long I spent lying on the bed. It was pretty horrible when I could hear what my mother was saying to me when I was eight years old. I didn't know then. I thought she meant I should be a good girl and wash my hands, that it was time to eat. Things like that. But while I remembered what I thought and felt then, I knew and understood as if I were an onlooker and at the same time I felt myself right in the midst of it, that mother was saying that to me, grown-up me as well as to eight-year-old me.

Each year it got worse. I tried to lose myself in my studies but I never did. I kept telling myself I was oblivious to everything and I believed it, but I wasn't. High school was a nightmare, and some of the boys touched my breasts when they would walk past, and everything my mother said became alive. I had just one date in college, and it was awful. Now I know he just asked, but I felt so awful unclean. I prayed and prayed and thought God had deserted me.

Then that awful scene at home and then the running from myself, one job after another. Everywhere I ran I found myself. I knew I was going crazy. I followed myself all over Europe, to Japan and the Phillipines. I was getting worse and the psychiatrist knew it and I knew it and I wouldn't believe it.

Then I was crying in that women's lounge, I was so desperate, and that patient of yours told me to see you. I knew it wouldn't do any good, it was hopeless. I couldn't do anything. But I wanted you to do something, so I didn't let you say no. So I came.

Genuine Age Regression with an Adult Observer

When I got that fear, I began remembering what happened in the office. I didn't know until then that I was in a trance in your office. I looked at that paperweight, and the next thing I knew *I was a little baby crawling on the floor at home. And I was also a grown-up person watching me.* I never thought about that until these memories came to me.

I did the whole thing over again. I watched me grow up. I heard my mother talk to me. The big me could hear you. The little me could hear mother - seeing, feeling, being little. I went all the way through all the things that happened in the office. I watched me that day when I talked things over with you. I felt proud of me as I listened to me talk to you. Was I in a trance then? I was really so proud of all I had accomplished, and then the next time I walked in your office I had a feeling that I was going to say something important, and then I felt as if you had hit me with a horrible club. I saw everything stripped raw and bare. I knew that all you had done was just to uncover a horrible job I had to do. I knew I was the only one that could do it, and I hated you. I couldn't see how you did it, but all of a sudden I was right in the middle of the most turbulent and terribly deadly, hateful emotions. I wanted to die, but I couldn't. I got tired.

Then I heard you send me back to my room, and I kept thinking how tired I was and how good the bed would feel. I didn't see me come into the room or flop on the bed because the next thing I watched was what I did on the bed. I watched me go crazy with fear and desperation. Then I just reviewed everything.

All I can say now, Dr. Erickson, is that the job is done. The past is past, it belongs to me, it doesn't hurt, and I don't want to tell such unhappiness. But I probably will need some mature thinking and advice on how to plan my future.

CHAPTER 10

Creating Identity: Beyond Utilization Therapy?

Up to this point we have emphasized that hypnotherapy involves the utilization of the patient's own life experiences and that the indirect forms of suggestion are the means of evoking those experiences for therapeutic change. What happens, however, when the patient has been severely deprived in some basic life experiences? Can the therapist supply them vicariously in some way? Sensitive therapists have long recognized their role as surrogate parents who do, in fact, help their patients experience life patterns and relationships that have been missed.

In this final chapter we will present some of the senior author's approaches to supplying a patient with a personal relationship in a manner that anchors her within a more secure inner reality around which she can create a new identity for herself. This is the case of a young woman who so lacked the experience of being mothered that she gravely doubted her own ability to be one. Through a series of age regressions the senior author visited her in the guise of the February Man: A kindly granduncle type who became a secure friend and confidant. A series of such experiences enabled her to develop a new sense of confidence and identity about herself that led her eventually to a rewarding experience of motherhood with her own children.

The senior author has actually played the role of the February Man with a number of patients throughout his career. So complex are some of the details of his work in these situations, however, that he never quite completed any of his manuscripts about them. The following case is thus a synthesis of several of the senior author's original manuscripts together with commentaries on them by the junior author.

The reader is invited to explore with us some of the approaches and issues involved in the work of the February Man. There is much about this work that is beyond our own understanding. The use of indirect suggestions to integrate hypnotic and real-life memories to create a self-consistent internal reality is an art that does not entirely lend itself to rational analysis. We do try, however, fully realizing we have fallen short and are in need of the reader's creativity to fill some of the gaps and to carry the work further.

Case 16 The February Man

Initial Interview: A Lonely Childhood

At midterm of her first pregnancy the wife of a young doctor on our hospital staff approached the senior author for psychiatric help. Her problem was that although happily married and pleased with her pregnancy, she was fearful that her own unhappy childhood experiences would reflect themselves in her handling of her child. She stated that she had studied too much psychology since it made her aware of the possible inadvertant unfortunate handling of a child, with resulting

psychological traumatization.

She explained that she had been a most unwanted child. Her mother never had any time for her. Her care rested in the hands of her mother's unhappy spinster older sister who, in return for a home, acted as nursemaid, housekeeper, and general factotum. Her preschool days had been spent almost exclusively in her nursery, and she was left to devise her own games and entertainment. Occasionally, when her mother gave a social tea, she would be trotted out briefly for exhibition and told what a sweet, pretty little girl she was and then dismissed. Otherwise, her mother, between social engagements, looked in upon her in the nursery briefly and casually. She had been sent to a special nursery school and later to various private schools for her grade school and high school education. During the summers she was sent to special camps to further her education. During these years her mother took time out from her round of pressing social engagements and trips abroad to see her daughter as often as was humanly possible. Essentially she and her mother had remained strangers.

As for the father, he, too, was a busy man, greatly absorbed in his business enterprises and traveling much of the time. He did have a genuine affection for his daughter, however, and had frequently found time to take her, even as a small child, out to dinner, to the circus, to amusement parks, and to other memorably delightful places. He also had bought her toys and presents befitting her needs, in contrast to the horribly expensive dolls with which her mother showered her, but with which her aunt would not let her play because they were beautiful and valuable. She had received only the best of everything from her mother, but her father had always given her many little things that were really nice. At the age of eighteen she had rebelled against finishing school and, to her mother's intense distress and resentment, had insisted on attending a state university. Her mother's chief argument was the debt the daughter owed her for practically ruining her figure in order to give birth to her. The father, greatly dominated by his wife but much in love with her, had secretly abetted his daughter in her decision and had encouraged and aided in every possible way, but without trying to overindulge her.

Her university adjustments had been good scholastically, but she felt that she had made insufficient use of her social opportunities. Early in her senior year she had met an intern, five years older than she, with whom she fell in love. She had married him a year later. This had distressed her mother, since the intern lacked social position, but the father had privately expressed his approval.

Because of this history she now wondered what kind of mother she would be. Her psychological reading had convinced her that her rejection by her mother and her emotional starvation as a child would in some way adversely affect the handling of her own baby. She wanted to know if, through hypnosis, her unconscious could be explored and either her anxieties relieved or she could be made aware of her deficiencies and thus make corrections. She asked the senior author to consider her problem at length and to give her another appointment when he felt he might be able to meet her needs.

She was told that before this could be done, it would be necessary for her to relate at length all her anxieties, fears, and forebodings. In so doing she was to give as comprehensive a picture of their nature, variety, and development as possible. It was explained that the primary purpose of

this report was to make certain that the senior author appreciated as fully as possible her feelings and thoughts before any attempts were made to ascertain causes and remedies. From this additional material, of course, he privately hoped to learn more details of her life history that he could use to facilitate the hypnotherapeutic work.

Second Interview: A Spontaneous Catharsis

At the next interview the patient was exceedingly fearful, anxious, and tearful. She expressed disconnected fears of hurting, neglecting, and resenting her child. She feared feeling tied down by it, of being overly anxious, of giving overcompensatory attention to it, of making it a hideous burden in her life instead of a pleasure, of losing her husband's love, of never loving the child, and so on.

She elaborated upon these ideas poorly but in relationship to every possible stage of the child's eventual development.

She wept throughout the interview, and while intellectually she regarded her fears as groundcless, she declared that their strong obsessional character was causing insomnia, anorexia, and severe depressive reactions that terrified her.

If she tried to read or to listen to the radio, the printed page or the program would be obscured by vivid, compelling memories of her own childhood unhappiness. She recognized that all her fears were abnormally exaggerated, but she felt helpless to do anything about them.

Except for innumerable anxieties little actual history was obtained. She asked tearfully if the writer thought he could help her, since she felt she was breaking down more rapidly than ever. She was assured that before her next appointment a therapeutic plan would be worked out for her.

Third Interview: The Interpolated Trance; Age Regression and Amnesia.

At the next interview she was assured that an elaborate program had been worked out and that the results would undoubtedly be most satisfying to her. What the plan was could not be disclosed to her yet, but through hypnosis her unconscious would acquire adequate understanding. All that she needed to know consciously was that hypnosis would be employed and that the task could be begun immediately if she wished. She acquiesced eagerly. In this session approximately five hours were spent training her adequately as a hypnotic subject. Particular emphasis was placed upon age regression. Her intelligence and excellence as a subject made possible the elaborate training considered necessary for the planned procedure.

During the training slowly and cautiously she was regressed in time repeatedly to some safe past situation into which, in some fashion, the writer could enter directly or indirectly, without distorting the regression situation. Thus the first regression was to the first interview with her. In having her relive that interview, it became easily possible to introduce a new element not actually belonging to the situation but that could easily fit into it. In accord with her revivification of that

interview the writer merely remarked, Do you mind if I interrupt and introduce a thought that just came to my mind? It just occurred to me that you could easily be a good hypnotic subject, and I wonder if you would mind closing your eyes and sleeping hypnotically for a few moments, and then arousing and continuing from where I interrupted? Thus an interpolated trance was introduced into that reliving of the first interview, in which no hypnosis had occurred.

R: The first trance has the effect of dissociating the patient away from the surrounding reality into her internal environment. When you then interpolate a second trance into the first, it effects an even deeper regression into herself. The basic purpose of the interpolated trance is to get the patient further removed from outer consensual reality. It's particularly useful for age regression.

E: Yes, I don't have to help her withdraw from the outer environment with the interpolated trance. When she gets back to reality, it will be much more difficult for her to recover that interpolated trance for which she has an amnesia even in the trance state.

R: So an interpolated trance is another way of effecting a deeper hypnotic amnesia.

E: In future trances she's going to have an amnesia for the interpolated trance, but she would have to go through it to get a complete memory of the first trance in which it took place. I gave her many positive supportive suggestions during the interpolated trance. This served to reinforce all the positive values of that initial interview.

R: It's like a feedback loop, where what conies later reinforces the positive values of what occurred earlier.

E: Yes, and it's reinforcing what happens now by virtue of the past that I've transplanted into the initial interview. I work in all directions. In everyday life when strangers meet they may speak casually in a general way until they discover something common in their past: They might have vacationed in the same place or come from the same state or town or gone to the same school. Sometimes they discover to their delight that they have a few acquaintances in common and can now share more intimate details of their lives. They have now created a strong rapport in the present based entirely on experiences from the past.

R: They have created a shared phenomenal world in common (Rossi, 1972a). They have built associative bridges that now bind them together in friendship. This is a common everyday process of social relating that you are now utilizing to enhance your rapport with this patient. The interpolated trance is a way of rapidly creating a positive history that enhances current relations.

Rapport Protection: Indirect Suggestion and Contingent Possibilities

She was then regressed to an intern's party at which there was a number of the senior author's former medical students. In the process of regression the suggestion was implanted that she might meet him at that party or that someone would mention his name, and undoubtedly this would happen when someone approached her and attracted her attention by gently squeezing her wrist. Then, when this unexpected thing happened, she could make a full response to the wrist pressure and react in accord with whatever situational need developed. Primarily, this was to introduce a

physical cue to permit ready induction of a trance state at any time, even during the reliving of past events that had occurred long before meeting the senior author. Various such regressions were induced, aided by special information that had been privately supplied by the husband. These were utilized to condition her for trance induction in any set of psychological circumstances.

E: I was building rapport protection with this procedure. I once regressed *a* subject at Clark University to ten years of age. While regressed, he explained that he was on an errand to buy a loaf of bread for his mother. We could all see the abject terror on his face because he did not know anyone in that room (where as an adult he was being hypnotized). I spent a wretched four and a half hours trying to get back into rapport with him because he was afraid of me and afraid of everyone else. That taught me that thereafter I'd have a secondary way of establishing rapport with the subject such as touching a wrist. It's an attention-attracting but otherwise meaningless cue. The subject cannot easily incorporate it into the age-regressed pattern of behavior.

R: You did not directly tell her that pressure on her wrist was a cue to enter trance or to pay close attention to what you were suggesting.

E: If I had said it that directly, she could reject it. Therefore I put it in an indirect framework *of contingent possibilities:* She *might* meet me. Someone would approach her; she *could* make a full response to the wrist pressure and react in accord with *whatever situational need developed.*These (the italicized words) are all undefined. There is no demand or threat in all this, and therefore no need for resistance or rejection.

R: We usually don't reject undefined possibilities in everyday life. Rather, possibilities and contingencies usually evoke our sense of wonder, speculation, and expectation. Possibilities actually initiate pressures *of unconscious search*within us that may trip off useful unconscious processes. Whatever situational need also covers all possibilities, including whatever suggestions you give her. You give her the most general form of an indirect suggestion here.

E: A most general form that can be filled in by the patient's specific understanding.

Interpolating New Life Experiences: The February Man

She was trained to develop in good fashion extensive regressions that were made to serve merely as a general background and situation for new, interpolated behavioral responses. She was regressed to past situations, and that frame of reference was employed merely as a background into which new hypnotic behavior could be interpolated. When sufficient training had been completed to ensure good responses, she was regressed to childhood at the age of four. The month of February was selected because it was her birthday. She was oriented to the living room of her childhood in the act of merely walking through it. She had often walked through her living room. Since the state of regression was limited to that act, it would constitute only a frame of reference. The walking through could be arrested and new behavior introduced into that setting without altering or falsifying the situation. Thus the new behavior intruded into that situation could be related temporally to the events of that age-regression period.

As she roused somnambulistically in this regressed state, she was greeted by the senior author:

Hello, little girl. Are you your Daddy's girl? I'm a friend of your Daddy's, and I'm waiting for him to come in to talk to me. He told me yesterday that he brought you a present one day and that you liked it very much. I like your Daddy, too. He told me it would soon be your birthday, and I'll bet he brings you an awful nice present. This was followed by silence, and the senior author apparently absentmindedly snapped open and closed his hunting case watch, with no further effort to engage her in conversation or to attract her attention. She first eyed him, then became interested in the watch, whereupon he held it to his ear and stated that it went tick, tick very nicely.

E: Hello, little girl assigns her a hypnotic role.

R: In that first second when she opens her eyes in somnambulistic trance you immediately reinforce the age regression so there could be no doubt about it. Is she going to see you as Dr. Erickson or as someone she does not know in her past? Your opening remark orients her into the past.

E: And there have been people in her past who have said just such a thing.

R: You then attract her attention appropriately by playing with your watch. This is just about right for a four-year-old; you do not introduce yourself in a direct or demanding way. You behave very much as a visitor to her house might when she was a child.

Wrist Cue as a Nonverbal Signal for Metasuggestions Orienting the Somnambulistic State

After a few moments the suggestion was offered that she might like to snap the case open or to listen to the watch. She nodded her head shyly and extended her hand. Taking hold of her wrist as if to help her, the senior author handed her the watch. She looked at it and played with it. The suggestion was offered that if she listened to it for a little while, it would make her very sleepy. This was followed by the comment that soon the senior author would have to go home, but that some time he would come back, and, if she wished, he would bring his watch so she could open and close it and listen to it.

She nodded her head, and her hand holding the watch was guided to her ear. Her wrist was slowly squeezed, and trance suggestions were given accompanied by suggestions that maybe next summer the senior author would come again, and maybe she would recognize him.

E: I had to get out of her house. I ended that interpolated life experience with the wrist cue in an appropriate way (guiding her hand with the watch to her ear) and suggesting she would get sleepy as she listened to it.

R: Having her go to sleep is fairly appropriate behavior for a four-year-old listening to a watch, and her sleep allowed you to leave. It also enabled you to give her the posthypnotic suggestion about seeing her again next summer *maybe, and may be* she would recognize you. These possibilities are appropriate for her age because a four- to five-year old child might not recognize

a friend after a year. But why did you give her the rapport cue by squeezing her wrist as you added these suggestions?

E: Although she was in a somnambulistic trance, further hypnosis would be needed to effect an alteration of that state to induce other phenomena.

R: I see. Even during a somnambulistic state special rapport is needed to effect important suggestions. The wrist cue is an orienting signal for the metasuggestions you will use to guide the somnambulistic state; it tells her important suggestions are coming. I have had the difficulty of working with some subjects who were so obstinate during the somnambulistic state that I could hardly get a word in edgewise. Like self-centered children, such subjects would soon take over the situation and simply live out an inner experience without my being able to relate to them. This may be valuable for cathartic purposes, but it does not permit the therapist to interpolate new experience as you are doing here.

E: You need another hypnotic frame of reference to orient her to important suggestions without verbally defining it as such and without altering my role as a stranger, Daddy's friend.

R: Classical age regression has typically been a simple reliving of a past life experience. A catharsis or process of desensitiza-tion is relied upon as the therapeutic means of resolving pent-up emotions of life traumas.

E: That does not add anything. Here I'm adding to the past.

R: That's the object of the entire procedure. You regress her to establish a frame of reference into which you can interpolate therapeutic life experiences. You are adding new experiences to her memory bank; you're adding new elements of human relating that she missed in reality.

E: You can add belief to something that does not exist if you repeat it often enough. That's why I had to give her many experiences with me as the February Man. I'm adding reality to a nonexistent thing.

R: It becomes real in terms of internal reality. With this approach you can alter a patient's belief system; you cannot really change her past, but you can change her beliefs about her past.

E: You can change beliefs and values. It's not really that we can believe lies; rather, we discover more things. Patients believe their limited reality until they discover more reality.

R: I wonder if we can equate discover more reality with creating new consciousness? There is still a basic question here, however. Are you (1) really adding something new to the personality, or are you (2) simply helping her discover and experience a natural, inherent pattern of human relating (the archetypal child-parent relationship) that she very much needed and wanted? Utilization theory would emphasize the second alternative; you are structuring circumstances that allow her to evoke and utilize inherent (species-specific) behavior patterns that must be expressed for normal development. But you are certainly adding a new content within the framework of this inherent pattern.

Continuing Experiences with the February Man: Ratifying the Historical Reality of Age-Regressed Experience

She was then permitted to experience about fifteen minutes of profound hypnotic sleep. This sleep was a passage of time during which my departure and eventual return (as had already been suggested) could take place. Her wrist was then again gently squeezed, and suggestions were offered that she better be in the yard because the flowers were blooming for the first time since her birthday last winter, and perhaps her Daddy's friend might come again. At all events she could really open her eyes very, very wide to see the flowers. She opened her eyes and was apparently enjoying her visual hallucinations when the writer, from behind, addressed her, Hello, little girl. Do you remember me? She turned, eyed him carefully, smiled, and said, You're Daddy's friend. The reply was made, And I remember your name. It is R. In this way the senior author became established as an actual figure in her past life without impinging upon realities or distorting them, but merely by adding to them by a simple process of temporal association. Thereupon a casual conversation was initiated at a childish level about the red and pink and yellow flowers (she said they were tulips), whereupon she reminded the writer about his watch, and essentially the same course of events ensued as had previously. Many more comparable instances were developed to ensure the possibility of the writer's intrusion into her past without invalidating the regression state. She was given extensive experience with the February Man, a figure that became more and more established in her life history.

E: I had learned from the initial interviews that her childhood home did have extensive flower gardens with red, pink, and yellow flowers. I would further ratify the historical aspects of the experience by pretending to have an unclear memory of my previous visits with her. How clear does anyone remember an experience of a year ago? Two years ago? Four years ago? I also introduced changing views. As she gets older, she gets a different perspective on things. I'd say, That first doll you had was really very nice. Remember your enthusiasm for that first circus? I might make such remarks to the ten- or twelve-year-old girl about the six-year-old girl.

R: You built associative bridges between the trance experiences at different age levels that established the historical reality of your visits with her.

Indirect Posthypnotic Suggestion

Finally she was placed in a profound trance and given extensive posthypnotic suggestions to ensure a comprehensive amnesia for all trance events and to ensure continued cooperation. I'd gently squeeze her wrist and say You have now completed that task. I want you to go into a profound trance at this time. I want you to enjoy resting, I want you to feel fresh after you've awakened, comfortably enjoying the feeling of being wide awake, prepared for a new day's activities.

E: That latter suggestion, prepared for a new day's activities, implies that she will be ready for more work; we are just beginning.

R: That's how you also imply a posthypnotic amnesia without directly telling her she would not

remember. You could then put her back into trance for another experience with the February Man.

Time for Hypnotic Work

In subsequent sessions, usually of several hours' duration, essentially the same procedure was followed.

E: I had to have several hours in order to let her have an experience with the February Man at one age level, rest, and then another experience at another age level. Time is expandable and compressible, but a certain amount of real clock time is still needed for careful work. Initially you really don't know what the patient's capacities are. Time is needed to explore them.

Integrating Hypnotic and Real-Life Memories: Creating a Self-Consistent Internal Reality

A number of hypnotherapeutic sessions now took place following this same pattern. She was regressed to many different periods of her life, usually in a chronologically progressive fashion, taking care not to let the created situation impinge contradictorily upon the actual realities of the past. For example, on one occasion, regressed to a nine-year-old level, she manifested intense astonishment upon opening her eyes and seeing the senior author. Cautious inquiry disclosed that she was visiting a distant relative for the first time and had just arrived the previous night. A few questions elicited enough information to orient the senior author so that he could claim a business friendship with her relative. This laid a foundation very necessary for the subsequent ubiquity of him in her life experience. Aiding in the acceptance of his ubiquity was the fact that both of her parents traveled extensively and often unexpectedly, and that they had innumerable acquaintances and friends. Hence it was easily assumed that the same was true of the senior author as Daddy's friend. Also of importance was the February Man's knowledge of various cities she had visited and the fact that he, as well as she, had studied psychology, all of which provided a wide background permitting her to accept him unquestioningly. As the procedure continued, the technicalities of securing responsive behavior became minimal, and a dozen regressed states could be developed in an hour's time. These were all utilized to secure a report by her of things and attitudes current to the regression period, as well as an account of expected or anticipated events. Anticipated events served admirably in enabling the senior author to direct regression states to safe periods. However, care had to be exercised, since anticipations were not always fulfilled. Frequently, however, the visit was devoted to an account of what had happened since the last visit that is, the preceding regressed state. She learned to look upon the senior author as a recurrent visitor and as a trusted confidant to whom she could tell all her secrets, woes, and joys and with whom she could share her hopes, fears, doubts, wishes, and plans.

From time to time it became necessary to induce comprehensive amnesias, obliterating various of the senior author's visits, and to regress her to an earlier age and to go over an already partially covered period of her life more adequately. Thus, some sudden change in her life, not anticipated at an earlier age regression, might have become established before the period of the next age regression, thereby creating a situation at variance with established understandings. On such

occasions the last age regression would be abolished by amnesia suggestions, and a new regression to an earlier time would be induced to permit the securing of pertinent data.

R: You made a very careful and extensive effort to integrate hypnotic and real memories so they were molded into a self-consistent inner reality. This would ensure the permanence of the new attitudes you were facilitating in her. If there were contradictions and a lack of consistency between the hypnotic and real memories, self-corrective processes within the unconscious would have tended to gradually eliminate the hypnotic suggestions as foreign intrusions. This may be why so much hypnotic work in the past has had only temporary or partial effect. Direct suggestions made even while a patient is in a deep somnambulistic state are not programmed within the mind forever in a rigid way. The human mind is a dynamic process that is continually correcting, modifying, and reformulating itself. Inconsistencies are either worked out in a satisfactory manner or are expressed as problems (complexes, neuroses, psychosomatic symptoms, etc.). There is thus nothing magical or mysterious about the effectiveness of your approach: It is based on very careful, thorough work integrating real memories with hypnotic experience.

Facilitating Therapeutic Attitudes: A Therapy of Life Perspectives: Dreams and Hypnosis

The consistent and continual rejection she experienced from her mother presented many opportunities to reorganize her emotions and understanding. By this procedure the senior author's role became one of friendship, sympathy, interest, and objectivity, thereby giving him the opportunity to raise questions concerning how she might later evaluate a given experience. Thus, in expressing her grief over breaking a cheap little china doll her father had given her and which she treasured, she could declare that, when she grew up and became a mother and had a little girl who broke her doll, she would know that it wasn't something awful bad but that she would know just how her little girl would feel. Similarly, a fall on the dance floor in her teens was regarded by her as an utterly and completely devastating experience. Yet she manifested a readiness to understand the senior author's comment that she should rightly appreciate it as such in the present but that at the same time she could also understand how, in the future, it could really be regarded as a minor and completely unimportant event, perhaps even amusing. Her first adolescent infatuation, her jilting by the boy, and her tremendous need to understand herself in relation to that event were dealt with. Her resolution to leave the finishing school, to enter the university, her choice of studies, her scholastic struggles, and her limited social life were all covered. The meeting with the man who became her husband, her doubts and uncertainties about him, the eventual engagement, and the mother's attitude toward him, toward the marriage, and toward the subsequent pregnancy were all detailed to the senior author in current accounts of what was happening to her. Numerous other instances of rejection, neglect, and disappointment by her mother and father were relived and discussed with the February Man. Real happy memories were also relived and integrated with the hypnotic memories to ensure a comprehensive integration of them.

R: Whenever she had a traumatic life situation, she could now discuss them with her father's friend, the February Man. In effect you became a therapist at such times. This is a curious state of

affairs, you as her current therapist became a therapist in her past, helping her deal with her difficult life situations as they occurred. I've noticed something similar in dreams. Some patients seem to relive their past in dreams but correct the traumatic aspects of their past with their current adult perspectives (Rossi, 1972a; 1973c). This again points out the self-corrective aspect of the psyche; it is in a continual process of reformulating or resynthesizing itself to achieve a more integrated pattern of functioning. You utilize and facilitate this resynthesizing aspect of psychic functioning with your role as the February Man. You are doing hypnotically what frequently happens naturally during dreams.

E: Yes. [The senior author now recalls such a dream of his own, when the adult Dr. Erickson observed himself as a child (Erickson, 1965a).] Dreams give us the opportunity to relive past events and appraise them critically from an adult perspective.

R: Dreams are autotherapeutic processes that help the mind correct and integrate itself. I also believe we are synthesizing new phenomenological realities in our dreams that become the basis of new patterns of identity and behavior (Rossi, 1971; 1972 a, b; 1973 a, b, c.).

A Reversal of Realities: Deepening the Therapeutic Frame of Reference

Toward the end of this extensive reorganization of her attitudes about her past, a new memory was recalled: Her secret resolve years ago to have hypnotic anesthesia should she ever marry and become pregnant. As she now again considered this possibility, she received a letter of foreboding from her mother requesting that the term grandmother never be used - in essence, rejecting the unborn baby. This letter intensified the patient's anxieties and fears anew.

To deal with these renewed anxieties a variation in our hypnotic procedure was developed. In this variation a blanket amnesia was first induced for all her previous hypnotic work, and she was asked to again relate all her fears and anxieties. In this state, as expected, her account was comparable to her original expression of her problems before hypnotherapy.

A new trance state was then induced in which the blanket amnesia was removed. She was then regressed to a week ***before*** the arrival of her mother's letter. In this state of hypnosis she was asked to recall fully all the many visits, talks, and discussions over the years she had had with the senior author as Daddy's friend. As she recalled his many visits and their conversations on so many subjects, the suggestion was offered that she ought to consider the present minor worries against that total background. As she began this correlation of her unhappy ideas in the past as she conceived it at the moment, she began to develop amazing insights, understandings, and emotional comfort.

Having reestablished the new attitudes developed in the hypnotic work, the senior author next led her into an age-regression state covering the period just ***after***the receipt of the mother's letter. After expressing some sensible views about her mother's problem, she was asked to give the reactions she could develop if she did not include in her thinking all she knew about her past. She was told that she ought to speculate aloud on how she could really enlarge her reactions into exaggerated fears and anxieties by just not being comprehensive in her thinking. She was urged to offer speculative statements expressing such anxieties. She then proceeded to verbalize them as

she thought would be possible if she did not think intelligently. This speculative account was identical with that which she had originally given just before therapy began and the previous account with the blanket amnesia for all the hypnotherapeutic work. But it was given as a speculative account which was decidedly different from the new reality of her emotional life that now included the new frames of reference she had developed with the February Man.

Subsequent regression states were similarly utilized. Her speculations about how she could exaggerate her fears always gave accounts similar to the one she gave originally before hypnotherapy. These speculations were always in sharp contrast to her real attitudes developed with the help of Daddy's friend, the February Man. She now drew extensively upon her actual past history, with all its interpolated experiences with Daddy's friend. During this period a tremendous amount of her past history came out in clear relevance to her entire current problem. As this type of activity continued, she developed insights that were remarkably corrective.

R: This is an ingenious twist: what was originally a painful reality now becomes the speculative account, while the new attitudes introduced by hypnosis become the abiding reality. That is, she is now accepting her expanded frame of understanding developed with the February Man as her real views, while her previous behavior is now seen merely as a speculative account of how badly things could be if she did not think intelligently. This procedure may be helping her integrate the February Man frame of reference at an even deeper level. This is particularly the case because she is already in a deep hypnotic state as she experiences this reversal of realities.

Termination: A Final Conscious Integration of All Trance Work

Finally, as she progressed in this regard, the topic of hypnotic anesthesia for the delivery of her child was mentioned increasingly by her while she was in trance. She was reassuringly told that as the months of pregnancy passed, it was absolutely certain that all of her anxieties would be comprehensively and comfortably understood and thus become a resolved experience of the past. In their place would be a realization that in some way she would meet someone who would teach her to understand herself happily. Since she was in an age-regressed state, this was naturally a reference by implication to the senior author as someone she would meet in the future. In so doing she would be trained to become an excellent hypnotic subject and thereby her college resolve for a hypnotic delivery would be fulfilled.

The termination of therapy was accomplished rather simply. She was regressed to the time of preparation for her first visit to the senior author's office. She was assured by him - still in the role of Daddy's friend - that her trip would be fully successful in many more ways than she really expected. The scene was then shifted to the office, and she was much astonished to see the February Man. The senior author was also astonished! She was puzzled at his presence, explained that she had come to see Dr. Erickson. She was assured that she would see Dr. Erickson and that he would meet her wishes fully, but that, for a few minutes, she should sleep most profoundly. During this trance approximately one half-hour was spent instructing her so that after she awakened she would recall from the beginning, in chronological order, every trance experience she had had, together with all insights and understandings that she had developed up to the date shown by the day's newspaper on the desk. At the close of the interview she was told to spend a few delightful days reviewing her memories, making certain that she understood, remembered,

and accepted all her past in an adjusted fashion. As for the hypnotic anesthesia, she would be certain of it, but the minor details would be arranged in the next interview.

R: This was a final summation for a final conscious integration of all her therapy. She now finally learns how you played the role of the February Man, how you reversed her realities, and so on. Yet this does not undo the effectiveness of the new attitudes and frames of reference you helped her develop. Why doesn't it? After all your incredibly complex efforts to develop a new frame of reference, integrate it, and deepen it, why do you end the therapy with this complete denouement?

E: Because I may have made some errors. She may have made some errors. Let's make sure we get the whole set of errors corrected.

R: You are not afraid of undoing your therapeutic work because you actually, have helped her develop new frames of reference and understandings that have therapeutically altered her emotional life. This case contrasts sharply with those cases in which you like to maintain an amnesia for all hypnotherapeutic work. What is the difference?

E: Some personalities need amnesia, some do not. It's a matter of clinical experience to distinguish them.

R: Those patients whom you judge to have destructive conscious attitudes toward the therapy might do better with an amnesia.

E: This patient was actually left with some amnesia for the negative emotions she experienced in relation to her mother. My final posthypnotic suggestion to her was to spend a few delightful days reviewing her memories, making certain that she understood, remembered, and accepted all her past in an ***adjusted*** fashion. This precluded any regression into the catastrophically negative affects and anxieties she was experiencing before therapy.

Training for Obstetrical Analgesia: A Two-Year Followup

At the next session some days later she stated that she had been interested primarily in thinking about her hypnotic delivery. After much discussion with her husband, during which he was primarily the listener, she had decided on an analgesia if it were possible. She explained that she wished to experience childbirth in the same fashion as she had, as a child, sensed the swallowing of a whole cherry or a lump of ice, feeling it pass comfortably and interestingly down the esophagus. In a similar manner she would like to feel labor contractions, to sense the passage of the baby down the birth canal, and to experience a sense of distension of the birth canal. All this she wished to experience without any sense of pain. When questioned about the possibility of an episiotomy, she explained that she wanted the sensation of the cutting without pain and that she wanted to feel in addition the suturing that would be done. When asked if she wished at any time to experience any feeling of pain merely as a measure of sampling it, she explained: Pain shouldn't have any part in having a baby. It's a wonderful thing, but everybody is taught to believe in pain. I want to have my baby the way I should. I don't want my attention distracted even a single minute by thoughts of pain. Accordingly, as a measure of meeting her wishes, she was taught to develop complete hypnotic anesthesia. (Usually the procedure is to proceed from numbness to analgesia to

anesthesia.) Since in this instance an analgesia was the primary goal, anesthesia was induced extensively and then systematically transformed into an analgesia. (That a complete transformation of anesthesia to analgesia could be effected is doubtful, but the patient's wishes could be met in this manner, and whatever anesthesia remained would only supplement the effectiveness of the analgesia.)

When she had been trained sufficiently to meet various clinical tests for analgesia, extensive training was given to her to effect the development of a profound somnambulistic posthypnotic trance with that degree and type of analgesia you have just learned, so that she could enter into labor without any further contact with the senior author.

Additional instructions were that she would awaken at the completion of labor with a full and immediate memory of the entire experience. Then, when she returned to her room, she would fall into a restful, comfortable sleep of about two hours' duration, and thereafter she would have a most pleasant hospital stay, planning happily for the future.

About seven weeks after the delivery she and her husband and baby daughter visited the senior author. They reported that, as she entered the hospital, she had developed a somnambulistic trance. During the labor and delivery her husband was present. She had talked freely with her husband and the obstetrician and had described to them her labor contractions with interest. She had recognized the performance of the episiotomy, the emergence of the head from the birth canal, the complete delivery of the baby, and the suturing of her episiotomy - all without pain. The expulsion of the placenta caused her to ask if there was a twin because she felt another one moving down. She was able to laugh at her error when informed it was the placenta. She counted the stitches in the repair of her episiotomy and inquired if the doctor had cheated by giving her a local anesthetic because, while she could feel the needle, it was in a numb, painless way that she associated with the numb feeling of her cheek after a local dental anesthetic. She was relieved when informed that there had been no local anesthetic.

She was shown the baby, looked over it carefully, and asked permission to awaken. She had been instructed to be in full rapport with her husband and the obstetrician and to do things as needed to meet the situation. Hence, inexperienced in the situation, she carefully met the need of abiding by the situation by making sure it was in order to awaken. She again looked the baby over. Then, upon telling her husband that she had full memory of the entire experience and that everything had occurred exactly as she desired, she suddenly declared that she was sleepy. Before she left the delivery room, she was sound asleep, and slept for one and a half hours. Her stay in the hospital was most happy.

Two years later she announced to the senior author she was having another baby, and asked that she be given a refresher course, just to make certain. One session of about three hours in the deep trance sufficed to meet her needs. Much of this time was used to secure an adequate account of her adjustments. They were found to be excellent in all regards.

EXPERIENCING HYPNOSIS:

THERAPEUTIC APPROACHES TO ALTERED STATES

Dr. Milton Erickson and Dr. Ernest Rossi

We dedicate this volume to Elizabeth Erickson and Margaret Ryan, whose thoughtful editorial work has made it possible.

CONTENTS

INTRODUCTION

This book is a continuation of our earlier work in *Hypnotic Realities* (Erickson, Rossi, & Rossi, 1976) and *Hypnotherapy: An Exploratory Casebook* (Erickson & Rossi, 1979), whereby the senior author, Milton H. Erickson, trains the junior author, Ernest L. Rossi, in clinical hypnosis. Taken together, these three volumes present a deepening view of what hypnosis is and the ways in which a creative process of hypnotherapy can be achieved. The material in these volumes touches ultimately on the nature of human consciousness and suggests a variety of open-ended approaches to facilitate its exploration in hypnotherapy as well as in more formal research situations.

Indirect communication is the overall concept we use to cover what we have variously described as two-level communication, the naturalistic approach, and the utilization approach. The common denominator of all these approaches is that hypnotherapy involves something more than simple talk on a single, objective level. The readily apparent, overt content of a message is like the tip of an iceberg. The recipient of indirect communication is usually not aware of the extent to which his or her associative processes have been set in motion automatically in many directions. Hypnotic suggestion received in this manner results in the automatic evocation and utilization of the patient's own unique repertory of response potentials to achieve therapeutic goals that might have been otherwise beyond reach. In our previous volumes we outlined the operation of this process as the *microdynamics of trance induction and suggestion.* Although this is the essence of the senior author's original contribution to modern suggestion theory, we will review in this volume some of the many means and meanings that other authors have used as they struggled to reach an understanding of indirect communication in the long history of hypnosis.

The first section of this volume presents an historically important lecture on clinical hypnosis by the senior author wherein we witness his transition from the older authoritarian approach to hypnosis to the new permissive approaches, which he pioneered. Due to the unique nature of this presentation, an audio cassette of it accompanies this volume. We strongly recommend that our professional readers listen to this cassette and savor it a bit before dealing with the lecture as presented in the text.

The second and third sections of this volume focus on the phenomena of catalepsy and ideomotor signaling, two of the senior author's basic approaches to trance induction and hypnotherapy. The primary concern is the practical question of how to induce therapeutic trance and how to evoke the patient's repertory of life experiences and involuntary response systems that are utilized in hypnotherapy. As is characteristic of our previous work, the growing edge of our current understanding of the subjective experience of clinical trance and altered states is discussed throughout.

A film of Erickson made by Ernest Hilgard and Jay Haley at Stanford University is available from Irvington Publishers for study by serious students who wish to observe the nonverbal aspects of Erickson's I innovative work utilizing the reverse set in hypnotic induction presented in Section III. We believe that further research on and development of this reverse-set approach will greatly expand our understanding of the dynamics of trance and serve as the foundation for a new generation of more effective approaches in hypnotherapy.

The fourth section, dealing with the experiential learning of hypnosis, illustrates one of the senior author's favorite occupations in recent years: the training of professionals in the use of clinical hypnosis by allowing them to experience the process themselves. The two sessions presented in this section are illustrative of the problem faced by a modern, rational, scientifically trained mind in learning to experience hypnotic phenomena. Herein are illustrated many of the phenomena and paradoxes of modern consciousness as it seeks to understand more about itself by making an effort to transcend its current limitations.

Ernest Rossi *Malibu, California*

SECTION I

The Indirect Approach to Hypnosis

We begin here by illustrating the indirect approach to hypnotic communication through the transcription of a lecture given by the senior author before a group of his professional colleagues. We then outline our current understanding of this approach and its relevance for facilitating the processes of hypnotic induction and therapeutic trance.

A. HYPNOSIS IN PSYCHIATRY: THE OCEAN MONARCH LECTURE

This lecture is an unusually clear and succinct presentation of the senior author's approach to hypnotic induction and hypnotherapy. Given at the height of his teaching career, it represents an important shift away from the authoritarian methods of the past to his pioneering work with the more permissive and insightful approaches characteristic of our current era. In the actual words of this presentation we can witness how important concepts are in transition. While Erickson still uses the words *technique* and *control* a number of times—and even *manipulate* and *seduce* appear once each—it is evident from the broader context that they are outmoded in the traditional authoritarian sense in which they had been used.

A paradigmatic shift is taking place in this presentation: It is now recognized that the most significant person in the hypnotherapeutic interaction is the patient, not the therapist. The patient's potentials and proclivities account for most of the variance (what actually happens) in hypnotherapy, not the purported "powers" of the hypnotist. The therapist does not command the patient; rather, as the senior author says, "It is always a matter of offering them [patients] the opportunity of responding to an idea." It is now recognized that the hypnotherapist offers the patient many *approaches* to hypnotic experience rather than imposing hypnotic *techniques.* The concept of *technique* implies the mechanical and repetitious application of a particular procedure in the same way to every patient with the intent of producing a preconceived and predictable response. The concept of *approaches* implies the profferance of alternatives to help each patient bypass his or her own particular learned limitations so that the various hypnotic phenomena and hypnotherapeutic responses may be experienced.

Therapists do not "control" the patients; rather, they help the patients learn to "utilize" their own potentials and repertory of unconscious skills in new ways to facilitate the desired therapeutic outcome. This new orientation requires the development of many observational and performance skills by hypnotherapists. More than ever it is required that they learn to recognize and appreciate each patient as a unique individual. Every hypnotherapeutic interaction is essentially a creative endeavor; certain known principles are being applied, but the infinite possibilities within each patient require an essentially exploratory approach to achieve the therapeutic goals.

This lecture is highly characteristic of the senior author's style of presenting his approach to hypnotic induction and hypnotherapy. Listening to it on the cassette accompanying this volume in a relaxed mood may have important values for the reader that are not contained in the edited version presented in this volume. Before reading any further, then, the reader may best listen to the cassette labeled "Hypnosis in Psychiatry: The Ocean Monarch Lecture." Those readers who are familiar with our two previous books in this series will know why we recommend listening to the cassette first. Other readers will understand the reasons after

reading the discussion of this tape that follows its edited version on these pages. Please listen now to the lecture.

A. HYPNOSIS IN PSYCHIATRY: The Ocean Monarch Lecture

The Conscious and the Unconscious Mind

I do not necessarily intend to demonstrate hypnosis to you today so much as to discuss its use in psychiatry. However, the use of hypnosis in psychiatry actually applies to the use of hypnosis in any other medical field, whether dental, dermatology, or whatever it might be. The first idea I want to impress upon you is one way of thinking about your patients clinically. It is desirable to use this framework because of the ease of concept formation for the patient. I like to regard my patients as having a conscious mind and an unconscious, or subconscious, mind. I expect the two of them to be together in the same person, and I expect both of them to be in the office with me. *When I am talking to a person at the conscious level, I expect him to be listening to me at an unconscious level, as well as consciously.* And therefore I am not very greatly concerned about the depth of the trance the patient is in because I find that one can do extensive and deep psychotherapy in the light trance as well as in the deeper medium trance. One merely needs to know how to talk to a patient in order to secure therapeutic results.

Learning One's Own Method of Suggestion Following the Patient's Lead

Now the next thing I want to stress is *the tremendous need for each doctor to work out a method of suggestion for himself.* In developing my own technique, I worked out what I felt was a good hypnotic technique. It was about 30 typewritten pages, single-spaced, of the various types of suggestions necessary to induce a deep trance. And then I slowly cut it down from 30 typewritten pages single-spaced to 25, to 20, to 15, to 10, to 5, and so on, so that I could use the whole 30 pages or I could use just one page or one paragraph. But I learned thoroughly how to graduate my suggestions, and how to lead from one suggestion to another. When one does that sort of thing, *one learns how to follow the leads given by his patient.*

Trance Induction: Catalepsy to Heighten Responsiveness

In inducing a trance in your psychiatric patient or, for that matter, any patient, it is the fashion in which you present the suggestion to the patient that is important. For example, some of you have seen me demonstrate the proper way to take hold of a patient's wrist. Too often, a doctor will grab hold of a wrist and lift it up forcibly. But when I lift someone's hand, I purposely do so in a very, very gentle fashion so that there is just a suggestion that I am lifting the arm, and just a suggestion that I am trying to move it this way or that way. And the more gentle you can be in the physical touch of the arm, when you are lifting it up in the air to induce catalepsy, the more effective it is. Any forcible seizure of the patient's arm causes difficulty because you want to stimulate the patient to be responsive to you. Hypnosis is primarily a state in which there is increased responsiveness to ideas of all sorts. And one employs that responsiveness not by trying to force, but by trying to elicit an immediate response—and to elicit it by having the patient participate.

In exactly the same way, I do not like this matter of telling a patient, "I want you to get tired and sleepy, and to get tired and sleepier." That is an effort to force your wishes upon the patient. That is an effort to dominate the patient. It is much better to suggest that they *can* get tired, that they *can* get sleepy, that they *can* go into a trance. For it is always a matter of *offering them the opportunity of responding to an idea.*

Patient's Freedom to Respond: Positive and Negative Suggestions

I have found that patients often have the notion that hypnosis is a powerful tool that can compel them to act according to my wishes. I like to *approach* my psychiatric patients—whether they are neurotic, emotionally disturbed, prepsychotic, or even psychotic—in a fashion that lets them *feel free to respond to whatever degree they wish.* I never tell a patient that he has to go into a deep trance, or into a medium trance, or for that matter into a light trance. I suggest also that he never tell me anything more than he really wants to tell me. I usually tell my patient that he can *withhold whatever he wishes,* and to be sure to withhold whatever he wishes. I am emphasizing this point because I want you to have some understanding of positive and negative suggestions. To tell a patient, "Now, tell me *all,"* is a rather threatening, even dangerous request to make. Rather, you want the patient to be willing to tell you this, willing to tell you that, so that as they begin telling you this and that, *they also begin to develop a certain sense of confidence.*

Rapport: Utilizing Ambivalence and Naturalistic Modes of Functioning

Now and again you will meet a patient with whom you have an immediate rapport, and then you can take the dominant attitude. But one really ought to be cautious. In using positive and negative suggestions, one tries to make it possible for the patient to exercise his own ambivalence for your benefit and for his benefit. He is both willing and unwilling to secure help from you, so you try to define the situation for him in such a way that he can get help in one direction and refuse help in another situation. In that way the patient develops a readiness to go along with you.

Now in hypnotizing the psychiatric patient I think one of the important things to do first is to establish a good conscious rapport. Let him know that you are definitely interested in him and his problems, and definitely interested in using hypnosis if in your judgment you think it will help. So often I have had patients come in and demand that they be hypnotized, to which I usually counter with the statement that it is better for the doctor to prescribe than for the patient to prescribe. And surely if they can benefit from hypnosis, I will employ it. But then I will ask their permission to employ it in the way that is most helpful to them.

And what have I really suggested? I have suggested that it be employed in a way most helpful to them. Usually I go through the preliminary explanation that they are going to remain conscious. But I point out to them that the fact that they can hear the clock on the wall, that they can see the bookcases in the room, that they can hear any disturbing sounds, is rather unimportant. The essential point is that they pay attention, not necessarily to me, but to their own thoughts—especially the thoughts that flash through their mind, including the manner and the sequence in which those thoughts flash through their mined. [Hypnotic suggestion always utilizes such naturalistic modes of functioning; it never imposes anything alien on the patient.]

Now, hypnosis is something that allows you to manipulate *[sic*—we now prefer *utilize!]* the personality in its various ways of functioning. One can ask a patient in the trance state to remember something of the past, or to speculate upon the future, or to shift from one gear to another gear. Too often there is an attempt to follow through in a consistent way on one

particular problem, long after the patient has become too fatigued or too disturbed emotionally to do that. You must realize that hypnosis allows you to come back to a particular idea, or fear, or anxiety so that it is never necessary to ask a patient to experience too much distress or emotional discomfort at any one time.

Questions Facilitating Rapport and Trust

What are some of the uses of hypnosis in psychiatry? The first, and I think the primary, use of it should be in establishing a good personal relationship with the patient. Once you have hypnotized patients, they will often feel that they can trust you. And, it is important to give them the opportunity of discovering that they can trust you. Therefore, I usually ask patients in the hypnotic trance some question that I know they should not answer at that time. I ask a question, and before they can possibly hear it, I point out to them that it is a question that should not yet be answered, and that they ought not to answer it until the right time comes along. Then I ask them to think about what I have said. As a result, they realize that they can answer questions freely and easily, but are under no compulsions to answer a question before the right time comes. I make this clear to patients in the waking state as well as in the trance state, because you are dealing with a person that has a conscious mind and an unconscious mind.

Integrating Conscious and Unconscious Learning

This brings us to another important point regarding the use of hypnosis. Because you are dealing with a person who has both a conscious mind and an unconscious mind, achieving good results with a patient in a deep trance does not mean that the patient will benefit from it in the ordinary waking state. There has to be an integration of unconscious learnings with conscious learnings. This should be foremost in your mind whenever you use hypnosis on psychiatric patients. You can recognize that you can resolve a conflict, a phobia, or an anxiety in the trance state. But unless you do something about it in the waking state, the patient is still likely to have that anxiety or phobia. You can remove a phobia for a certain color in the trance state so that the patient behaves normally. Nevertheless, when he awakens from the trance state, he will still have conscious habit patterns of response to that particular color. And therefore it is essential to integrate the unconscious learnings with the conscious learnings.

While a patient of mine was recovering a traumatic experience, she developed a fear of the color blue. She had seen her sister nearly drown, and her sister had looked decidedly blue in appearance. The patient didn't really recover from her fear of blue, although she could handle anything blue and look at anything blue in the trance state, until she had a feeling of conscious comfort while dealing with blue cloth and blue colors of all sorts in the waking state. She did not necessarily need to have a complete knowledge of her sister's near drowning, but she did need to have an awareness that blue used to be associated with very uncomfortable things. Therefore, in dealing with patients it is always necessary to decide how rapidly and how thoroughly they will need to integrate what they learn unconsciously with what they learn consciously.

Dissociating Intellect and Emotion in Dealing with Anxiety, Phobia, and Trauma

Hypnosis can also allow you to divide up your patient's problems. For example, a patient comes to you with some traumatic experience in the past which has resulted in a phobic

reaction or an anxiety state. One can put him in a deep trance and suggest that he recover only the emotional aspects of that experience. I have demonstrated this phenomenon in the past by having one of my demonstration subjects recover all the merriment of a joke without knowing what the joke was. And yet that subject laughed and laughed in the merriest fashion over the joke, wondering at the time what the joke was! Later, I let my subject remember the actual joke. In other words, one can split off the intellectual aspects of a problem for a patient and leave only the emotional aspects to be dealt with. One can have a patient cry out very thoroughly over the emotional aspects of a traumatic experience and then later let him recover the actual intellectual content of the traumatic experience. Or, one can do it in a jigsaw fashion—that is, let him recover a little bit of the intellectual content of the traumatic experience of the past, then a little bit of the emotional content—and these different aspects need not necessarily be connected. Thus, you let the young medical student see the pitchfork, then you let him feel the pain he experienced in the gluteal regions, then you let him see the color green, then you let him feel himself stiff and rigid, and then you let him feel the full horror of his stiffness and rigidity. Various bits of the incident recovered in this jigsaw fashion allow you to eventually recover an entire, forgotten traumatic experience of childhood [a gangrenous wound from an accidental stabbing by a pitchfork] that had been governing this person's behavior in medical school and handicapping his life very seriously. [See Erickson & Rossi, 1979, for detailed examples of these approaches.]

Facilitating Recovery and Amnesia of Traumatic Events

This brings us to the possibility of inducing a complete memory of traumatic experience, and then inducing an amnesia for it. Often patients come to you not knowing why they are unhappy or distressed or disturbed in any way. All they know is that they are unhappy, and they give you a wealth of rationalizations to explain it: Things aren't going right, the mortgage is too much of a burden, their job is too difficult, when actually it may be the lingering, unconscious effects of the father relationship, the mother relationship, of their childhood. One can actually regress the Patient, return him to his childhood, and get him to remember forgotten incidents with remarkable clarity and detail. One can secure all of that information from the patient which gives you complete understanding of many aspects about your patient, and then awaken the patient with a total amnesia of what he has told you. The patient doesn't know what he is talking about, but you know what he is talking about. And therefore, you can guide the patient's thinking and speaking closer and closer to the actual problem. You can detect the significant words that refer to the traumatic experience of which he is consciously unaware and thus understand the deeper implications of what he is talking about. [Eventually, the patient will probably be able to deal consciously with the traumatic experience. But while conscious awareness of it is still too painful, you can help him deal indirectly or metaphorically with the problem.]

Learning the Indirect Approach

In this regard, you need the practice of repeatedly attempting to get a patient to talk about something in ordinary, everyday life. You need the practice of trying to get normal hypnotic subjects to talk about the lighting, for example, in the corner of the room. Of course, the lighting is not important, but how you guide them to talking about it is important. How can you do this? You merely need to observe their ordinary utterances and casual conversation. Then, emphasize the fact that all of a sudden they said the word *corner,* and you wonder why. Soon, they will say something is light, and very shortly you can have them talking about the lighting in the corner of the room. It is a matter of directing them. In a similar way, as long as you know some of the traumatic past of the subject, you can guide every one of your remarks in that direction.

Psychological Reorientation for Discharging and Displacing Resistance: Facilitating a Yes Set

What are some of the obstacles that you will encounter in using hypnosis? Your patients in the psychiatric field are often exceedingly difficult. They are fearful to begin with, they are distressed—they do not know how to handle themselves or they would not be your patient. You can employ all of the various hypnotic phenomena. I can recall one of my patients who came to me and spent the time explaining that he just could not talk to me. There was nothing he had to say, and he felt too miserable to be able to have any thoughts at all. My response was simply this: That he could go into a light trance and experience some interesting and rather helpful phenomena. He agreed that he needed some help, but he didn't know how to get it. And so, in an apparently random fashion, I stated that I could place a chair right there, that it would be just about so far from the bookcase, about so far from the door, about so far from my desk, and it would be really very nice to sit in that chair and be able to talk when sitting in that chair. My patient tended to agree with me that if there were a chair over there, it would be so far from the bookcase, it would be so far from my desk, it would be so far from the door.

At this point I had elicited three excellent agreements from my patient which brought us to the statement that if he were sitting in the chair in such-and-such a relationship, he might find it helpful to him in talking about himself. Of course he risked nothing in saying that he might find it helpful if he sat there in that chair—since there was no chair! I had not had him hallucinate one. I simply had him imagine it just as all of you can. But what is the subject really doing? He is agreeing with me without knowing it that he would find it easier to speak more freely if he were sitting in a different position in the office. Then I suggested that it was impossible, really, to talk in this chair—the one that he was actually sitting in—but all that would be necessary for him to do would be to take the chair, put it over there, sit down, and begin talking. I've had a patient more than once pick up his chair, move it to another side of the room, and immediately begin discussing his problems and giving me the information he needed to give. In effect, he has left all of his resistances in the room orientation that he had when sitting in *this* chair. But by sitting in *that* chair, which had just been moved over there, he saw the room in a different way entirely.

I have found that whatever you can do to alter the orientation of your patients in the office aids them tremendously in communicating with you and examining their problems. [Reorienting a patient physically and spatially often helps to reorient him psychologically. The chair in its old position represents the patient's old patterns of thinking and behaving. Moving the chair to a new position represents the patient's willingness to look at himself in a different way and gives him, literally and psychologically, a different perspective.] Hypnotically, of course, it is very easy to induce a deep trance and reorient patients completely, even to depersonalize them. That is why I emphasize the importance to all of you, no matter what field of medicine you are in, to work with normal subjects. Spending a little time with normal subjects will enable you to discover all the various hypnotic phenomena.

Harvey, the Sad Sack: Depersonalization and Projection to Free the Intellect for Therapeutic Change

Depersonalization and the projection of the self are other very helpful hypnotic phenomena. You can teach a subject to hallucinate a movie screen and to see his "self" up there on the screen. You can then have him forget his name, his identity, to forget everything about himself—the way all of us do normally in the theater when observing a suspense movie or anything that completely absorbs our attention. Then have your patient look at the

screen and tell him that he is going to see a continuous series of events—you can have them in the form of moving pictures, or you can have them in the form of stills.

I can think of one person, a sad sack, who came to me, and the question was, could one ever make a man out of that sad sack? I was challenged to do that, and I had to conduct psychotherapy on that man using hypnosis and having an audience of antagonistic psychoanalysts and residents in psychiatry—some of whom were undergoing psychoanalysis. The simple procedure I used with the sad sack was this: Harvey had every known ache and pain, every known sense of inferiority. But he was intelligent, even though he didn't manifest much intelligence. He was fearful, and that was all I really needed to know about the man, because knowing that he was intelligent, I also knew that he could have a rather rich fantasy life. And so I suggested to him that he see a series of movie screens or crystal balls in which he would see still-life pictures of tremendous importance. I had Harvey forget his name, his identity, his age, the fact that Harvey as a person really existed. All he was was an intelligence that was looking at all those things that I had scattered around the room for him to look at. He saw the little boy on his way to school as a moving picture—most of them were moving pictures. He followed the little boy to school. He saw the little boy getting his hands racked by the school teacher. He saw the schoolteacher forcing the little boy to change from the left hand to the right hand in writing. He saw the little boy getting punished rather brutally by the teacher. One particular day, he saw that boy walking home very sadly. And Harvey looked and commented on the paltriness of the scene. He saw that little boy walking home, reaching home, and looking into the yard over the gate. And there he saw the sheriffs deputy with a gun in his hand. The deputy had just finished shooting the little boy's dog. And then he saw the little boy crying.

And then I told him to start there and see another picture several years later when that same emotion would come forth. And he saw that same boy at the age of 10 out in the woods hunting with his brother and feeling terrible about killing a rabbit. Then he saw the boy about the age of 15 lying on the top of a ruined dam and thinking about all the dreadful things that can happen to human beings. And then seeing a young man of about 22 who had just been turned down by a girl and felt very wretched and very inferior. And then he saw that same young man in the same emotional state of depression who was walking out of a courthouse. He'd just been divorced and felt rather suicidal and tremendously inferior. And then he saw the young man at the age of 28 getting discharged from the job he liked. And then he saw the young man at the age of 30 feeling horribly wretched.

And I asked Harvey the intellect to review all of those pictures and what they probably meant, and Harvey reviewed and analyzed them for me. And we spoke about the thread of continuity and the repetition of traumatic experiences that goes through life. But Harvey didn't know that he was talking about himself, and Harvey didn't know that he was seeing himself. And I could ask him to speculate on what would happen to that young man. And his statement was that if anything more like that happened to him, he would undoubtedly try to commit suicide—always on the losing end, since he had lost out on everything throughout life, and maybe tried to commit suicide on the losing end. But the losing end meant what? [Erickson then helped Harvey resolve one of his problems in trance: He was to practice writing clearly instead of the self-humiliating scrawl he usually presented. Finally, Harvey was able to follow a posthypnotic suggestion to write clearly when he was awake.] "This is a beautiful day in March." He wrote that, looked at it, and jumped to his feet and said, "I can write clearly! I can write legibly!" And he went around and around that group of doctors and demanded that everyone praise his writing. He was literally a jubilant little boy. And he was utterly embarrassing to the audience because of his jubilance until they recognized the tremendous force of that.

Now Harvey's job was a fifth-rate job where his boss kicked him around. Harvey did this writing, and during the rest of the evening he bragged and bragged about his excellent handwriting. And I suggested that he would keep that sense of accomplishment, that sense of personal pride, with him, and that he would use it in every essential way. The next day when Harvey went to work, he talked back to his boss for the first time and he demanded an increase in payment in his salary. And he got it. Then he demanded a better desk. Harvey

drove a car to work. He always parked it in a particular place in the parking lot. And there was one other employee there who always boxed him in with his car. And that employee worked half an hour longer than Harvey. Harvey would sit and fume helplessly, Casper Milquetoast fashion, in his car waiting for the other man to come to move his car. That night Harvey went out and told the guy, "Listen you big lug, I possibly could pick a fight with you for parking your car in that nasty fashion. You've done it for a long time and I've taken it. We could have a fight about it, but I'd rather invite you in for a glass of beer, so let's go talk it over."

That was the last time that guy ever parked his car in such a manner as to box in Harvey's car. Harvey repainted his car because he felt a joy of possession in it. He got new slipcovers. He changed his restaurant for a better one. He changed his rooming house for a better rooming house. That surge of joy over the simple matter of writing his name legibly and then writing a simple sentence, "This is a beautiful day in March," and giving him permission to feel that tremendous, boyish surge of jubilant joy was enough to carry him along.

I think it would have been an error for me to tell him to go down and demand better pay or to tell off that guy who parked that car in the wrong fashion—because he didn't need a direction about what to do. But he did need motivation. And that is one of the things in psychotherapy and the use of hypnosis—the motivation of a patient to do things. Not the things that you necessarily think they ought to do, but the things that they as personalities have the feeling that they really ought to do. And one usually starts with rather simple things. Because human beings are essentially, fundamentally, rather simple creatures. And therefore, you ought to start simply and let the patients elaborate in accord with their own personality needs—not in accord with your concepts of what is useful to them. You only interfere when they try to destroy themselves.

Indirect Suggestion and Implication

Much of hypnotic psychotherapy can be accomplished indirectly, like I had done with Harvey, with the use of posthypnotic suggestion. Often I will suggest to a patient, "Go home today and let your unconscious mind think over all the things that have been said, all the things that have been thought." I can think of one patient in particular who was making a psychoneurotic out of herself by going out into the sunlight and developing an extremely severe rash on her arms, neck, face. Then she would claw at the rash all night long until her arms and face and neck were horrible sights to look upon. She came to me because every dermatologist and doctor she had consulted had said that it was jut pure cussedness on her part. She stated very definitely that she also expected me to tell her that it was pure cussedness on her part. So I told her it wasn't necessary for me to tell her that because she had already told me, and I would take her word for it—but I was still entitled to believe my own thoughts on the matter. Thus, I accepted what she said to me, but at the same time I gave tremendous reservations. I was still entitled to believe my own thoughts, and she could believe her own thoughts.

My suggestion to her was rather simple—namely, that she ought to enjoy as much of the sunlight as she wished, that she really ought to enjoy the sunlight as much as she wanted to. I told her to go home (the patient was in a medium trance) and lie down for an hour or two and let her unconscious mind think over what that meant. She said that she didn't need to, that she consciously remembered what I had said. After she had gone home, after she had proceeded to sit down and rest for an hour, her reaction was to get up and go out into the garden. But she was also motivated to put on a very wide-brimmed hat and long sleeves. Now she found it very enjoyable out in her yard, and she worked in her flower garden.

In the past she had been told, sensibly enough, to avoid the sunlight, to keep out of the sunlight, to shade herself, to protect herself from the sunlight. I, on the other hand, told her to enjoy it. Now, what does enjoyment of the sunlight mean? It means putting yourself in a

situation where you do not have to fight against it, do not have to protect yourself, but can really enjoy it. She did like her flowers very much, and they were out in the sun, and therefore she was able to enjoy the sunlight. Do you see the implications of my suggestion to her? I did not tell her to avoid the sunlight, I did not tell her to protect herself, I told her to enjoy it. And her enjoyment of the sunlight would include enjoying herself post-sunlight, enjoying herself during her sleep, enjoying herself the next day. All I needed to do was to give her the motivation to enjoy the sunlight. Since she was a rather hostile and antagonistic person, my suggestion did not leave her with anything to fight against. Her rash cleared up very promptly, at which point she protested that I charged too high a fee. And I told her, "Yes, my fee was high, but your enjoyment was much higher, and why not pay me my fee for the little that I have done." She sent me a total of 10 other patients, even though she protested my high fee. I had accepted her protests, and accepted them on the grounds that were acceptable to her. In other words, you try to accept the patient's ideas no matter what they are, and then you can try to direct *[sic*—we now prefer *utilize]* them.

Use of Regression and Amnesia: Gaining Control over Traumatic Experiences, Memory, and Repression

Regarding this matter of regression, I like to initially regress my psychiatric patients to something pleasant, something agreeable. I admit that we are wasting time because we are there to correct the unpleasant things, not the pleasant things. But in the trance state I impress upon them that it is tremendously important to realize that there are some good things in their past, and those good things form the background by which to judge the severity of the present. And so I use the happy memories of their past to train them to recover fully and completely the various traumatic experiences. I have them recover the traumatic experiences completely, then I repress them, then have them recover the memories again, and repress them again for the patient.

[The dynamics underlying this technique are the following.] A patient comes to you with forgotten, repressed memories. Once you get a hold of the memories and relate them to the patient, once you have the patient remember them, he can again use his repressive powers and forget those things. But if you yourself repress or create an amnesia for those memories, the patient is unwittingly turning over the control of those traumatic experiences to you. This means that you are at liberty to reproduce the memory, to cover it up again, to bring it forth again, to cover it up again, until your patient builds up enough strength to face any particular issue. Since hypnosis provides you easy access to, and control over, both the recovery and repression of material, the repressions of the patient are not likely to take over and control the situation.

Suggestion and the Centering of Resistance

The type of suggestions you give to a patient depends upon the attitude of that patient toward you and the therapeutic process. I have dealt experimentally and clinically with the negative, hostile patient and found various ways of meeting this particular brand of resistance. The patient can come into my office, intending to be totally contrary, absolutely resolved to try my patience, absolutely resolved not to go into a trance. I can recall the doctor who came to see me for therapy. He had called me long distance several times and written letters previous to our meeting, and from these contacts I knew I had an exceedingly antagonistic man on my hands. When he walked into my office, his shoulders were thrown back, his jaw jutted out, he sat down perfectly upright in the chair, and said, "Now, go ahead doctor and hypnotize me."

I told him I thought he had far too many resistances. And he said that he didn't care about his resistance—my job was to hypnotize him, not to make excuses. Would I please get going. I told him I would, and I proceeded to suggest that he go into a trance. The man had some knowledge of hypnosis, so I used the straightforward, domineering technique, knowing full well that it would be a total failure. I worked on him for about an hour, using the best domineering technique I knew, while he sat there smiling at me and resisting me very effectively. After I had built up his resistance in every possible way, I abruptly said, "Excuse me for a moment." (I had prepared for this, having heard him over the phone, having read his letters.)

I stepped out into the other room and came back with a young college girl—a psychology student and hypnotic subject of mine. I brought her into the room and said, "Elsa, I would like you to meet Dr. X. Dr. X came here to be hypnotized. Elsa, would you please go into a deep trance right now." She went into a deep trance, and I demonstrated a few hypnotic phenomena on her. Then I told her to sit down and put the doctor in a trance and to call me just as soon as she had the doctor in a trance. With that, I totally walked out of the room. Fifteen minutes later, Elsa came to the door and called me back into the office.

What had I actually done? The doctor had his load of resistances, which I centered all on me so that when I walked out of the office, I carried out that whole load of resistance. Furthermore, how can you resist somebody who is in a trance, somebody who is merely responding to hypnotic suggestions? Of course Elsa used good hypnotic technique and was able to induce a very satisfactory trance. Very often I use this technique in training especially resistant patients or subjects to go into a trance. It is one thing to resist me, but how can you really resist someone who is in a trance, whose one and only purpose is to put you in a trance, not to make any other kind of allowances for you. It's very difficult to do that.

Indirectly Establishing Rapport with Resistant Subjects

I knew two doctors in Phoenix on whom you could work all night long without inducing trances in either of them. They are both excellent hypnotists and they were both very critical of me because I hadn't been able to put them in a trance. So one night I asked them to sit down facing each other, and I told them, "Doctor, you hypnotize Doctor, and Doctor, you hypnotize Doctor. And while you are hypnotizing each other, go into a trance yourself and really demonstrate to the other how deeply into a trance you want the other to go." They both went very neatly, very deeply, into an hypnotic trance. But of course they went into the trance at my suggestion. After they had put each other into a deep trance, I took charge of the situation for both of them. That is one technique *[sic*—we now prefer *approach]* that I think all of you should try out sometime because it will teach you a great deal about establishing rapport. Neither of those doctors realized that my instructions would result in his being in rapport with me after he had put the other doctor in a trance. I quite often have my patients put into a deep trance by someone else, especially those patients who are utterly resistant and will not let the doctor do it. I usually try to get them to be as resistant toward me as possible, so that I can gather up all their resistances, leaving none for the person who is going to put them in a trance.

Resistance and the Surprise Technique

Another means by which I overcome strong resistance in my patients is the introduction of a surprise technique. Allow me to illustrate. One doctor had come 2,000 miles to have me put him in a trance. He walked into my office, laid a check in my desk, and said, "This is to compensate you for your time." I heard that word *time.* That check was to compensate me for my time. But he had come to be put in a trance by me. Now, obviously, the check was not to compensate me for putting him in a trance, but just to compensate me for my time. So I knew

right then and there what he was going to do. And he did one of the most beautiful jobs of resisting me that I ever saw, although consciously he felt that he was cooperating. I spent two hours on the man, using every technique that I knew of to seduce *[sic*—we now prefer *facilitate]* him into hypnosis. But I failed absolutely, and finally I said, "Doctor, you've paid me for my time. And that is about all I've been able to give you. I'm awfully sorry I failed. But before you leave, I'd like to take you out into the other room and introduce you to my wife. She would like to meet you."

So we went out into the next room, and I called my wife and stated that Doctor Q was on his way home, that he had to leave immediately, but he thought he would like to meet you. Then I said, "I would like to shake hands before we leave, Doctor." He very graciously put out his hand and I lifted it slowly, induced a deep hypnotic trance, led him back into the office, and did the work that he wanted me to do.

Surely you do not hypnotize a man after you say goodbye to him! He had no defenses, no guard, no way of protecting himself. When I reached out to shake hands goodbye and slowly, gently, suggestibly lifted his arm, inducing catalepsy (see Section II for details of catalepsy and the handshake induction) all the other suggestions I had given him previously about going into a trance took effect. So I took him back into the office and spent a couple hours more with him, correcting some difficulties that had prevented him from using hypnosis for over 15 years. He had begun his practice using hypnosis but had run into a personal traumatic experience. Thereafter he could not induce hypnosis and was, in fact, terrified of it. But after I unexpectedly induced that trance in him, he returned to his practice and began using hypnosis extensively.

The Utilization Approach to Hypnotic Induction: Adapting Hypnotic Induction to the Patient's Behavior

In other words, one of the things I've mentioned is this matter of surprise technique. One always tries to use whatever the patient brings into the office. If they bring in resistance, be grateful for that resistance. Heap it up in whatever fashion they want you to—really pile it up. But never get disgusted with the amount of resistance. That doctor certainly had plenty of resistance unconsciously when for two hours I did everything I could to put him into a trance. And then when I took him out into the other room to introduce him to Mrs. Erickson, his resistances had been piled up and left in the office. One really ought to recognize that.

Now this may seem as if I'm using anthropomorphic thinking, but it's an easy way of conceptualizing these matters. *Whatever the patient presents to you in the office, you really ought to use.* If they prevent you from hypnotizing them by sighing or giggling or by shifting around in the chair or by doing any number of things, *why not utilize it!*

One of my patients demanded that he be hypnotized by me, and I agreed to do so. He insisted on beating time with his foot—first his right foot, then his left foot, then his right hand, then his left hand. Next he would get up to stretch and then settle back down in the chair more comfortably. What I did in the matter of hypnotizing him was to note when he was about to shift from the right foot to the left foot; when it was too late for him to change, I would give him the suggestion that he shift from the right foot to the left foot. And then when he was shifting from the left hand to the right hand, I would note just when he was about to do that and then suggest that he use his right hand now, and then his left hand. When I saw he was about to stretch, I would suggest it was time to get up and stretch. What difference did it make to me whether I was inducing hand levitation, moving laterally, up or down—whether he wanted to beat time with his hands and feet and get up and stretch? If he wanted that type of behavior, let him have it. *But I really ought to be willing to use it.* If he wants to laugh at my technique, my suggestions, I encourage him to laugh, and gently suggest "that now here is another suggestion you will probably find very, very, funny. But then again I may be mistaken, and you may not find it funny at all. I really can't tell." And so

I've covered all possibilities. He may find it funny, or he may not find it funny at all, but then I really don't know—he'll have to demonstrate to me whether it is funny or unfunny, but in doing so, he doesn't realize that he is obeying my suggestion that he demonstrate it is funny or unfunny.

Utilizing Ordinary Behavior and Resistance

You must observe ordinary behavior and be perfectly willing to use it. I have had patients come and spend their time cursing me because "you think that you are a such and such an hypnotist." And I tell them, "That's right, I *do* think I am such and such an hypnotist. And here are a couple of more words that you could have added to make it a much more emphatic statement." So, I can suggest even stronger words, and they can accept my suggestions, and the first thing they know they are accepting other words, other suggestions from me. In that way I can meet them easily on their own level. [They do not resist my suggestions because the suggestions accept, amplify, and utilize their resistance.]

Too often there is a tendency for the operator to think that he must correct the immediate behavior of the patient. One must not have that attitude. One takes the attitude that the patient is there to benefit *eventually*—perhaps in a day, a week, a month, six months, but within some reasonable period—*not* in the immediate moment. This tendency to correct the immediate behavior must be avoided because the patient really needs to show you that particular behavior.

Utilizing Silence: Facilitating Unconscious Process Via the Conscious-Unconscious Double Bind

Then there are the patients who make urgent appointments with you over the phone and them come into the office and sit there very silently. You might be inclined to express your lack of understanding of this behavior. But I tell them that no matter how silent they are, their unconscious mind is beginning to think, beginning to understand, that they themselves do not need to know consciously what is going on in their unconscious mind. What are you actually saying to them? *You are saying that their unconscious mind can now work, and work secretly, without the awareness of the conscious mind.* In this way you are making use of their conscious silence and letting them understand that they do not have to verbalize consciously at all. *Their mere presence within hearing distance of you allows their unconscious mind to work satisfactorily.* I see no reason why one should resent the patient sitting quietly for a whole hour. But it is a waste of time on your part if you don't use it for the patient. You don't need to say very much—simply tell the patient, "Let your unconscious mind work while your eyes roam around the office, while you note this book title and that book title, while you look at the carpet, while you ignore looking at me, while you attend to external noises." What happens? The patient's own unconscious mind begins to respond to your suggestions, and you discover that the hour of conscious silence has been used to prepare the patient for experiencing an hypnotic trance in the future—perhaps even in the very next session.

Questions and Answers: Duration of Sessions

Q. How much time do you generally take for a session? For how much of the session do you prefer to have the patient in the hypnotic state? How much time do you like to spend with the patient out of the trance state for discussing consciously what took place under hypnosis?

A. I take the length of time necessary for the patient's needs. I use my judgment as to how much he can absorb. I've seen patients for as long as 16 consecutive hours. I had the patient hallucinate his meals, but during that time I went hungry! I've seen patients for 12 hours, for eight hours, preferably for four hours, and often for two or three hours, depending upon the patient's problem and the degree of urgency. Usually I like to see a patient for only one hour—the first part of the hour may be used for hypnosis and the last half-hour may be spent in discussion. Or, I may tell the patient in the trance state that this matter will come up for discussion at some future date and that he is to feel comfortable about it until such time. In other words, I use the hypnosis to govern the way in which things are presented to the patient. The patients that can learn and adjust rapidly I will see four, five, six, sometimes seven times a week. Other patients cannot integrate it any faster than once a week, and now and then I have worked with people who cannot tolerate the sessions any more frequently than once a month. Instead of having any set, routine pattern for my patients, I arrange a completely random schedule for them. I shift them from once a month to seven sessions per week, each a two-hour session. Or I might shift the patient from a four-hour session daily to once a week according to his capacity to digest psychotherapy.

Overcoming Effects of Previous Hypnotic Experiences

Q. How would you develop a rapport with an individual who has either been hypnotized previously or accidentally, and in both cases has no recall of the hypnotic experience? [How do you detect such an unconscious hypnotic state in the individual, and what techniques do you use to overcome possibly inhibitory suggestions from previous, amnesic hypnotic experiences?]

A. Very often a patient will go into an autohypnotic trance just to get away from you. The precatatonic and schizophrenic patients are especially excellent in this matter of going into an autohypnotic trance and literally defying you to touch them in any way psychologically. Occasionally you will encounter people who have been hypnotized previously and told that they must never, never, never be hypnotized again. And so you cannot succeed in hypnotizing them.

Recently at a seminar I conducted in Phoenix two of the dentists participating in the seminar brought in an excellent subject and told me that she was a newcomer and that they wanted me to train her to become a good hypnotic subject. But, unknown to me, they had carefully given her suggestions not to let me hypnotize her at all. As I was attempting to hypnotize her, I noticed one thing immediately—although she was very friendly, very cooperative, she overstressed everything she said to me: "I really don't believe you can hypnotize me, Doctor. I really *don't!"* And as I listened to those statements, I realized that they were not the simple statements of a person who truly didn't believe it possible to be hypnotized. Rather, I felt they were the statements of a person who was expressing a conviction too emphatically that was foreign or alien to her. So I asked her what members of the group she knew, and of course she promptly mentioned that she knew Meyer and Bill and several others. But Meyer and Bill were the first names she mentioned. I asked her how she felt she would respond to hypnotic suggestion given by Bill or by Meyer. She said that she might be able to respond more favorably to either of them. And I asked her if my technique in any way resembled Bill's or Meyer's. She said that their technique resembled mine since I had taught them. Do you see what is happening to her already? Then I suggested that if Bill said that now your arms are getting heavy, would they get heavy? And if Meyer said that they were getting heavier and heavier, would they be getting heavier? And of course they began getting heavier. And all I did was to recognize that there must have been a previous hypnotic situation operating within her. I speculated as to who was guilty and then tried to identify myself with them in her mind. In this case, it had been Meyer and Bill who had given her the previous suggestions.

On another occasion a subject voluntarily stated, "I've been hypnotized before, and it's been tried by many doctors since, but I've always failed to go into hypnosis." I asked who the hypnotizers were, and how long ago did the hypnosis occur. "It was a stage hypnotist, and he told me never again to be hypnotized, and so while I've wanted hypnosis, I've always failed to go into a trance."

It happened five to seven years ago, in Chicago. Then I asked her a barrage of questions: "Do you remember the name of the theater? How many people were up on the stage with you? See how many of them you can remember. What are the other circumstances you can remember? Did you go there with friends? Did you leave with friends? Did you dine afterward? Did you have a drink? What happened when the stage hypnotist approached you? Did he tell you to close your eyes and get sleepy? Did he tell you to feel very sleepy? Did he have a voice like mine, or was he more commanding and domineering? Did he tell you to go to sleep now? Did he tell you to get your arms rigid?" In this way I am trying to evoke in her memory all the forgotten details surrounding the hypnotic experience and to identify myself with the stage hypnotist at the time.

Occasionally you will encounter patients who have been hypnotized by one of your colleagues who has told these patients not to let any other doctor hypnotize them. Very sympathetically and interestedly, inquire into the details of that situation. As they begin recalling the details, they begin to develop the trance behavior of that situation. And as they develop the trance behavior, they will then go into a trance, and at that point you put in the suggestions: "Yes, you were told not to go into a trance then, just as I am telling you now not to go into a trance again in the future. Just as I am telling you now not to go into a trance *again* in the future." But before they can accept that suggestion of not going into a trance again in the future, they have to go into a trance right there in order to accept the suggestion. Their past training has been to accept it. They have been abiding by that sort of suggestion for perhaps five years.

They will gradually go into a trance to accept a reinforcement of that suggestion, but after you've gotten them in a trance state, right then and there you can qualify that original instruction: "Never again will you go into a trance for silly purposes. Never again in the future will you go into a trance for a useless, worthless, uninformative purpose." [By evoking memories of the previous hypnotic experience, you evoke the conditions of another hypnotic experience. By accepting and utilizing the admonition *not* to let any other doctor hypnotize them, you in fact re-create the original experience, thus making it possible for hypnosis to occur again.]

This is something all of you ought to practice in cooperation with one another. Get a good, intelligent, normal subject. One of you put that subject in a deep trance and tell that subject *not* to let so-and-so put him in a trance. Then let so-and-so work out in his own mind the verbalization to correct that suggestion. You use the same technique in the matter of psychotherapy. A patient tells you, "For the last ten years I haven't been able to sit down at the table without first getting up and washing the silverware and the plates at least seven times." One of the first things I want to know about that is *how* did that person sit down at the table previous to the time of the problem, more than seven years ago. And if I can get him to demonstrate, I do so. The patient never recognizes that I am putting him in a trance and regressing him to a period of seven years ago.

I've had subjects tell me that they didn't think they could go into a trance for me. So I try to put them in a trance and let them demonstrate that they can't go into a trance. In that way, I've met their needs. Then I begin reminiscing with them about the time they used to go into a trance, and they promptly go into a trance [evoking past memories of trance tends to reinduce another trance]. Then I point out to them in the trance state how I have tricked them, how I have manipulated them, and I offer to give them a posthypnotic suggestion never to go into a trance for me again. Or, I suggest that they might want to understand why they had a trance experience despite their expectation *not* to have one. In that way, you can meet their resistance to you and at the same time undermine that resistance while achieving a great deal in the way of psychotherapy. The one thing in the use of hypnosis is this: You really ought to know more about it than your patients do. You ought to know it so thoroughly

that no matter what develops in the situation, you can think of something, you can devise something, that will meet your patient's needs.

Utilizing Sleep or Spontaneous Trance

[Someone from the audience notices that a woman named Mary is asleep. He shouts this out to Erickson, who then addresses Mary.] Did you want to speak to me, Mary? Are you asleep or awake, Mary? Whichever way you are, Mary, listen to me. I want you to continue sleeping if that is your wish. I want you to wake up if that is your wish. I want you to enjoy listening to me. I want you to enjoy hearing what I have to say. I want you to remember and give Glen whatever advice and counsel he needs. And I want you to remember things that he is likely to forget. And don't let anybody annoy you. Give them a merry push-aside whenever they try to intrude on you.

Hypnotizing an Entire Audience

Q. I made mention in one of your previous seminars that it might be better to hypnotize the entire group when these lectures are given. In fact, I am wondering if I am hypnotized now. My arm is beginning to feel funny!

A. That's right, doctor, you've always gone into a trance whenever I've been lecturing. Now keep your seat and your chair and hold it comfortably. And let your back and your shoulders be comfortable but sufficiently rigid. You have been listening to my lecture in a trance, and you will undoubtedly remember it all the better. There are some other members of the audience that have been doing some very nice hypnotic sleeping.

Duration of Posthypnotic Suggestion

Q. On the average, how long does a posthypnotic suggestion last?

A. It depends upon the posthypnotic suggestion. In the early 1930s I was doing some experimental work with a woman who had a Ph.D. in psychology. When it came time for Harriet to leave for some other part of the U.S., I asked her if we could investigate this matter of the persistence of posthypnotic suggestion. She thought it was a good idea. So I explained that I didn't know when we would meet again: "It may be next year, it may be five years, it may be 10 years, or 15, or 20 or 25. But this is the posthypnotic suggestion that I would like to give you. When we meet again, if the situation and the setting is suitable after greeting me, fall into a deep hypnotic sleep."

Fifteen years later I was attending the American Psychology Association meeting. I was in the company of Gregory Bateson, the anthropologist. We went into a restaurant for lunch and looked around for a booth that we could sit in while eating and conversing. He found only one booth available, but there was a woman sitting in it. He asked her if we could join her. I was in the front of the restaurant and not visible to her yet. She agreed, so he came down to the counter and picked up my tray and his tray and took them up to that booth.

As I entered the booth, I saw that the woman was Harriet, whom I hadn't seen for 15 years. Harriet looked at me, then looked at the man. I introduced her to Gregory Bateson. She recognized the name, acknowledged the introduction, and then went into a deep trance. The situation, the setting, was suitable. The stranger with me was obviously a friend of mine, he was obviously a student, she knew his name, knew that he had published in the field of anthropology, and therefore should be scientifically interested in hypnosis. There were only three of us in the booth, and therefore Harriet went into a trance to the astonishment of Gregory Bateson. I asked Harriet how everything was going, how her work was, and then I

had her awaken, at which point she thought I had just completed the introduction to Bateson. She didn't know that she had been in a trance. Clearly, the posthypnotic suggestion had endured for 15 years! And I am certain that if I meet her again after not seeing her for quite some time, and the situation is suitable, she will go into a trance.

I've done this with quite a number of my patients that I haven't seen for years. Upon meeting them, they will readily go into a trance again, will readily carry out some posthypnotic suggestion. Usually I give to my patients some little thing to carry along in life, a good feeling, toward me and toward themselves. I can think of one patient I had in Baltimore as an example. I certainly would not think of seeing that patient without a very bright purple tie at least. That patient first came to me because of morbid fear of the color red. Our work together helped to give her a very comfortable feeling about color, so that whenever there is a chance I might meet that patient, I'll put on one of my brightest purple ties. My action shows that I have a good feeling toward color, and my patient has a good feeling toward color. That is a posthypnotic suggestion that I hope stays with her for life.

Why Are Audience Members Hypnotized?!

Q. If you have given no direct verbalizations for induction to the audience, why is it that certain individuals in the audience are showing hypnotic behavior? Have these individuals worked with you before and are therefore more inclined to respond to you?

A. As far as I know, several of the people who went into a trance are strangers to me. To my knowledge, I haven't seen them before—although some of them may have been in the audience last Sunday when I last presented a lecture.

Q. What is the explanation for the trance induction?

A. The trance induction is this: I spoke to you at the beginning about the unconscious mind and the conscious mind. Their unconscious mind was listening, and they were unconsciously interested in trying to understand my ideas. Haven't you seen the parent who is very eager for the baby to chew solid food go through a chewing motion? Every time the parent wants the baby to open its mouth, the parent opens his mouth, hoping the baby will imitate the action. I have often found that people, when attending a lecture on hypnosis, will go into a trance in order to listen better, to hear better, to understand better. Dr. Rogers here always goes into a trance, and she remembers much more of the material that way—because she is listening with utter intensity. When you listen to a radio program of music, for instance, if you want to single out the instruments, you don't look at a bright light or thumb through a book. You close your eyes, you unconsciously turn your dominant ear toward the music, and you very carefully shut out visible stimuli. If you are holding a cold glass in your hand, you put it down so that the coldness does not divert your attention away from the music. You are not necessarily aware of performing these actions because your unconscious mind has directed their performance. It knows how you can best hear the music. Similarly, in a lecture on hypnosis, people will close their conscious mind so that they can listen better with their unconscious mind.

Q. Will the people present in the audience who are now in a trance state take personally your descriptions of all these posthypnotic phenomena?

A. They are very aware of the fact that this is a lecture, that it is not personally directed to them, and that all that is directed to them is the general understanding of the lecture.

Indirect Suggestion Facilitating Unconscious Processes

I might say something about indirect suggestion. I'm going to give indirect suggestion to somebody in this audience right now—someone I looked at, eye to eye, just a little while ago, and who is aware of it. In that person's mind the identification has been made. And what are the indirect suggestions? *There are a lot of things that you want to accomplish. Your*

unconscious mind can work on them. And really work on them. [E's voice has softened and his speech has slowed considerably here.] *Work on them at its convenience and work very hard. [Pause] And three months from now, six months, nine months from now a great deal can be accomplished. Your unconscious mind can really work on those matters. [Pause] Really work on them. There are a number of them, [Pause] and you can really work on them, and that applies to everybody in the audience. There are a lot of things that you can do, there are a lot of things that your unconscious minds are interested in. And you can really work on them in the next few months, the next six months, the next nine months, the next twelve months, a tremendous amount can be accomplished. And I hope all of you take a tremendous unconscious pleasure in letting your unconscious mind work for you. And I think I'll call it an afternoon, so rouse up everybody, wider and wider awake.*

B. UTILIZATION APPROACHES TO INDIRECT COMMUNICATION

While the previous lecture began as a straightforward presentation of some of the important dynamics in hypnotic induction and hypnotherapy, by the end it becomes apparent that it is also a demonstration in group hypnosis: Those members of the audience who choose to do so can let themselves go into trance, the better to receive the material. This is the reason we suggested that the reader might obtain important values by listening to the cassette recording before reading the written material.

There are several frames of reference that could be used to conceptualize this approach to group hypnosis or the hypnotic facilitation of learning. From the frame of classical theory in the history of hypnosis, the senior author uses the format of a lecture to evoke a series of important *ideodynamic processes* within the audience. That is, the presentation of ideas on an apparently intellectual level actually evokes psychodynamic processes that alter the listener's psychological state: This is the essence of the utilization approach to indirect communication; talking about food can make us actually hungry; a discussion of the dynamics of hypnosis with interesting case histories can evoke an actual experience of hypnosis in the listener. Many of the senior author's statements in this lecture-demonstration had ideodynamic implications that could evoke the following within the audience: (1) interest, motivation, and expectancy; (2) learning sets; and (3) patterns of inner search and autonomous unconscious processes that could facilitate the experience of trance and the enhancement of the listener's own professional skill over a period of time. A number of these statements with such ideodynamic implications were placed in italics.

It is by now a truism to say that most words, gestures, and statements can have multiple levels of meaning. The senior author's naturalistic approach to indirect communication is one of the first that seeks to utilize these multiple levels in a systematic manner, however. He maintains that he is simply following nature's way in this (Erickson, 1958). To believe that the mind processes information in a linear, one-track, single-cause-and-effect manner is an illusion, perhaps perpetuated by our widespread reliance on technical devices such as linear type and printing, the digital computer, and the use of logical argument that proceeds systematically from premises to conclusion. But these are only tools, artifices. Nature does not work that way. Nature is economical in adapting and utilizing its already existing forms for new evolutionary purposes. In an analogous manner, Erickson helps people break out of their learned limitations so they can then reframe their life experience from a broader perspective. He believes that our current-day emphasis on expanding awareness and heightening consciousness is essentially this process of breaking out of our limiting preconceptions to a broader understanding of our human possibilities.

The application of modern linguistic and communication theory to the process of therapeutic communication emphasizes the view that multiple levels of meaning (metalevels) can structure any statement in many ways (Rossi, 1973a, 1973b, 1973c; Erickson & Rossi, 1974, 1976, 1979; Erickson, Rossi, & Rossi, 1976; Watzlawick, Weakland, & Fisch, 1974;

Bandler & Grinder, 1975; Grinder, Delozier, & Bandler, 1977). Neuro-psychological studies suggest that the left and right hemispheres of the brain have different styles of handling information, and thus any communication can be processed in more than one way (Rossi, 1977; Watzlawick, 1978; Erickson & Rossi, 1979; Shulik, 1979). The common denominator of all these approaches is that human relations involve vastly more than the simple exchange of objective information on one level. Every word, phrase, pause, sentence, voice inflection, and gesture we use can have multiple meanings and neuropsychological effects. The study of indirect communication involves the investigation of all these multiple meanings and neuropsychological processes that take place automatically, in an involuntary manner, below our usual level of awareness.

From his earliest childhood, Erickson developed an unusually high degree of awareness of how everyday conversation can proceed on many levels of meaning (Erickson & Rossi, 1977). That is, he developed a sensitivity to implication and the unconscious aspects of communication. In what follows we will first present a few recent conversations wherein he indicates how he developed this sensitivity, then outline how it was used in the foregoing Ocean Monarch Lecture.

1. Language and the Art of Suggestion

E: The art of suggestion depends upon the use of words and the varied meanings of words. I've spent a great deal of time reading dictionaries. When you read the various definitions that the same word can have, it changes entirely your conception of that word and how language may be used. You can *run fast* or hold *fast*. And then some women are *fast.* Take the word *change.* A *change* of mind is very different from *change* in your pocket or a *change* or horses. And when you *change* horses in the middle of a river, that is a different kind of change. When you *change* clothes, that is another different thing entirely. You are not *changing* the clothes, you are *changing* what you are wearing. And on and on it goes. There are so many words with multiple uses! When you begin to recognize them, you can then know the difference between *really* and ***really*** (spoken with a deeper and more emphatic intonation). *Really* for ***real*** means something certain to a small child.

R: So much of the art and science of suggestion is in knowing and correctly utilizing these multiple meanings of words, as well as the vocal emphasis and dynamics with which they are spoken.

2. Multiple Levels of Communication in Hypnosis

E: From my childhood on, I practiced talking on two or three levels. I could be talking to some playmates, and one playmate thought I was talking about the dog, another thought I was talking about a kite, and another thought I was talking about a football.

R: You were always dabbling in multiple levels of communication?

E: That's right; now it becomes automatic when I do hypnotic work. Therapeutic trance enables patients to receive multiple levels of communication more easily.

R: Can you provide any general principles of how this works? How would you set up multiple levels of communication?

E: You have to know enough about the other person, especially their interests.

R: You use words that have connotations, associations, and patterns of meaning that have multiple applications for the person's interests and individuality. Is that the basic principle you use in your indirect approach to hypnotic communication?

E: Yes.

3. Internal Responses as the Essence of Suggestion

Erickson's meaningful use of vocal dynamics is demonstrated by the following commentary on his use of pauses. This example provides clear evidence of his view that *the essence of suggestion is in the patient's internal responses* to stimuli offered by the therapist. These internal responses are the indirect aspects of hypnotic communication.

E: I'll sometimes begin a hypnotic induction by saying,
I don't know

> This is a negation whereby I pick up their resistance and utilize it for constructive purposes.

[Pause]

> The pause implies, "What have you not told me that's important for the problem at hand?"

when

> *When* then means by implication that an event (trance) will take place.

you'll go into a deep trance.

> This is a direct suggestion that does not seem like one, since it is buried in a broader context of "I don't know."

R: You make a lot of statements to patients that evoke certain *natural associative responses* within them. It is these responses *within them* that are the essence of hypnotic suggestion.

E: That is the hypnotic stuff, yes!

R: So this is an indirect or utilization approach to effecting hypnosis: You provide verbal stimuli that will by association evoke the hypnotic responses within the patients. You facilitate the patients' saying the suggestion to themselves.

E: *Yes, cause them to say it to themselves!*

R: Could we develop a hypnotic dictionary—words and phrases that you know will evoke certain predictable responses (the actual hypnotic suggestion) in the subject? We need not even talk about hypnosis at all; we just give certain verbal stimuli and gestures that will evoke in the patient certain responses that are of a hypnotic nature.

E: Such an hypnotic dictionary would probably have only limited application because you must attune your vocabulary to the individuality of each listener. [Erickson tells an anecdote of how his wife had to hide the Easter eggs for one of their children because this child did not readily understand her reasoning. If Erickson hid the eggs, the child found them quickly because he understood the way his father's mind worked. The child would ask at the beginning of the hunt, "Are they hidden the way Daddy does or the way Mommy does?" This anecdote reveals how even a child can become intimately attuned to the behaviors and by implication the internal associations of the different people about him. It is just this sensitivity that hypnotherapists need in their work.]

4. Indirect Communication in the Ocean Monarch Lecture

We will now outline a few of the approaches to indirect communication that the senior author discussed in the Ocean Monarch Lecture while at the same time he evoked them within some members of the audience. That is, while the audience initially expected to hear a lecture about hypnosis in psychiatry, some members of the audience actually experienced

hypnosis. An apparently objective lecture about the naturalistic and utilization approaches to communication actually gave rise in an indirect manner to hypnotic experiences within responsive people in the audience.

Implication and the Negative

Erickson's very first statement, "I do *not necessarily* intend to demonstrate hypnosis to you today ..." contains the implications of its opposite—as do all communications containing negatives, disclaimers, or limiting qualifications. Politicians know this well: They will introduce unpopular measures or their own candidacy to the public by first proclaiming that they would never support such-and-such a measure, or they are definitely not a candidate at this time. The listener's conscious mind may accept these denials at face value. Simultaneously with this surface acceptance, however, most listeners will also explore and process on an unconscious or metalevel the opposite of any denial and the implications of even the most trivial remarks. When these automatic inner explorations are at great variance with the surface message, the listener will be flooded with conflict that must be resolved via his or her own particular patterns of psychodynamics. The history of the investigation of psychopathology from Freud (Breuer & Freud, 1895/1957) to Bateson (1972, 1979) is the record of our efforts to understand these psycho-dynamics.

The Conscious and Unconscious Double Bind

In the first paragraph of the Ocean Monarch Lecture Erickson introduces a form of the double bind: "When I am talking to a person at the conscious level, I expect him to be listening to me at an unconscious level, as well as consciously." Few in the audience will recognize this as a subtle form of the conscious-unconscious double bind, which we have discussed in detail previously (Erickson & Rossi, 1975,1979). Many in the audience who are listening to Erickson carefully "at the conscious level" will now, without quite realizing it, also be listening and receiving ideodynamic suggestions "at an unconscious level." Certainly not all listeners will be receptive to this indirect communication. It is primarily those members of the audience who have a heightened expectancy and favorable rapport with Erickson who will be most likely to receive and utilize his words on a personal level.

Matters are not quite this simple, however, for some in the audience will not be disposed to the lecturer and will not have a positive expectancy and motivation at the conscious level. However, even some people with such conscious resistance will receive and utilize some of the indirect communication being offered. Evidently something within them on an unconscious level can recognize and accept the value of what's being offered in spite of the limitations of their conscious attitudes.

Catalepsy to Heighten Responsiveness

In the next sections on methods of learning suggestion and catalepsy to heighten responsiveness, Erickson provides a number of ideodynamic suggestions to the audience while discussing one of his major innovations in trance induction and hypnotherapy. Catalepsy is not just an interesting hypnotic phenomenon; it can be utilized to heighten a patient's sensitivity and responsiveness when it is induced in a very gentle manner. In hearing about "increased responsiveness," many members of the audience will respond with increased responsiveness in the here-and-now situation of listening to Erickson "offering them the opportunity of responding to an idea."

The audience members next hear that they can "feel free to respond to whatever degree they wish," but they can "withhold whatever [they] wish" so that "they also begin to develop a certain sense of confidence."

We could go on for many pages, analyzing phrases within each topic of this lecture for their possible communication value for members of the audience as well as the patients Erickson is ostensibly talking about. Our readers will by now probably prefer to do this for themselves as a valuable training exercise, however. Simply reviewing the successive topic headings on Rapport, Ambivalence, Integrating Conscious and Unconscious Learning, Dissociating Intellect and Emotion, and so on can provide the reader with sound understanding of Erickson's naturalistic approaches to communication and the wealth of ideodynamic associations members of the audience can pick up automatically to utilize in their own unique way. In the following sections of this volume we will explore further illustrations of the practical means of utilizing this indirect approach to facilitating hypnotic processes and the experience of altered states in a manner that can bypass some of the learned limitations of so-called normal, everyday consciousness.

SECTION II

Catalepsy in Hypnotic Induction and Therapy

Catalepsy, the suspension of voluntary movement, is generally recognized as one of the most characteristic phenomena of trance and hypnosis. Because its significance and meaning have changed over the generations, we will begin this section with an overview of catalepsy in historical perspective. Since we regard all hypnotic phenomena as aspects or derivatives of normal behavior, we will then outline some of the spontaneous forms of catalepsy we can observe in everyday life. When these spontaneous catalepsies are seen in the consulting room, they become important cues regarding the patient's inner state and offer an important avenue for inducing therapeutic trance in the most natural manner. As we can infer from the previous section, a simple discussion of these everyday occurrences of catalepsy could be an excellent way of beginning an hypnotic induction, evoking ideodynamic aspects of catalepsy and trance before the patient even realizes it.

We will then present some of the senior author's approaches to facilitating catalepsy in a formal process of trance induction. Since it is essentially a nonverbal process, catalepsy becomes an unusually effective means of bypassing the learned limitations of many of our typically modern and overintellectualized patients, who want to experience therapeutic trance but have misunderstandings that interfere with its development. Catalepsy can then be used as a means of sensitizing a patient's receptivity to the nuances of inner and outer stimuli so he or she can more readily accept and carry out processes of therapeutic change.

While it may be interesting for professionals to receive these new conceptions of the utilization of catalepsy on an intellectual level, it can become truly effective therapeutically only when the hypnotherapist has developed a facility in coordinating the observational and performance skills in evoking catalepsy in a practical manner in the consulting room. Because of this, we end this discussion with a number of exercises to guide the practitioner's acquisition of these skills.

We will then provide an extended demonstration of the use of catalepsy by the senior author. This demonstration was recorded recently (1976), when the junior author had the opportunity of tape-recording the senior author's efforts to induce hypnosis in a blind subject by the hand-levitation approach. Erickson failed in this demonstration; that is, the subject responded in such a minimal manner that Erickson was challenged to use a vast repertory of his approaches. Because of this the demonstration is an excellent vehicle for studying his work.

An audio-visual record of Erickson's approaches to catalepsy that emphasize processes of dissociation is available for his demonstration with Ruth, which is presented in Section III under the title An Audio-Visual Demonstration of Ideomotor Movements and Catalepsy: The Reverse Set to Facilitate Hypnotic Induction. In the fourth section is another recent demonstration of catalepsy with particular reference to how it is experienced subjectively by a skeptical consciousness that is in the process of learning to experience altered states.

A. CATALEPSY IN HISTORICAL PERSPECTIVE

Historically, catalepsy was regarded as one of the earliest defining characteristics of trance. Esdaile (1850/1957) used mesmeric passes to achieve a state of catalepsy wherein patients were able to experience surgical anesthesia as follows:

> I usually proceed in the following manner, and am inclined to think that its comparative rarity in Europe is owing to the mesmeric influence not being at once sufficiently concentrated on the patient, by transmitting it to his brain from all the organs of the operator, and through every channel by which it can be communicated. With the necessary degree of patience, and sustained attention, the following

process is so effectual in producing coma, that in a large enough field, and with properly instructed assistants, it may here be obtained daily, for the purpose of procuring insensibilities to surgical operations. No trial under an hour should be reckoned a fair one: two hours are better; and the most perfect success will often follow frequent failures, but insensibility is sometimes induced in a few minutes.

Desire the patient to lie down, and compose himself to sleep, taking care, if you wish to operate, that he does not know your intention: this object may be gained by saying it is only a trial; for fear and expectation are destructive to the physical impression required. Bring the crown of the patient's head to the end of the bed, and seat yourself so as to be able to bring your face into contact with his, and extend your hands to the pit of the stomach, when it is wished; make the room dark, enjoin quiet, and then shutting your patient's eyes, begin to pass both your hands, in the shape of claws, slowly, within an inch of the surface, from the back of the head to the pit of the stomach; dwelling for several minutes over the eyes, nose, and mouth, and then passing down each side of the neck, go downwards to the pit of the stomach, keeping your hands suspended there for some time. Repeat this process steadily for a quarter of an hour, breathing gently on the head and eyes all the time. The longitudinal passes may then be advantageously terminated, by placing both hands gently, but firmly, on the pit of the stomach and sides;—the perspiration and saliva seem also to aid the effect on the system.

It is better not to test the patient's condition by speaking to him, but by gently trying if the cataleptic tendency exists in the arms. If the arms remain fixed in any position they are left in, and require some force to move them out of every new position, the process has been successful; the patient may soon after be called upon by name, and pricked, and if he does not awake, the operation may be proceeded with. It is impossible to say to what precise extent the insensibility will befriend us: the trance is sometimes completely broken by the knife, but it can occasionally be reproduced by continuing the process, and then the sleeper remembers nothing; he has only been disturbed by a night-mare, of which on waking he retains no recollection. (1957, pp. 144-145)

There are a number of observations in this passage that are noteworthy for our current understanding of trance and catalepsy. The first is that *time* itself is a very important consideration. Trance sufficient for surgical anesthesia required one or two hours of induction. Then as now, however, there was extreme variation in susceptibility to hypnotic experience; some patients required only a few minutes.

Another interesting observation is the importance of the element of surprise; fear and a knowledge of the doctor's intention "are destructive to the physical impression required." This sort of "surprise surgery" is certainly not in keeping with modern tastes, though we can understand how it may have been needed in Esdaile's day. It does indicate the importance of distraction and surprise as an important facilitator of hypnosis. What is an appropriate distraction and surprise can vary from one subject to another, however. It is a part of the art of the hypnotherapist to utilize appropriately constructed surprises suitable for the individuality of each subject.

The use of catalepsy as a test of the adequacy of the trance state was also characteristic of the Esdaile period. The operator's uncertainty about the patient's condition has always been a basic problem in studying hypnosis and in its practical utilization. The natural and spontaneous variations in trance "depth" made early hypnotic anesthesia an apparently unreliable phenomenon, so that "trance is sometimes completely broken by the knife." Fortunately, trance could be reinduced and the patient frequently had an amnesia for the entire process.

From this early description we gather that Esdaile believed there actually was some sort of a physical "mesmeric influence" transmitted to the patient from all the organs of the operator. In other passages Esdaile confirms this view by maintaining "that the imagination has nothing to do with the first physical impression made on the system by Mesmerism as practiced by me" (1957, p. 246). He believed "that water can be charged with the mesmeric fluid" and that the mesmeric influence could be transmitted through the air for considerable distances and even through dense metals (1957, p. 246).

Subsequent experimentation by other pioneers in hypnosis such as Braid (1855) established that trance required no fluids or magnets but was simply "a state of abstraction or concentration of attention." The italics in the following passage quoted from Braid (cited in

Tinterow, 1970) are ours to emphasize Braid's clear articulation of this modern view of hypnosis.

It was in 1841 that I first undertook an experimental investigation for the purpose of determining the nature and cause of mesmeric phenomena. Hitherto it had been alleged that the mesmeric condition arose from the transmission of some magnetic fluid, or occult influence, fluid, or force, projected from the body of the operator, impinging upon, and charging the body of the patient. However, I was very soon able to demonstrate the fallacy of this objective influence theory, by producing analogous phenomena simply by causing subjects to gaze with fixed attention for a few minutes at inanimate objects. It was thus clearly proved that it was a subjective influence, resulting from some peculiar change which the mind could produce upon the mental and physical functions, when constrained to exercise a prolonged act of fixed attention. I therefore adopted the term hypnotism, or nervous sleep, to characterize the phenomena producible by my processes. I became satisfied that *the hypnotic state was essentially a state of mental concentration, during which the faculties of the mind of the patient were so engrossed with a single idea or train of thought as, for the nonce, to render it dead or indifferent to all other considerations and influences.* The consequence of this concentrated attention, again, to the subject in hand, intensified, in a correspondingly greater degree, whatever influence the mind of the individual could produce upon his physical functions during the waking condition, when his attention was so much more diffused and distracted by other impressions. Moreover, inasmuch as words spoken, or various sensible impressions made on the body of an individual by a second party, act as suggestions of thought and action to the person impressed, so as to draw and fix his attention to one part or function of his body, and withdraw it from others, whatever influence such suggestions and impressions are capable of producing during the ordinary waking condition, should naturally be expected to act with correspondingly greater effect during the nervous sleep. when the attention is so much more concentrated, and the imagination, and faith, and expectant ideas in the mind of the patient are so much more intense than in the ordinary waking condition. Now, this is precisely what happens; and I am persuaded that this is the most philosophical mode of viewing this subject; and it renders the whole clear, simple, and intelligible to the apprehension of any unprejudiced person, who may at once perceive that *the real object and tendency of the various processes for inducing the state of hypnotism or mesmerism is obviously to induce a state of abstraction or concentration of attention—that is, a state of monoideism*—whether that may be by requesting the subject to look steadfastly at some unexciting, and empty inanimate thing, or ideal object, or inducing him to watch the fixed gaze of the operator's eyes, his pointed fingers, or the passes or other manoeuvres of the mesmerizer. (pp. 372-374)

While Braid had a clear insight into the psychological aspect of hypnosis, other investigators continued to search for its physiological basis.

In his early efforts to establish hypnosis as a somatic phenomenon Charcot (1882) outlined three progressive stages—the cataleptic state, the lethargic state, and the state of artificial somnambulism. He described the first as follows (cited in Weitzenhoffer, 1957):

The Cataleptic State—This may be produced: (a) primarily, under the influence of an intense and unsuspected noise, of a bright light presented to the gaze or, again, in some subjects, by the more or less prolonged fixing of the eyes on a given object; (b) consecutive to the lethargic state, when the eyes, which up to that moment had been closed, are exposed to the light by raising the eyelids. The subject thus rendered cataleptic is motionless and, as it were, *fascinated.* The eyes are open, the gaze is fixed, the eyelids do not quiver, the tears soon gather and flow down the cheeks. Often there is anesthesia of the conjunctiva, and even of the cornea. The limbs and all parts of the body may retain the position in which they are placed for a considerable period, even when the attitude is one which is difficult to maintain. The limbs appear to be extremely light when raised or displaced, and there is no *flexibilitas cereas,* nor yet what is termed the stiffness of a clay figure. The tendon reflex disappears. Neuromuscular hyperexcitability is absent. There is complete insensibility to pain, but some senses retain their activity at any rate in part—the muscular sense, and those of sight and hearing. This continuance of sensorial activity often enables the experimenter to influence the cataleptic subject in various ways, and to develop in him by means of suggestion automatic impulses, and also to produce hallucinations. When this is the case, the fixed attitudes artifically impressed on the limbs, or, in a more general way, on different parts of the body, give place to more or less complex movements, perfectly coordinated and in agreement with the nature of the hallucinations and of the impulses which have been produced. If left to himself, the subject soon falls back into the state in which he was placed at the moment when he was influenced by the suggestion, (p. 283)

Charcot's use of the word *fascinated* to characterize the early stage of catalepsy is entirely in keeping with our modern view of catalepsy as a state of heightened sensitivity and receptivity. The problem with his overall description is that it does not give sufficient recognition to individual differences. Different subjects experience to varying degrees the associated phenomena of fixed gaze, tearing, anesthesia, lightness or stiffness of limbs, and alterations of auditory and visual sensation and perceptions, etc. It is an important aspect of the therapist's skill to learn to recognize just what spontaneous alterations in functioning the subject is experiencing.

Many of Charcot's contemporaries were unable to reproduce his results, and thus believed that they were actually the result of suggestion or preeducation. Bernheim then gave a classical description of "suggestive catalepsy" as an early stage of hypnosis in his *Suggestive Therapeutics: A Treatise on the Nature and Uses of Hypnotism* (1886/1957) that could hardly be improved upon today:

> This degree is characterized by suggestive catalepsy. By this word the following phenomenon is meant. If, as soon as the patient falls asleep, the limbs being relaxed, I lift his arm, it stays up; if I lift his leg, it remains uplifted. The limbs passively retain the positions in which they are placed. We call this suggestive catalepsy, because it is easy to recognize that it is purely psychical, bound up in the passive condition of the patient, who automatically keeps the attitude given just as he keeps the idea received. In fact, in the same or in different patients, one sees the phenomenon more or less marked according to the depth of the hypnotic influence and the psychical receptivity. At first, this cataleptiform condition is hardly apparent. The lifted limb remains up a few seconds, but falls down afterward with a certain hesitancy; or the fore-arm only remains lifted. If one wishes to lift up the whole arm, it falls down again. The individual fingers do not keep positions into which they are put, but the entire hand and the forearm remain fixed.
>
> With some patients, for example, if one arm be quickly raised and let alone, it falls back again, but if it is held up for a few seconds to fix the idea of the attitude in the brain, so to speak, then it remains up.
>
> Finally, with others, catalepsy is only obtained through a formulated verbal suggestion. The person hypnotized has to be told, "Your arms remain up. Your legs are up." Then only do they remain so. Some keep the new position passively, if nothing is said to them, but if they are dared to change it they regain consciousness, so to speak, call upon their dull will power, and drop the limb. Then they often wake up. (1957, pp. 6-7)

A more modern view of catalepsy would emphasize that it is a function of an *actively accepting and receptive attitude* rather than a "passive condition" due to a "dull will power." The patient who quickly and easily responds to a guiding touch is actually in a cooperative and responsive mood. Patients who maintain their limbs in a fixed position after being given a nonverbal suggestion to do so (as when the therapist simply holds the limb in one position for a few seconds) are actually responding with exquisite sensitivity to the therapist's slightest directive. We may, therefore, expect that patients who quickly learn to maintain a catalepsy are experiencing a favorable attitude and acceptance set for further trance work. This may be the reason why Erickson developed so many ingenious approaches to catalepsy, not only in the selection of good subjects for demonstrations of hypnosis, but for the induction and deepening of trance as well.

B. RECOGNIZING SPONTANEOUS CATALEPSY

The senior author's concept of the "common everyday trance" is actually a form of catalepsy. We frequently describe these spontaneous catalepsies as a period of reverie, inattention, or quiet reflection. At such moments people tend to gaze off (to the right or left, depending upon which cerebral hemisphere is most dominant—Baken, 1969) and get that "faraway" or "blank" look. The eyes are usually fixed in focus, immobile, and they may actually close. The face tends to lose its animated expression and becomes lifeless, taking on a certain flat, "ironed-out" look. The entire body remains immobile in whatever position it

happens to be in, and certain reflexes (e.g., swallowing, respiration) may slow down. Such individuals seem momentarily oblivious to their surroundings until they once again recover their general reality orientation (Shor, 1959). We have hypothesized that in everyday life consciousness is in a continual state of flux between the general reality orientation and the momentary micro-dynamics of trance (Erickson & Rossi, 1975).

Recent research on the 90-minute dream cycle during sleep indicates that this cycle is also present throughout the entire 24 hours of the day in what has been named the Ultradian Rhythm (Hiatt & Kripke, 1975). Fantasy intensity, alpha waves, eye movements, and hunger are all related in this basic rest-and-activity cycle throughout the day. It may well be that what the senior author calls the "common everyday trance," wherein catalepsy tends to be manifest spontaneously, is actually coincident with the rest, high-alpha, and fantasy portion of the circadian cycle. If this is so, we may expect that future research will establish that, in general, trance induction and hypnotic experience will be experienced more readily during this rest period of the 90-minute Ultradian Rhythm.

It is noteworthy that the senior author likes to spread important hypnotherapeutic sessions over a period of a few hours. It may well be that at least a portion of his success in facilitating deep trance work is that he intuitively selects that rest period of the circadian cycle, when the patient is spontaneously manifesting tendencies to catalepsy, fantasy, and inner focus. We strongly recommend that experimental research be conducted to test the hypothesis that trance induction can proceed more easily—and more hypnotic phenomena be manifest—during this high-alpha and fantasy portion of the circadian cycle.

There is actually a vast array of diverse phenomena described as catalepsy in the literature of hypnosis (Weitzenhoffer, 1953). These phenomena include practically every form of human and animal immobility, whether brought on *by fascination* (an experience of the unusual or awesome), *startle* or *fright* (a sudden bright light or intense noise), or *fatigue* or *illness.* Many authors also describe various forms of "animal hypnosis" (more properly called "tonic immobility"), which appears to have survival value in nature. The opossum, for example, will "freeze" when trapped by a predator, who then gives up his prey as dead (Cheek & LeCron, 1968; Hallet & Pelle, 1967). Other investigators have demonstrated how to induce catalepsy in an animal through shock and fear by turning it over quickly and holding it immobile for a few moments (Volgyesi, 1968; Moore & Amstey, 1963). The similarity between animal and human tonic immobility when humans are exposed to deep-threat conditions has been described (Milechnin, 1962). It is the association between catalepsy and the deeper nonverbal levels of the personality that makes its use of such potential value in hypnotherapy.

For the purposes of modern hypnotherapy, Erickson's functional definition of *catalepsy as a form of well-balanced muscle tonicity* is probably broad enough to help us understand most of its applications. The following examples taken from everyday life extend our traditional understanding of what catalepsy is and prepare us for a more incisive understanding of its utilization in modern hypnotherapy.

A. When writing a letter, one pauses for a moment to think. During that moment one is oblivious to the pen in one's hand, which is maintained comfortably poised in an immobile, cataleptic position. In fact, the entire body is usually immobile in a cataleptic pose during that moment when consciousness is focused and receptive to one's inner thoughts.

B. When considering a question or problem, one will frequently glance to the left or right and usually a bit upward with eyes fixed in what we can regard as a comfortable cataleptic position. Again, this is a moment of special sensitivity and receptivity to one's inner processes.

C. When absorbed in a book, lecture, or movie, one's entire body will remain immobile, cataleptic, for long periods of time. One's arm may even be nudged to a new position by a seatmate without our realizing it. The arm may then remain comfortably fixed in its new position. With our attention focused on the interesting movie, we pay no attention to the irrelevant stimuli related to our body position. Intense interest and receptivity to certain

stimuli are apparently compensated by a corresponding cataleptic insensitivity to other stimuli.

D. At an athletic event an entire crowd will frequently lean forward and remain momentarily suspended in a fairly awkward cataleptic position. This moment of cataleptic suspension, of course, is precisely the moment when a critical event of absorbing interest is being played.

E. Address an absorbing question to one engaged in a motor activity like writing, painting, tying a shoelace, mixing a cake, sawing a board, or whatever, and the person frequently stops activity in mid-stroke to remain cataleptic in that fixed position for a moment while considering an answer. The question actually suspended external muscle activity so that an answer could be received through an inner focus of attention.

F. Erickson likes to point out how an Eskimo will sit immobile in a comfortable cataleptic pose for 24 hours or more beside a hole in the ice waiting for a seal to appear. Like hunters in many societies, he can instantly respond to the appropriate stimulus even though he seems completely oblivious to all the irrelevant environmental stimuli.

G. In most critically important or emergency situations of everyday life people tend to "freeze" with *fascination* and remain cataleptically immobile as *they focus* their entire attention to *receive* and understand the important event. Thus someone must finally shout, "Don't just stand there, call a doctor!"

In all these examples there tends to be a gap in the subjects' awareness as they wait expectantly for an appropriate response from within themselves or from the outside. At such moments, when they are cataleptically posed in immobile suspension, they are open and receptive to appropriate stimuli. *At such moments an appropriate suggestion can be received and acted upon in a seemingly automatic manner. This momentary gap in awareness is essentially a momentary trance. The heightened receptivity during that moment is essentially what we mean by the term* hypnotic.

An association between catalepsy, or body immobility, and heightened receptivity to important stimuli was characteristic of all our examples. It is also apparent in the teacher's perpetual injunction for students to "sit still and pay attention!" Recent research (Dement, 1978; Goleman & Davidson, 1979) has established that this immobility of the body is likewise associated with the heightened periods of intense inner mental activity during dreaming. During REM (Rapid Eye Movement, which occurs during those stages of sleep when dreaming takes place) sleep most physiological variables (e.g., EEG, respiration, pulse, penile erection, eye movements, etc.) indicate a state of heightened arousal. Only the correlates of muscle tension are depressed, indicating an immobility of the muscles. The frequent analogy drawn between trance and dreams, wherein mental activity seems to proceed effortlessly and autonomously while the body remains apparently inert (cataleptic), thus has some empirical confirmation. Just as dreaming may indicate a state of heightened vigilance during sleep, so is catalepsy a state of heightened expectancy while awake.

C. FACILITATING CATALEPSY

Catalepsy is facilitated by any procedure that (1) arrests attention and (2) leads to progressive body immobility with (3) an inner attitude of inquiry, receptivity, and expectancy of further directing stimuli from the therapist. The receptivity that allows a part of the body to become immobilized reflects a corresponding mental receptivity to the therapist's further suggestions. Catalepsy thus becomes a major means for facilitating and gauging a patient's state of mental receptivity for appropriate stimuli.

This can be illustrated even with a subject who cannot or will not experience catalepsy by the typical approach of guiding an arm upward.

Catalepsy can usually be achieved indirectly by handing the subject an article such as a book and then withdrawing it with a distracting remark when the subject reaches to take it. The subject's arm will remain momentarily suspended in a cataleptic position, as if still awaiting the book. During that precise moment, when arm and hand are suspended, the

patient's mind is also suspended and open; this momentary gap in awareness can be filled by any appropriate suggestion offered by the therapist at that precise moment.

This openness is well illustrated in Erickson's description of a dental colleague's casual utilization of catalepsy to facilitate his patient's receptivity to suggestions for relaxation. (direct quotations of the senior author that are not otherwise cited are from his workshops, seminars, and audio recordings with the junior author; the quotations span two decades of work from the 1950s through the 1970s)

"He doesn't attempt to relax them directly. He doesn't attempt a coaching technique. He asks the patient to sit down in a chair. He asks the patient if he, the dentist, can take a hold of the patient's wrist and very carefully lay it on the arm of the chair. In so doing he moves the patient's hand up and down while addressing some simple, casual remark to the patient. What he is really doing is asking the patient's permission to manipulate the arm. Then he proceeds to manipulate the arm up and down a bit. The patient cannot see any particular purpose in it. As the patient wonders and speculates about it, he is literally wide open for the presentation of an idea.

"In hypnosis what you want your patient to do is to respond to an idea. It is your task, your responsibility, to learn how to address the patient, how to speak to the patient, how to secure his attention, and how to leave him wide open to the acceptance of an idea that fits into the situation. When the dentist takes hold of the wrist and then starts moving the hand slowly up and down, the patient can wonder, 'Is he testing me for relaxation? Is he trying to fit my hand over the end of the arm of the chair? What does he want my hand to do?' With the patient fixated in that sort of receptive wondering, the dentist can effectively suggest to the patient, 'and just continue relaxing more and more.' That technique lasts about 10 to 30 seconds. The patient in that moment of inquiry— 'What does he want my hand to do?'—is completely ready to accept whatever idea is presented to him. Now all of you have seen me take hold of a volunteer's wrist, lift the arm, and suggest that they go into deep trance. That is exactly the same sort of technique as the dentist uses. I do it in front of a group because I want to demonstrate hypnosis as a deep phenomenon rather rapidly. I am willing to attract attention and then allow the patients to be in mental doubt as to what they should think and do in that particular situation. This makes the patients amenable to any suggestion that fits that immediate situation.

"Hypnosis doesn't come from mere repetition. It comes from facilitating your patient's ability to accept an idea and to respond to that idea. It doesn't have to be a wealth of ideas—it can be one single idea presented at the opportune moment so that the patient can give full attention to that particular thing. In dealing with patients, your entire purpose is to secure their attention, secure their cooperation, and to make certain that they respond as well as they can."

Erickson's actual technique of guiding a patient's arm and hand to a cataleptic pose is an art in itself. In his paper on pantomime techniques in hypnosis (Erickson, 1964b) he describes how he induced trance nonverbally:

"I showed the girl my hands, which were empty, and then I reached over with my right hand and gently encircled her right wrist with my fingers, barely touching it except in an irregular, uncertain, changing pattern of tactile stimulation with my fingertips. The result was to attract her full attention, expectant, wondering interest in what I was doing. With my right thumb, I made slight tactile pressure on the latero-volar-ulnar aspect of her wrist, as if to turn it upward; at the same moment, at the area of the radial prominence, I made a slightly downward tactile pressure at the dorso-lateral aspect of her wrist with my third finger; also at the same time, I made various gentle touches with my other fingers somewhat comparable in intensity but nonsuggestive of direction. She made an automatic response to the directive touches without differentiating them consciously from the other touches, evidently paying attention first to one touch and then to another.

As she began responding, I increased varyingly the directive touches without decreasing the number and variation of the other distracting tactile stimuli. Thus, I suggested lateral and upward movements of her arm and hand by varying tactile stimuli intermingled with a

decreasing number of nondirective touches. These responsive automatic movements, the origin of which she did not recognize, startled her, and as her pupils dilated, I so touched her wrist with a suggestion of an upward movement. At that her arm began rising, and I gently discontinued the touch so that she did not notice the tactile withdrawal, and the upward movement continued. Quickly shifting my fingertips to hers, I varied the touches so as to direct in an unrecognizable fashion a full upward turning of her palm; then other touches on her fingertips served to straighten some, to bend others, and a proper touch on the straightened fingertips led to a continuing bending of her elbow. This led to a slow moving of her hand toward her eyes. As this began, I attracted her visual attention with my fingers and directed her attention to my eyes. I focused my eyes for distant viewing as if looking through and beyond her, moved my fingers close to my eyes, slowly closed my eyes, took a deep sighing breath, sagged my shoulders in a relaxed fashion, and then pointed to her fingers, which were approaching her eyes.

"She followed my pantomimed instructions and developed a trance that withstood the efforts of the staff to secure her attention or to awaken her in response to suggestions given in English." (p. 66)

On other occasions Erickson described his approach together with its rationale as follows.

"You take hold of the wrist very, very gently. What is your purpose? Your purpose is to let the patient feel your hand touching his wrist. That is all. The patient has muscles that will enable him to lift his arm, so why should you do it for him? *The body has learned how to follow minimal cues. You utilize that learning. You give your patient minimal cues. When he starts responding to those minimal cues, he gives more and more attention to any further cues you offer him. As he gives more and more attention to the suggestions you offer, he goes deeper into trance. The art of deepening the trance is not necessarily yelling at him to go deeper and deeper; it is giving minimal suggestion gently, so the patient pays more and more attention to the processes within himself and thus goes deeper and deeper.*

"I think all of you have seen me take hold of a patient's arm and lift it up and move it about in various fashions. I induce a trance in that way. 1 have tried to teach a number of you how to take hold of a wrist, how to take hold of a hand. You do not grip with all the strength in your hand and squeeze down on the patient's wrist. What you do is take hold of it so as to very, very gently suggest a grip on his wrist, but you don't actually grip it; you just encircle the wrist with your thumb and index finger with light touches. You suggest a movement of the wrist with only the slightest pressure. You suggest a movement of the hand upward. And how do you suggest it upward? You press with your thumb just lightly, while at the same time you move your index finger this way to give a balance (Figure 2). You move your fingers laterally, and while the patient gives attention to that, you have your thumb actually lifting the hand. This is essentially a distraction technique: while the thumb very lightly and consistently directs the hand upward, your other fingers make touches and distracting movements in a variety of other directions that tend to cancel out each other.

"Another approach to guiding the hand upward is to attract the patient's conscious attention with a firm pressure by your fingers on top of his hand and only a gentle guiding pressure by your thumb on the underside of his hand. The only way the firm touch can remain firm is for the patient to keep moving his hand up against your fingers. At the same time the lower touch of your thumb is kept gentle by the patient by constantly moving upward away from it. The therapist needs to practice these movements over and over because they are one of the quickest and easiest ways of distracting the conscious mind and securing the fixation of the unconscious mind.

"You lift the hand in that fashion, letting your fingers linger here and there so that the patient unconsciously gets a sense of the lingering of your hand. You want the patient to have that nice comfortable feeling of the lingering of your hand because you want his attention there in his hand and you want the development of that state of balanced muscle tonicity which is catalepsy. Once that state of balanced muscle tonicity is established to achieve catalepsy, you have enlisted the aid of the unconscious mind throughout the patient's body. Because you can get catalepsy in one hand, there is a good possibility there will be catalepsy in the other hand. If

you get catalepsy in the other hand, then you probably have catalepsy in the right foot, in the left foot, and throughout the body, face, and neck. As soon as you get that balanced tonicity of the muscles, then you have a physical state that allows the patient to become unaware of fatigue, unaware of any disturbing sensations. It is normally hard to maintain that balanced muscle tonicity and pay attention to pain. *You want your patient giving all of his attention to that balanced muscle tonicity because that distracts him from pain and other proprioceptive cues so that numbness, analgesia, and anasthesia are frequently experienced in association with catalepsy. If you have balanced muscle tonicity throughout the body, catalepsy throughout the body, you have reduced the sensations that exist within the body to those sensations that go into maintaining that catalepsy. A patient then becomes decidedly responsive to a wealth of other ideas."*

The introspective comments of subjects who have experienced the induction of catalepsy in this manner tend to support Erickson's view of the dynamics of distraction in the process. Most subjects report that their hand seemed to have a peculiar tendency to move upward and about by itself because they could not distinguish the consistent pressure upward by the therapist's thumb from the distracting touches and movements by his other fingers. The therapist's minimal cues and the patient's responses to them take place at a faster rate than the patient's cognition can follow. Most of the tactile stimuli and responses are mediated automatically by the proprioceptive-cerebellar system so that the patient's ego awareness on cortical levels is bypassed.

Facilitating Catalepsy with the Resistant Subject

When we speak of resistance, we are not usually concerned with the classical Freudian psychoanalytic problem of a preconscious or unconscious force actively blocking the entry of certain material into consciousness. Rather, resistance to hypnotic work is usually a function of a patient's lack of understanding of what responses are required or of how to allow the required response to happen all by itself. Many highly intelligent patients, for example, need some background understanding before they will permit a catalepsy to occur. Erickson provides this background understanding in a preinduction talk somewhat as follows:

E: You can forget anything. You forget that you had to learn to lift your hand as an infant. You had to learn how to move your hand. At one time you didn't even know it was your hand. There was a time when you did not know how to lift it. There was a time when you were surprised to watch that interesting thing [the infant's own arm] move. There was a time when you tried to reach with your right hand to touch your right hand. You didn't even know it was attached to you.

R: It is these early infantile memories that you are reactivating so they can be utilized to effect a catalepsy?

E: Yes. Once you can get that through to some of these highly intellectual, skeptical subjects, then they can recognize the truth and possibility of such a cataleptic experience.

D. UTILIZING CATALEPSY

In a letter to Andre Weitzenhoffer in 1961 Erickson outlined a number of other approaches to facilitating catalepsy and utilizing it to induce sleep or trance, to evaluate hypnotic susceptibility, and as a springboard for facilitating other hypnotic phenomena. His edited notes are as follows:

Catalepsy is a general phenomenon that can be used as:
1. a testing procedure for hypnotic susceptibility
2. an induction procedure
3. a reinduction procedure
4. a procedure for deepening trance

Absolutely requisite for the successful facilitation and utilization of catalepsy are:
1. a willingness on the part of the subject to be approached
2. an appropriate situation

3. the suitableness of the situation for a continuation of the experience

CATALEPSY TO INDUCE SLEEP WITH ARM LIFT AND LOWERING

Erickson's letter to Weitzenhoffer continues:

I have tested absolute strangers while waiting in line or seated in restaurants, train stations, and airports. I have secured excellent cataleptic responses followed by startle and questioning reactions. I then rely upon some casual comment both to justify our interaction and close the incident.

In airports and only in the presence of both parents with children under six (usually when the children are tired) I will strike up an appropriate conversation with the parents. I identify myself as a doctor, remark upon how tired the child is, how medically I can see that the child is about ready to fall asleep, that if the child only for a moment would stop wiggling or shouting, it would immediately fall asleep. This can be said in the presence or the absence of the child. I further explain that you can't hold the child still, that you just move its arm gently. "Look, I'll show you," and I slide down to the other end of the waiting room bench. The wiggling child looks me over. I gently pick up its arm and perhaps gesture as if to lift the other arm. I carefully lift the arm to get the child to look at the hand and then lower the hand close to the body so that the child will lower its lids as I lower the hand gently to the body. (Sometimes you may have to follow through with the other hand.) As I let the hand come to rest gently on the child's lap, there will be a closure of the eyes, a deep breath, and the child obviously falls asleep. I hastily but casually remark, "You know, that child was a lot more tired than I realized." I then lose all apparent interest in the child and promptly start a conversation with the parents about themselves.

I avoid children over six and mothers under 25—society reaches false conclusions too easily—and I avoid the mother not accompanied by her husband. However, once in a large airport about midnight I saw a harried mother whom I diagnosed (correctly) as having the flu with four children, ages four to nine, all tired, cranky, and overactive. I sat down beside the mother and made all the appropriate comments. She started to say something but then closed her mouth. She seemed attentive and interested, so I explained that the kids were tired, overactive, had to have their attention attracted, and would fall asleep the second they were still. Thereupon I ostentatiously and laboriously tore a couple of narrow strips from a newspaper, tied them awkwardly into a knot, laid them on the floor. The kids sat quietly watching that performance. I then did the hand lift close to their bodies so their eyelids would lower as the hand lowered. All four went to sleep immediately, and I quickly turned to the woman to ease myself conversationally out of the situation, but she said, "Here comes my husband. He was getting a cup of coffee." Then to her husband she said, "Honey, Dr. Erickson has just been demonstrating child hypnosis to me." Both husband and wife were M.D.s. She had recognized me, but I had not recognized her. They both had taken a seminar under me a couple of years before. That's the only time I ever got caught.

Catalepsy by Apparently Maintaining an Arm

Another approach for facilitating catalepsy with adult strangers is by apparently maintaining an arm. In an airport I will notice someone seated, staring into space in what I recognize as the *common everyday trance.* I will sit beside him and begin to stare into space until he begins to notice me. I may nod and look appreciatively at the ring on the stranger's hand resting on his knee. I'll comment on the ring and then casually lift his hand to see it more closely. I then gently release my contact with his arm in such a subtle fashion that it appears as if I'm still holding it. The catalepsy is manifest when the stranger's arm simply maintains itself comfortably in that fixed position for a minute or two while I continue to verbalize about the ring.

The Handshake Induction

(This section of Erickson's 1961 letter to Andre Weitzenhoffer was published in *Hypnotic Realities* (Erickson, Rossi, & Rossi, 1976) and is reprinted here with permission of the publishers.)

Initiation: When I begin by shaking hands, I do so normally. The "hypnotic touch" then begins when I let loose. The letting loose becomes transformed from a firm grip into a gentle touch by the thumb, a lingering drawing away of the little finger, a faint brushing of the subject's hand with the middle finger—just enough

vague sensation to attract the attention. As the subject gives attention to the touch of your thumb, you shift to a touch with your little finger. As your subject's attention follows that, you shift to a touch with your middle finger and then again to the thumb.

This arousal of attention is merely an arousal without constituting a stimulus for a response.

The subject's withdrawal from the handshake is arrested by this attention arousal, which establishes a waiting set, an expectancy.

Then almost, but not quite simultaneously (to ensure separate neural recognition), you touch the undersurface of the hand (wrist) so gently that it barely suggests an upward push. This is followed by a similar utterly slight downward touch, and then I sever contact so gently that the subject does not know exactly when—and the subject's hand is left going neither up nor down, but cataleptic. Sometimes I give a lateral and medial touch so that the hand is even more rigidly cataleptic.

Termination: If you don't want your subjects to know what you are doing, you simply distract their attention, usually by some appropriate remark, and casually terminate. Sometimes they remark, "What did you say? I got absentminded there for a moment and wasn't paying attention to anything." This is slightly distressing to the subjects and indicative of the fact that their attention was so focused and fixated on the peculiar hand stimuli that they were momentarily entranced so they did not hear what was said.

Utilization: Any utilization leads to increasing trance depth. All utilization should proceed as a continuation or extension of the initial procedure. Much can be done nonverbally. For example, if any subjects are just looking blankly at me, I may slowly shift my gaze downward, causing them to look at their hand, which I touch as if to say, "Look at this spot." This intensifies the trance state. Then, whether the subjects are looking at you or at their hand or just staring blankly, you can use your left hand to touch their elevated right hand from above or the side— so long as you merely give the suggestion of downward movement. Occasionally a downward nudge or push is required. If a strong push or nudge is required, check for anesthesia.

There are several colleagues who won't shake hands with me, unless I reassure them first, because they developed a profound glove anaesthesia when I used this procedure on them. I shook hands with them, looked them in the eyes, slowly yet rapidly immobilized my facial expression, and then focused my eyes on a spot far behind them. I then slowly and imperceptibly removed my hand from theirs and slowly moved to one side out of their direct line of vision. I have had it described variously, but the following is one of the most graphic. "I had heard about you and I wanted to meet you and you looked so interested and you shook hands so warmly. All of a sudden my arm was gone and your face changed and got so far away. Then the left side of your head began to disappear, and I could see only the right side of your face until that slowly vanished also." At that moment the subject's eyes were fixed straight ahead, so that when I moved to the left out of his line of vision, the left side of my face "disappeared" first and then the right side also. "Your face slowly came back, you came close and smiled and said you would like to use me Saturday afternoon. Then I noticed my hand and asked you about it because I couldn't feel my whole arm. You just said to keep it that way just a little while for the experience."

You give that elevated right hand (now cataleptic in the handshake position) the suggestion of a downward movement with a light touch. At the same time, with your other hand, you give a gentle touch indicating an upward movement for the subject's left hand. Then you have his left hand lifting, right hand lowering. When right hand reaches the lap, it will stop. The upward course of the left hand may stop or it may continue. I am likely to give it another touch and direct it toward the face so that some part will touch one eye. That effects eye closure and is very effective in inducing *a* deep trance without a single word having been spoken.

There are other nonverbal suggestions. For example, what if my subject makes no response to my efforts with his right hand and the situation looks hopeless? If he is not looking at my face, my slow, gentle out-of-keeping-with-the-situation movements (remember: out-of-keeping) compel him to look at my face. I freeze my expression, refocus my gaze, and by slow head movements direct his gaze to his left hand toward which my right hand is slowly, apparently purposelessly moving. As my right hand touches his left with a slight, gentle, upward movement, my left hand with very gentle firmness, just barely enough, presses down on his right hand for a moment until it moves. Thus, I confirm and reaffirm the downward movement of his right hand, a suggestion he accepts along with the tactile suggestion of left hand levitation. This upward movement is augmented by the facts that he has been breathing in time with me and that my right hand gives his left hand that upward touch at the moment when he is beginning an inspiration. This is further reinforced by whatever peripheral vision he has that notes the upward movement of my body as I inhale and as I slowly lift my body and head up and backward, when I give his left hand that upward touch."

Erickson's description of his handshake induction is a bit breathtaking to the beginner. How does one keep all of that in mind? How does one develop such a gentle touch and such skill? Above all, how does one learn to utilize whatever happens in the situation as a means of further focusing the subject's attention and inner involvement so that trance develops? Obviously a certain amount of dedication and patience are required to develop such skill. It is much more than a matter of simply shaking hands in a certain way. Shaking hands is simply a context in which Erickson makes contact with a person. He then utilizes this context to fix attention inward and so set the situation for the possible development of trance.

As he shakes hands, Erickson is himself fully focused on where the subject's attention is. Initially the subjects' attention is on a conventional social encounter. Then, with the unexpected touches as their hand is released, there is a momentary confusion and their attention is rapidly focused on his hand. At this point "resistant" subjects might rapidly withdraw their hand and end the situation. Subjects who are ready to experience trance will be curious about what is happening. Their attention is fixed and they remain open and ready for further directing stimuli. The directing touches are so gentle and unusual that subjects' cognition has no way of evaluating them; the subjects have been given a rapid series of nonverbal cues to keep their hand fixed in one position (see last paragraph of the initiation), but they are not aware of it. Their hand responds to the directing touches for immobility, but they do not know why. It is simply a case of an automatic response on a kinesthetic level that initially defies conscious analysis because the subjects have had no previous experience with it. The directing touches for movement are responded to on the same level with a similar gap in awareness and understanding.

The subjects find themselves responding in an unusual way without knowing why. Their attention is now directed inward in an intense search for an answer or for some orientation. This inner direction and search is the basic nature of "trance." Subjects may become so preoccupied in their inner search that the usual sensory-perceptual processes of our normal reality orientation are momentarily suspended. The subjects may then experience an anesthesia, a lacuna in vision or audition, a time distortion, a deja vu, a sense of disorientation or vertigo, and so on. At this moment the subjects are open for further verbal or nonverbal suggestions that can intensify the inner search (trance) in one direction or another.

The following demonstration in front of an audience illustrates how catalepsy may be initiated and utilized to facilitate trance experience and the learning of other hypnotic phenomena.

Establishing Rapport

E: And you're?

J: Janet.

E: You certainly made an impression on that tape recorder. It gave the best whistle it could. How do you feel about being in front of an impressive audience like this?

J: I'm *scared to death.*

E: Actually, you know, I think that they're the ones that are likely to be put in a trance. Can you tell me how you feel?

J; Better.

E: Are you quite as frightened as you were?

J: No.

R: The first movement is to establish rapport—a humorous remark about the whistle in the tape recorder and a question about her feelings in front of the audience to evaluate her here-and-now emotional status. She responds that she is "scared to death." Since it is said in a semihumorous vein (in response to Erickson's initially humorous remark about the tape recorder's inadvertent whistle), she is already following Erickson's lead. He responds by making an effort to reassure her. It is important that this reassurance and rapport be established as the first stage of an induction. Her immediately positive responses of "better" and not being frightened now indicate that a favorable climate for a formal induction is established.

Arm-Lift Catalepsy

E: Just relax. I am going to lift your hand up. And I would like to have you watch it.

R: As you simultaneously do a hand-lift catalepsy and request that she watch her hand, her attention is being fixed and focused via two sense modalities.

Visual Hallucination

E: Now look at this hand. And watch it. And you *see it right there.*

R: "See it right there" is a two-level suggestion: On one level it means simply to see the hand. On another level it is a suggestion for a possible visual hallucination to continue seeing the hand "there" even when it is no longer there."

Fixing Arm Catalepsies

E: And I'm not going to put it down. I am going to leave it right there. And just keep watching that right hand. And you can watch your hand. And just keep watching your right hand. And I am going to leave your left hand right there. And now, slowly . . .

R: Many subjects initially do not maintain their arm in a fixed position but let it fall back heavily to their lap when the therapist lets go of it. Erickson then gives these indirect suggestions for maintaining the arm in catalepsy. Having learned a right-arm catalepsy, a left-arm catalepsy is rapidly established to compound her involvement.

Dissociation

E: . . . your hands will open. That's right. And I would like to ...

R: Opening a hand "slowly" while watching it carefully is a fairly unusual task that tends to promote a dissociated attitude and automatic response.

Questions for Inner Focus

. . . have you watch your hands. Your hands are opening. Would you like to watch your hand?

R: We don't normally have to watch our hands so carefully, so the peculiar dissociated attitude continues to develop, spurred on by a *question* as a hypnotic form that now focuses attention within the subject's own associative processes.

Indirect Eye Closure

E: And you can continue watching your hand, if you wish, with your eyes closed. And your hands are opening more and more.

R: This indirect suggestion for eye closure is made contingent on (1) her continuing to watch the hand (that is, a visual image or hallucination is to be maintained within her mind), and (2) her own *wishes.* The first is another step toward learning visual hallucination, while the second tends to mobilize her positive motivation. If she now closes her eyes to relieve them of the strain of this peculiar situation, then by implication it means she is following her own *wish.* Erickson's suggestion for eye closure has become the subject's own wish; the suggestion is completely internalized as an ego-syntonic response.

Pause to Permit the Learning of Automatic Responses

[A 47-second pause]

E: If there is anything that you would like to have me understand, you can nod or shake your head.

R: The hands opening very slowly is a positive indication of trance behavior. She is relearning movements—from voluntary self-directed control to that automatic quality where the hands open slowly, seemingly by themselves, at the therapist's suggestion.

Head Signaling

E: And so that you will get a little practice, I would just like to have you nod your head very slowly. And now turn your head from side to side very carefully.

R: This is a peculiar suggestion with many implications: (1) She is to begin learning ideomotor signaling with her head. (2) She is to communicate only in this restricted way, so most of her faculties can remain "asleep." (3) If she wants Erickson to understand something and simply lets him know by head nodding or shaking, that may imply a great deal of imagined or hallucinated conversation and communication between them. Rehearsing the "slow" head movement allows that automatic aspect of hypnotic behavior to develop.

Questions to Motivate and Deepen Involvement

E: And now, is there anything in particular you would like to learn or that you would like to have me do? [She shakes her head No.]

R: Such questions allow subjects a respectful degree of control in the situation. Why shouldn't their ego be allowed to make requests for trance behavior? This heightens motivation and can deepen involvement in trance processes.

Utilizing Comfort

E: All right, are you *pleased* with the feeling? [Head nods Yes.] Are you *enjoying* feeling more comfortable? [Head nods Yes.]

R: Questions about being "pleased," "enjoying," and feeling comfortable are actually powerful suggestions that enable the subject to evoke her own kinesthetic memories of comfort and utilize them to facilitate the current trance. *Comfort is a natural characteristic of trance.*

Contingent Suggestions for Awakening

E: And now, *what I would like to have you do* is to *discover that you can let your hands lower* to your lap *after* you have opened your eyes, and when they reach your lap, you can awaken.

R: There is actually a series of suggestions in this single sentence. "What I would like to have you do" suggests that she is following Erickson. As she carries out the following chain of three contingent suggestions, she is reinforcing her tendency to follow Erickson.

"Discover you can *let* your hands lower" implies that the subject is learning how to experience the automatic behavior of hand lowering.

Letting the hands lower *after* opening the eyes usually gives the subject a dissociated feeling because she is watching her hands move automatically while not yet completely awake.

An implied directive is utilized, so awakening is made contingent on the hands reaching the lap. If she must "awaken," this implies she must have been in a trance.

Structured Amnesia

E: *How do you feel?* How do you feel? J: Fine.

R: Returning again to the same question—"How do you feel?"— that was asked just before the cataleptic induction was begun tends to structure an amnesia for all trance events that came between the two identical questions.

E. SUMMARY

Although catalepsy was historically one of the earliest defining characteristics of trance, our understanding of its significance and utilization has shifted in recent decades. Whereas catalepsy was regarded by early investigators as a "passive" state of "dull will" characteristic of certain stages of trance, we now regard the ease with which individuals can learn to maintain a limb comfortably in a state of well-balanced muscle tonicity as a measure of their sensitivity and receptivity to suggestion. Erickson's approaches to catalepsy are designed to secure a patient's attention, to focus that attention inward, and to arouse an attitude of wondering or expectancy for further suggestion. Catalepsy is thus an ideal approach for inducing trance and assessing a patient's receptivity. It can be utilized as a basic foundation on which other hypnotic phenomena may be structured.

Catalepsy has a special relation to amnesia and analgesia-anesthesia. We hypothesize that the special focus of attention to minimal stimuli required during the induction and maintenance of catalepsy distracts and occupies an individual's attention so he or she tends to ignore other stimuli. On occasion this gives rise to an amnesia for other events occurring simultaneously with the catalepsy. When the patient's full attention is centered on the minimal proprioceptive stimuli of a well-balanced muscle tonicity characteristic of catalepsy, the patient tends to experience an analgesia or anesthesia for other sensations or pain in the body.

As is the case with all hypnotic phenomena, there are extremely wide individual differences in response to catalepsy. Associated phenomena— such as: fixed gaze; lightness, heaviness, or stiffness of the limb; a sense of automatic movement and dissociation, wherein the limb does not seem to be part of the body; visual and auditory perceptual alterations; spontaneous age regression, etc.—all tend to accompany catalepsy to different degrees in different individuals. Many of these associated phenomena occur spontaneously, seemingly as a result of the partial loss of the generalized reality orientation that occurs as the subject experiences the novel, unexpected, and surprising stimuli of a cataleptic induction. The well-trained hypnotherapist learns to recognize the spontaneous, incipient development of these associated phenomena, which can be further enhanced and utilized to achieve therapeutic goals.

F. EXERCISES WITH CATALEPSY

It is easy for the beginner to feel overwhelmed by some of Erickson's descriptions of his incredibly skillful inductions of catalepsy. It is well to be aware of the fact that these skills were developed only gradually over the decades of Erickson's life after much painful trial and error (see Erickson & Rossi, 1974, 1975, for examples). The student can therefore expect that the acquisition of these skills will require much patient observation and actual practice. These skills continue to develop over a lifetime of clinical practice and constitute one of the rich rewards of a therapist's dedication to the healing arts.

It is important that beginners obtain a certain degree of proficiency and confidence in their skills by practicing first with volunteers in the laboratory of the university or the workshops of organizations such as the American Society of Clinical Hypnosis. One does not

practice on strangers and patients. Erickson's experiences with strangers took place only after he was a master of his art. Patients have a right to expect that a clinician has already acquired the requisite skill to be confident, comfortable, and effective in any therapeutic encounter.

1. Catalepsy to Induce Trance by Guiding an Arm Up and Down

The simplest use of catalepsy to focus attention and induce trance may be by gently guiding a subject's arm to a point just above eye level and then slowly allowing the arm to lower to a resting position. The subject is requested to watch his hand carefully without moving his head. As the arm is lowered, the eyelids also lower. As the arm reaches the next position, the therapist can suggest that the subject allow his eyes to close completely—if they are not already closed.

Therapists develop their skills as they learn to observe and assess the subject's responses during the entire process.

a. Observe the readiness and cooperation that the subjects demonstrate in permitting the therapist to guide their arms upward. As the arm is guided to the highest point, the therapist can hesitate for a moment and very gently release contact with the arm. Does the arm tend to maintain a catalepsy in that position, with the therapist apparently maintaining it there?

b. How comfortably and well are the subjects able to follow the suggestion of focusing their eyes on their hands? This is another indication of their sensitivity and receptivity to suggestion. The therapist carefully watches the subjects' eyes in order to reinforce the suggestion, should the subjects' attention waver. This facilitates rapport between therapist and subjects and gives the subjects training in following the therapist's suggestions.

c. As the arm is lowered, the therapist can again test for catalepsy by gently disengaging touch while apparently still maintaining contact. Does the subject's arm stop and maintain itself in a stationary catalepsy? Does it continue to lower at the same rate as the therapist was moving? Both are satisfactory indications that the subject is following, but a stationary catalepsy might be the more sensitive indicator of trance potential.

d. As the subjects watch the progress of their hands, to what degree do they begin to manifest the eye and facial characteristics of trance? . . . The blank look, blinking, a possible dilation of the pupils, tearing, a softer or more flaccid facial expression, and so on.

e. The therapist learns to gauge the subject's level of expectancy and need for further suggestions. Every parent, teacher, and therapist learns to recognize when someone wants to ask a question: there may be a frown, a certain pucker or tautness of the mouth, a thrust of tongue, a fixed expression in the eyes, a slight holding of the breath, etc. The therapist then supplies such directives in the form of suggestions that will enhance trance or whatever hypnotic phenomenon or therapeutic goal is appropriate at that moment.

Therapists learn initially by observing only one or two of these stages. As they become familiar with the overall process and gain acquaintance with the range of possible responses given by a variety of subjects, therapists are better able to assess more observations and direct each subject in an individual and optimal manner.

How do therapists formulate their verbal suggestions to facilitate this trance induction by guiding the arm up and down? Obviously, a therapist will spend some time learning how to utilize the various hypnotic forms outlined earlier. Therapists can begin by utilizing each of those forms (truisms, compound and contingent statements, questions, etc.) to give suggestions for comfort, relaxation, or whatever during the arm lift and lowering. A few are as follows:

And how comfortable can that arm be

A *question* about comfort tends to facilitate comfort

resting right there?

while *implying* the arm will remain stationary in a cataleptic position.

You are looking at that hand

A truism facilitating a yes set.

and

A compound introducing the following suggestion

you don't need to see anything else.

of a negative visual hallucination for everything but the hand is phrased as a form of *not doing.* If trance and a literalness of perception exist, the subject will see nothing but the hand. Otherwise, nothing is lost, since most subjects will not even recognize that a suggestion for a negative visual hallucination has been given.

As your arm continues lowering to a resting position, you can feel more and more comfortable.

A *contingent* suggestion whereby comfort is made contingent on the ongoing and inevitable behavior of arm lowering. This is also a *truism:* We usually are more comfortable when we bring a limb to a resting position. The word *resting* keys all feelings of comfort by *association.*

2. Catalepsy by Guiding an Arm to a Stationary Position

A catalepsy whereby an arm is guided up and then nonverbally induced to maintain itself comfortably in a stationary position represents another stage of skill. All the observational competence of the first exercise is needed, along with new skills in orienting the subject's arm and hand with *directive* and *distracting* touches. There will be as wide individual differences in the tactics of therapists' approaches to such a catalepsy as there will be in the patients' responses. Beginners can initially follow Erickson's directions outlined in this chapter, but they will soon find their own ways of hand placement, movement, etc., for facilitating a stationary catalepsy. There are many creative variations that can be experimented with. For example, instead of the therapist's thumb actually lifting the hand, it can simply brush upward on the lateral radial prominence (side of the thumb). This very light upward brush may not be recognized by the subject, but it can serve as a cue for lifting the hand and arm.

With subjects whose arm remains heavy and limp, ready to fall back in their lap when released, it is important to use verbalizations to help secure the stationary catalepsy.

How comfortably can it remain there? And I'm not telling you to put it down.

It stays there all by itself.

Does the arm become fixed right there?

And you don't have to move it.

In working with volunteers when learning to induce catalepsy, it is important for therapists to get feedback from their subjects. To what degree was a therapist able to make distracting touches so that the subject did not realize that the therapist was actually guiding arm movement with his or her thumb? To what degree did the subject get a dissociated feeling in the arm so that it seemed to move by itself? To what degree did it not seem to belong to the subject's body? What other hypnotic phenomena tended to accompany the catalepsy spontaneously? How can the therapist learn to recognize them? How can the therapist facilitate and heighten the further experience of these associated hypnotic phenomena in each subject?

An interesting test of the therapist's success in the use of distracting touches in guiding the hand to a stationary catalepsy is to work with the subject's eyes closed. When subjects

evidence a spontaneous sense of surprise at the peculiar position their arms are in when they open their eyes, the therapist has been successful in confusing their sense of kinesthetic localization. As one confuses more and more such senses, the subjects gradually lose more and more of their generalized reality orientation and become amenable to experiencing trance.

3. Moving Catalepsy

A moving catalepsy, whereby a subject's arm is given a direction of movement that continues all by itself when the therapist has released contact, represents another stage of skill. The therapist learns to recognize when the patient's hand and arm begins to pivot easily around the wrist, elbow, or shoulder and utilizes that ease of response to impart a motion to the arm. The therapist then releases contact so gently that the subject does not recognize just when it happened. Most subjects readily experience a sense of "unreality" or dissociation when they watch the arm pleasantly float by.

It is important that the subject receive sufficient warm and empathetic support from the therapist at this point.

And that can be so comfortable moving all by itself.

You can enjoy just wondering about that.

Isn't it interesting to just continue watching your hand?

And you are at liberty to share as much as you would like about that interesting movement.

As the movement continues, involvement deepens, and the therapist can now create other verbalizations to give direction to the arm, hand, and finger movements. When both arms become involved, they can be made to rotate around each other in one of the traditional movements of trance induction and deepening.

Once the subject has the experience of a limb moving by itself, or has witnessed a demonstration of it, sensitivity can be further heightened by not actually lifting a limb but simply brushing lightly upward on the side of the arm to indicate a lifting motion. The therapist may even utilize a modified "pass," by lightly brushing the palm of his hand or fingertips from the subject's elbow, under the forearm, and up around to the back of the hand. This indicates a gently upward motion to the subject, whose arm will lift as if stuck to the therapist's hand. Having had this experience, most subjects will continue to respond to lighter and lighter "passes," until the therapist does not have to touch at all but simply makes a "pass" an inch or two above patient's arm for it to lift. The patient's arm and hand will then simply follow along wherever the therapist's hand moves. With a sensitive and agreeable subject, the therapist's motions can be abbreviated even further, so that finally only a "significant look" or slight gesture with a hand or finger will be enough to set the subject's arm afloat.

It is interesting to obtain the subjective reports of naive subjects about why their hand and arm is following the therapist's. Some subjects will say they feel a "connection," "a magnetic force," "a warmth," or "a mysterious power" that seems to be drawing their hand. Indeed, some subjects can close their eyes and be effectively blindfolded (so *effectively* that they cannot peek through or under the blindfold) and their limbs will still follow the therapist's, even though there is no actual tactile contact between them. It really does seem as if there is some sort of mysterious magnetic force! We can easily understand how early investigators were led to this belief. How are we to account for such sensitive following behavior? The question is still an open one. Is the subject responding to the warmth or sound of the therapist's hand? Can the subject sense movement from air currents set in motion by the therapist's hand? Is there a combination of these and other factors?

With such heightened sensitivity it will be easy for the therapist to experiment further by adding associated phenomena to the moving limbs. To what degree can tingling, warmth, coolness, pressure, numbness, and other sensations be experienced? Visual and auditory alterations?

4. The Handshake Induction

Having completed the above exercises on a few hundred subjects, therapists may now be ready for the handshake induction. Therapists will find their own individual variations and means of coordinating each step of the process after first experimenting with Erickson's approach outlined earlier.

Erickson has added other dimensions of *confusion* to the handshake induction in what he calls the "absentminded professor routine." As Erickson begins to release the hand in that gentle, uncertain manner, the subject naturally looks at Erickson's face and eyes for clarification of his developing question about what is happening. Erickson then adds to this confusion by focusing his eyes at a point beyond the subject. Searching in vain for eye contact, the subject gets a peculiar feeling of being unseen or "being looked through," and questions now multiply as confusion about the situation increases. Erickson then further compounds this confusion by mumbling something incoherently, so the subject is now desperately trying to understand what this absentminded professor is trying to say. At that precise moment when the subject is cataleptically poised in total, focused, inquiring attention, Erickson will make a clear, concise, clarifying suggestion that will then be seized upon by the subject as a means of terminating this uncomfortable uncertainty.

5. Electronic Monitoring of Catalepsy: A Two-Factor Theory of Hypnotic Experience

While the pendulum of current scientific thought has swung to the opinion that no objective measure of hypnotic trance exists, there is a long scientific tradition of measuring catalepsy. As early as 1898 Sidis published remarkably clear and convincing sphygmographic records distinguishing normal awakeness from catalepsy experienced during hypnosis. More recently Ravitz (1962, 1973) published tracings of the body's D.C. electrical activity (measured on high-impedance recorders) that underwent characteristic changes during the induction of catalepsy. The junior author has utilized a high-impedance recorder (input impedances ranging from 10 to 1000 megaohms with nonpolarizing electrodes placed on the forehead and the palm of one hand) for a number of years in his clinical practice as a convenient and convincing indicator of an objective alteration that takes place during trance. The record of a highly intelligent, normal, 24-year-old female subject during her first hypnotic induction is presented in Figure 3. The erratic, fast activity at the beginning of the record (A) is characteristic of normal waking awareness. Every impulse to activity seems related to an upswing, which then drops as soon as the impulse is carried through. During simple relaxation, meditation, and hypnosis the record smoothes out and usually drops dramatically as the subject gives up any active effort to direct mind or body (B). In Figure 3 a few slow upswings are noted during the beginning of the hypnotic induction, as the subject makes an effort to attend to the therapist's remarks (C). These drop out as trance deepens, and the record shows a characteristically flat, low plateau with only low-amplitude slow waves (D). With more trance experience even this low-amplitude activity drops out, and a smooth line record is obtained. As long as the subject remains mentally quiescent with an immobile (cataleptic) body, there are no peaks or valleys in the record. When the subject initiates mental activity or moves, peaks and valleys are usually recorded. The awakening period is also followed by a typical pattern (E). The waking-fast activity usually appears at a

higher level than the initial basal waking level. This higher level is maintained for a few minutes until the record comes back to normal.

The difficulty with accepting such records as valid measures of trance is that they appear whenever the subject quiets down during relaxation, meditation, or sleep, whether or not hypnosis has been formally induced. We would therefore offer a two-factor theory of hypnotic experience. First, there must be a state of openness and receptivity wherein subjects are not making any self-directed efforts to interfere with their own autonomous mental activity or the suggestions of the therapist. Ravitz's measurements, like those in Figure 3, are probably an effective indication of this state of quiet receptivity. The second factor might be called "associative involvement." This is the process whereby the hypnotherapist engages and utilizes a subject's associations, mental mechanisms, and skills to facilitate a hypnotic experience. We regard this process of utilizing a patient's own mental associations as the essence of "suggestion." Hypnotic suggestion is *not* a process of insinuating or placing something into the subject's mind. Hypnotic suggestion is a process of helping subjects utilize their own mental associations and capacities in ways that were formerly outside the subjects' own ego controls.

Students and laboratory workers who have access to the proper electronic equipment (the Heath-Schlumberger Model SR-255B Strip Chart Recorder is suitable) can explore a number of interesting relations between hypnotic experience and the electronic monitoring of the body's DC potential. Is the depth of the curve (Area D in Figure 3) related to "trance depth"? It will be found that some subjects are able to speak during this low portion of the curve without any raise in DC potential. Are these people better hypnotic subjects? Do any hypnotic phenomena other than catalepsy have a characteristic curve? Are the classical hypnotic phenomenon more readily evoked during the low plateau (D) of the curve?

DEMONSTRATION IN THE USE OF CATALEPSY IN HYPNOTIC INDUCTION: Hand Levitation in a Blind Subject

Dr. Z was a blind subject with professional training in psychiatry. She was in her fifties and had been blind since the age of two. She came to Erickson to determine if she could recall through hypnosis some of her early visual images. Could she learn to recall, in particular, the image of her mother's face? This was her first visit with Erickson. After being introduced to the junior author, she gave permission for him to record this session. The session began with a casual conversation about some differences between the functioning of sighted and blind people, during which Erickson recounted a few anecdotes from his extensive practice with the handicapped. Erickson then casually began the induction almost as if it were a natural part of the conversation.

The reader should be forewarned that this was a first induction and that there was only a minimal response. So unresponsive was Dr. Z, in fact, that Erickson was challenged to use a very wide range of his verbal repertory for induction by the hand-levitation technique. These verbalizations warrant careful study by the beginner in hypnosis, since (1) they provide an excellent demonstration of the wide range of verbal approaches a professional must be able to marshal when the occasion demands it and (2) they clearly reveal Erickson's active thought processes during an induction as he gropes for the appropriate concepts that will help Dr. Z's unique individuality learn to experience hand levitation. Erickson's verbalizations are not a routine and cliché-ridden "patter" but the expression of intense observation and inferential thinking about the dynamics of the "live" subject he is working with right here and now.

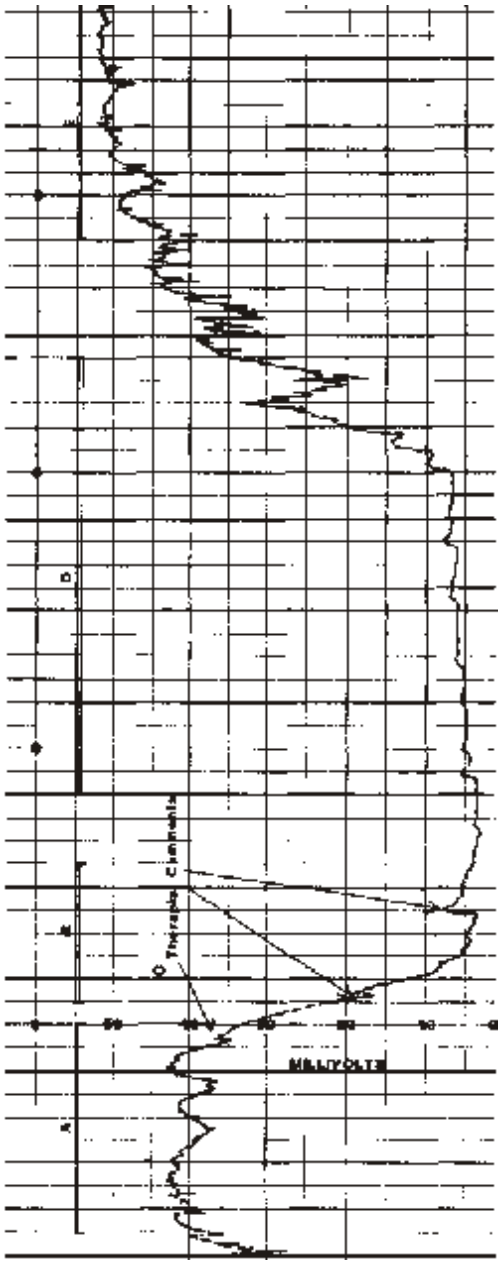

Figure 3: Electronic monitoring of DC body potential during catalepsy— millivolts on vertical axis, Time scale of 0.5 inch per minute on horizontal axis: (A) normal awakeness; (B) drop in DC potential during relaxation; (C) momentary response to therapist remarks; (D) characteristically low activity during catalepsy; (E) typical awakening pattern at higher level than (A).

Structuring Accepting Attitudes and Exploratory Sets

E: Now, can you sit straight with both feet together in front of you? Put your hands on your thighs. Elbows comfortable against the sides of your body. And learning something about a trance is essentially learning about the way you experience. *You don't know* just how changes take place in your feeling from the conscious state to the unconscious state.

> R: You introduce hypnosis to a fellow professional by emphasizing that she will learn about the way she experiences. You thereby establish a learning and exploratory set that will probably be highly acceptable to her. But you immediately point out that "You don't know" how changes take place. The implication is that her experiential learning will not be the usual conscious, intellectual learning so typical of professional training.

An Indirect Approach to Confusion, Evoking Expectancy, Receptivity, and a Need for Closure

E: Now the unconscious state of mine, the fact that the mind------ You know how to tie shoestrings, but if you are asked to specify the movements in order, you don't know them. [Pause]

R: You begin this section with two dangling phrases ("Now the unconscious state of mind, the fact that the mind-----") that seem preparatory to what follows, but I wondered if they were errors in your sentence structure?

E: That is a technique. Nobody likes hesitation. [Erickson now gives a nonverbal demonstration wherein his hand reaches and then hovers hesitantly over a few knicknacks on his desk. Since that arm is in part paralyzed, Rossi felt an obvious relief when Erickson finally managed to pick up one knickknack and present it to him.] There, I knew you'd be glad to accept it, since you formed an acceptance attitude and a desiring attitude as you watched me struggle to pick it up.

R: The dangling phrase develops an expectancy and an acceptance attitude in the patients because they want to grasp something, they want a closure to happen.

E: Yes! They want a closure to happen. They think, "Why the hell don't you finish your sentence?" That's the whole basis of the confusion technique, also.

R: On the conscious level the patients are only aware of their disconcerting uncertainty and confusion. They are not aware of the fact that this is your indirect approach to evoking the confusion that will automatically give rise to attitudes of expectancy, receptivity, and a need for closure. They will then be ready to accept whatever suggestions you can give them that will resolve this need for closure.

Loss of Body Orientation as an Initial Indicator of Trance: Doubt and not Knowing for Exploratory Sets

E: *You do not know* what the body orientation is in the matter of developing a trance. [Dr. Z is gradually sliding awkwardly to the side of her chair without making any effort to correct her position.] I have to watch for different orientations in your body responses. Now there is no hurry on your part. There is no rush.

R: That she is beginning to lose body orientation indicates she's already in an altered state. This is the third time within the first few sentences of this induction that you tell her something she does not know, and you continue this emphasis throughout this entire session.

E: You don't know all these things, but you would like to know something, wouldn't you?

R: This again sets up an expectant and desiring attitude in the patient.

E: It also implies that there is something to be learned here, even though I don't know what it is yet.

R: By introducing doubt and not knowing, you develop an exploratory set wherein the patient now wants to learn more about the things you are alluding to.

Not Doing: Indirect Suggestion for Relaxation and Comfort

E: You simply wait. *You let me do the talking.* In time I'll ask you certain things. And as it becomes a natural feeling with you, you will answer, but in your own way. [Pause]

E: When you wait and know you have to wait, you may as well be comfortable. I didn't have to tell her to relax.

R: Oh, so you're implying comfort here without asking for it directly.

E: "You let me do the talking" implies you don't have to do anything.

R: That attitude of not having to do anything is what you want in the patient, because trance performance is on an automatic or involuntary level. That is what actually defines trance behavior.

E: Yes.

Meeting the Patient's Individuality: An Indirect Approach to Evoking Autonomous Unconscious Processes

E: Now I'm going to call your attention to your hands. There are memories associated with your hands, with your arms, with your elbows. Just what all those memories are would be impossible to state. Now I'm going to make a statement to you about your behavior.

E: What are the memories you have of just how you sit down in a chair?

R: It's impossible to state verbally each individual muscular movement. But why do you bring this up here?

E: Because since she is blind, she has to depend upon the feel of the chair on her calf, etc.

R: So you're actually adjusting your induction verbalizations here to suit her particular individuality.

E: Yes. She has to know if she is right in front of the chair or to the side. Because of past memories she will know about her elbow in relation to the arm of the chair, etc., but because she has been blind since the age of two, these memories are by now all automatic on an unconscious level.

R: With a sighted person you would not use these particular phrases?

E: No, no! I'd take something they can watch *but not see,* like tying a shoestring, buttoning a coat. How does a woman put on her bra—right side first? Left side first? Or simultaneously?

R: Why do you want to point out something the patient can do but cannot specify consciously in verbal terms how it is done?

E: The knowledge is there in the unconscious. The unconscious can understand, but the conscious mind does not know.

R: This is your indirect approach to activating and facilitating her reliance on unconscious processes: You emphasize things her unconscious knows but her conscious mind does not. Her unconscious has relevant responses to your questions even if her conscious mind does not. Because of this your questions and comments on her behavior evoke a set of automatic, unconscious behavior patterns which, of course, are the raw material out of which hypnotic responses will be facilitated.

Differences in Conscious and Unconscious Behavior: Evoking Expectancy

E: When you just brushed back the hair from your face, the movement of your hand was that of strictly conscious mental set. The unconscious moves the hand in a *different* way. I'll call your attention to your hands again. I want you to *wait* until one

of them begins to move toward your face very slowly. Which one? You'll have to find out.

E: When you watch students in a classroom, you notice such differences. One student can brush back her hair with a deliberateness that says, "I hope the son-of-a-bitch reaches the end of the lecture soon." Then there's that unconscious brushing back of the hair that indicates they are attending to you.

R: The same behavior performed in different ways can say different things. The hypnotherapist comes to recognize the difference between consciously directed deliberate behavior and the more-or-less automatic behavior that is mediated unconsciously when the conscious mind is occupied elsewhere. In this case you point out that her hand movement in brushing back her hair was on the conscious level so she will learn that unconscious movements will be different.

E: By having her "wait," you build a desire to have something happen. And it's safe because she can wait till her hand starts lifting. She is now waiting with an expectation that her hand will lift.

R: And it's something in her that's doing it and not you. You are not being overdirective.

E: Yes. Her entire history is that she has to direct every movement with care and caution.

R: For a successful trance experience she needs to let go of that long history of watchful consciousness associated with physical movements.

Illusory Choice: A Double Bind Covering All Possibilities of Response

E: There will be a choice.

E: This is an illusory choice. There actually is no choice, because in the next three sentences I'm taking away "choice." It may be the right hand or it may be the left, but either way a hand will lift!

R: It's an illusory choice for her ego consciousness in the sense that you are determining there will be a response. When you offer such choices—as you do in the next section—that cover all possibilities of response, you are structuring a double bind that leaves it to her unconscious to choose a response.

"Ping-Pong": Depotentiating Consciousness to Facilitate Unconscious Activity

E: Maybe your right, maybe your left. If you are righthanded, it may be your left. If you are left-handed, it may be your right. Or it may be the dominant hand. You really don't know.

E: Now here her conscious mind must jump back and forth— right, left, right, left.

R: What does that do? You've got her following you?

E: Yes, she keeps jumping. You're keeping her in a state of shifting thought, so her unconscious will take over because her conscious mind is bouncing back and forth.

R: You play ping-pong with consciousness; you bounce consciousness back and forth in such a manner that it is depotentiated, thus allowing the unconscious to take over and actually levitate one hand.

E: That's right.

Waiting to Build up Expectation

E: *You just wait* and let your unconscious mind make the choice. And slowly you will become aware that the hand begins to lighten. [Pause as there is no evident movement or noticeable changes in the pulsations in the hand or the micromovements of her fingers.] *It may* feel somewhat different. [Pause] And you sense a tendency in the elbows, *a tendency to behavior.* You *may or may not* become aware of that.

E: Here I'm saying, "You just wait," again to build up an expectation that something will happen.

R: That expectant attitude makes the patient ready to achieve something from the unconscious. That is the ideal psycho-therapeutic attitude for the patient to have, since healing will come from inside once the rigidly erroneous sets of the conscious mind are bypassed. This is characteristic of your approach: When the patient is not responding readily, simply ask her to "wait." This waiting automatically builds up an expectancy that will tend to facilitate the response.

E: "It may" is giving a definite instruction.

R: Even though it sounds as if you are just being casual.

E: "A tendency to behavior" is an awfully elusive phrase.

R: It's a fail-safe phrase; whatever happens, you are still in tune with her behavior.

E: That's right, the patient will give you credit for whatever happens. You "may or may not" is another such safety phrase.

Depotentiating Conscious Sets to Facilitate Autonomous Responses

E: *It is sufficient that only your unconscious mind becomes aware.* [Pause] And be willing to show an increasing dominant choice. [Pause— no evident movement] Wait and enjoy *waiting.* * * * (asterisks indicate passages that have been omitted for economy in publication) *Certain things have been occurring of which you are unaware. Your blood pressure has altered. That you are unaware. Your blood pressure has altered. That is a matter of course in all subjects. [Pause—some minor movements in her hands]*

E: With this sentence, "It is sufficient that only your unconscious mind becomes aware," I'm really throwing out her conscious mind.

R: You are depotentiating conscious sets by implying that they are unimportant relative to the unconscious.

E: I'm not pushing her. We are both waiting. For what? For something! She may not even be aware that this waiting is exerting a pressure on her for something to happen.

R: Expectant waiting tends to facilitate unconscious responsiveness: Autonomous response tendencies tend to become manifest whenever we depotentiate some of our habitual conscious sets.

Indirect Associations Facilitating Ideomotor Response

E: Your hand is responding just a bit more, and *soon your elbow will come into play.* * * * *You may* be aware your breathing rate has altered, and the pattern of breathing. And now the thing is your heart rate has changed. I know this by virtue of the fact that

I can observe your pulse in the neck. I can also watch it in the ankles. Sometimes I can see it in the temple.

E: "Soon your elbow will come into play." How do you play with your elbow? To sort out the meaning of that, she must begin thinking about the elbow; that thinking is the beginning of ideomotor responses of bending the elbow and moving it.

R: Simply talking about movements in a provocative manner is an indirect way of facilitating movement responses: That's the ideomotor response.

E: "You may" means I'm giving her permission. I'm also ordering her. In common parlance and childhood games, "You may look now" means what? "You look!"

R: Yet it does not sound as if you are giving an order.

Multiple Levels of Meaning: The Paradox of Facilitating Unconscious Processes as the Essence of Erickson's Approach

E: But the important thing is for you to discover that *hand lifting* slowly upward. There is enough *dominance* in one hand for you to become aware of it. *You will be patient* because the unconscious is learning for the first time how to take over, *intentionally* responsive to another person. * * * *Your body has been responding in many ways on an unconscious level without your knowledge.* When you meet a person for the first time, there are certain muscles that contract, there are certain muscles that relax. And you respond differently to different people. [Hand shows some lifting, about half an inch.] Now your hand is lifting away from your thigh. *Lifting up.* And it will become higher and higher.

R: You are actually speaking of two different things in close proximity here—hand levitation and hand dominance. The word *dominate* in this context could refer to hand dominance or the fact that one hand is gaining dominance in levitating. Just which meaning she takes it to be doesn't matter.

E: It doesn't matter which way she takes it; heads I win, tails you lose. When I say "you will be patient," I'm utilizing the fact that a blind person has learned to be "patient."

R: You facilitate rapport by casually mentioning things she knows to be true; she has to agree with you. You are using a truism that is valid for any blind person in order to set up a yes set.

E: Without her awareness of it.

R: All she knows is that she feels at one with you, but she does not know the how or why of your metapsychological use of truisms.

E: Take the word *intentionally.* That is a brand-new idea to her because she previously thought that you could take over intentionally only with your conscious mind.

R: There is an interesting paradox in that: The unconscious that functions *autonomously* is to take over *intentionally.* Such paradox tends momentarily to depotentiate the patient's conscious sets. That is a very critical and important learning for a person who wants to experience hypnotic trance: Allow the unconscious to take over: let the unconscious be dominant to permit latent and therapeutic response potentials to become manifest. That is the essence of your approach, isn't it?

E: Yes.

R: "Your body has been responding in many ways on an unconscious level without your knowledge" is a very safe statement to make. It sounds profound and pregnant with meaning when you say it. And that, of course, tends to further facilitate unconscious processes.

Conscious Process Facilitating the Unconscious

E: Now think of it coming up, coming up ...

R: When you ask her to "think of it coming up," you are actually enlisting her conscious ideation to help the unconscious or involuntary levitation. It is as if conscious motivation or energy can spill over into the unconscious to facilitate its learning.

E: Yes. It is just like when the hero of a cowboy movie yells at the bad guy, "Look out behind you!" He evokes a startle response of turning on an involuntary level from a command shouted on the conscious level.

Emphasizing Individuality for Spontaneous Behavior

E: . . . and perhaps you can *feel it moving toward some object* just above your head. [Pause] A little bit higher. Now the elbow will get ready, and the wrist will lift. Now all of your learning has a certain carefulness. A slowness, a preciseness, inculcated in your pattern of learning. This is one bit of learning in which you do not need to learn to be responsible, and there is no rigid pattern for it to follow. It is purely a *spontaneous* sort of thing. Spontaneity of muscle effort on your part has been trained into one position and care. And that's one thing that is going to have to be altered. [Dr. Z's hand jerks up visibly a few times.]

E: The purpose of movement in a blind person is more goal-directed than in a sighted person. Sighted people are free to move spontaneously because they can see. Movement in the blind person is totally different than in the sighted. Because it is more goal-directed, the suggestion to "feel it moving toward some object" is particularly appropriate for someone blind.

R: In the next sentences about slowness and precision of movement you are again adapting your verbalizations to her particular individuality. A blind person since the age of two of necessity would have learned a certain cautiousness and more goal-directedness in body movements.

E: I'm defining her rigid pattern of learning and telling her she does not have to stick with it. The word *spontaneous* has for her the important associations of *involuntary* and *dissociated."* For a blind person such movements are normally disaster, since they cannot correct them as early as a sighted person.

R: Movements that are normal and spontaneous for a person who can use sight to automatically correct and control would be dissociated and involuntary if performed by the blind person— they do not have the automatic feedback control mechanisms of visio-motor coordination. That's rather profound: What's "normal" in the sighted becomes dissociated in the blind. There's an intimate relation between sensory processes and the continuum of voluntary-involuntary (dissociated) behavior.

Reinforcing Spontaneity and Individuality

E: And now you are making *still more progress!* [Pause] Showing your own particular pattern of hand levitation. And you are showing your elbow movements are not those of a sighted person. They are your patterns of elbow movement. That's fine because your arm has risen. And you begin to wonder when your hand will get all the way off your dress. Or you can wonder which will be the first to lose contact with your dress. It is losing contact here, there. *I don't even know if you know which hand it is,* but that is *not* important. [Pause.]

R: Your suggestion is apparently working because these upward jerks, the strongest thus far, seem to come in direct response to what you are saying. You quickly reinforce it, of course, by remarking on her "progress."

E: That's right. I'm emphasizing that her elbow movements are not those of a sighted person. I'm again emphasizing her individuality and spontaneity. When I admit that I don't know which hand is levitating, it implies that it's what she is experiencing and learning that is important.

Pauses Evoking Internal Questions That May Depotentiate Conscious Sets by Implication

E: Your pattern of learning may be to occlude the exclusion of your own awareness. [Pause] The exclusion of your awareness is not wrong, it's not necessary. You've been trained by experience to be *very aware,* as if awareness in this situation were important. But you're actually accomplishing something. It's going up more and more. You've already accomplished enough to achieve awareness if it's a necessary part of your learning. [Pause] To me it is important you learn in any way that you can. And I'm fully aware that your part is to learn a pattern of responses not common to me. [Some upward movements are apparent.] It's lifting higher and *higher!* Your unconscious mind has moved the hand. It's already made the elbow move, [Pause] and it is altering contact with your dress.

R: Here you are directly suggesting the possible exclusion or occlusion of awareness.

E: Yes.

R: You're continuing to depotentiate her awareness by locating the source of her training to be "very aware" and telling her this is a different situation. Hypnosis is a different situation in which your careful training in awareness need not apply.

E: During the pauses of this section I'm giving her time to ask herself, "Why should I be aware?" I'm telling her it isn't necessary. I pause here (the second pause) while she thinks it out. You see movements without complete conscious awareness in kids all the time. At the dinner table a child will ask, "Can I go to the movies?" And as he waits for an answer to this very absorbing question, you notice he's picked up a glass of milk and brings it to his lips, and only when it actually touches his lips does he make a slight startle of recognition that the milk is there ready to drink. You see that type of thing over and over again in work with children.

R: Children tend to do things automatically without conscious awareness.

E: Yes, on an automatic level.

R: It's that automatic level of functioning that you capitalize on in trance.

Push and Pull in Hand Levitation

E: And now sooner or later there'll be a push by your unconscious mind. It's going to *pull or push* your hand upward. [Pause] And you are actually increasing your learning. In a way you had a double purpose, which is very nice. You have a tendency of learning more than you are aware of. You can be aware of some and be unaware of some.

R: By including both "pull or push" you are covering more than one possible response; you are permitting her to utilize whichever mode of response she has more strongly built into her from previous life experience.

E: Her double purpose is: (1) to learn to be responsible at a motor level, and (2) without a conscious awareness. For a blind person it is so necessary to have a conscious awareness of any motor movement. A blind person has to be aware that such and such is just so far from my shoulder, my back, my thighs, etc. [Erickson demonstrates nonverbally with his body.] But sighted people have peripheral vision and are unaware even that they have it to handle such problems. Blind people have to goal-orient their movements as a consciously done thing; it is an entirely different type of movement than that of a sighted person. Now in hand levitation I'm asking her to learn to make movements that have no goal.

When you question subjects about hand levitation, some experience it as a force pushing their hand, while others experience it as a pull. Now blind people know what a pull is and what a push is. They relate that to goal-oriented purposes. So you isolate that pull or push knowledge into a nongoal-directed area.

R: A nongoal orientation is what we want in trance.

Uncertain Trial-and-Error Learning in Hand Levitation

[Dr. Z's hand is levitated a few inches, and though it bobs uncertainly in the air, it is actually always "actively trying," even when it momentarily lapses back on to her thigh.]

E: Lifting higher and *higher more rapidly.* And now it is lifting up very, very smooth. Your head is bowing down toward it very slowly.

E: This uncertain bobbing up and down, trial and error, is typical of all learning. You try to do something new, but there are many partial and abortive efforts—

R: —before you can get a smooth lifting of the hand autonomously.

E: With the emphasis on "more rapidly," I'm taking her attention away from the lifting to the question of speed.

R: Implying, therefore, that it will lift, it's now only a question of how rapidly.

Autonomous Head Movements as an Indicator of Trance

E: Bowing down toward your hand, and as your head bows, your hand will lift easily. Bowing down very slowly, and the hand lifting to meet the face. [Pause. Dr. Z's head bowing was a very slow micromovement indeed! R had to study Dr. Z very carefully to ascertain that it actually was taking place.]

E: How do you move your hand to your face? [R demonstrates a direct hand movement to his face without moving his head.]

R: Oh! You mean there is a difference in trance: In trance people tend to also move their head toward their lifting hand. So when you observe that head moving toward the lifting hand, you can take it as an indicator of developing trance?

E: Yes. Your guest at your dinner table is not going to ask you for a second piece of cake. You can watch him not ask you: His head moves toward the cake, his eyes look, there is a parting of the lips. But he is not asking verbally.

R: Nor does the guest always know what he is doing. Those head, eye, and lip movements sometimes occur involuntarily.

E: Yes.

R: So these head movements in trance are involuntary. That is why you prefer to use head movements for signaling Yes or No rather than finger signals; head movements

are much more built into the person, and so can function more easily on an involuntary level.

E: That's right.

The Rhythm Induction: Yo-yoing Consciousness to Get into the Therapist's Rhythm

E: Bowing down slowly, down, down, up, down, up, down, down, up, down, up. [Pause] Your head is getting lower. Your fingers are about ready to lose contact. More of that slight jerk, and some of the fingers will be off. Lifting. Lifting. [Pause]

E: What I'm doing with this down, up, down, up, etc., is associating the head and arm movement. This is also a yo-yo on the patients' thinking; they can't solidify their thinking. They can't think, "Now it's down, now it's up" because I've taken over that down and up, and it's now in my rhythm. Only they don't know it is my rhythm. They get into the therapist's rhythm.

R: It is important for the patient to get into the therapist's rhythm because it will enable her to follow a suggestion that will come eventually.

E: That's right. I am getting her away from her own habitual conscious patterns.

R: Which is the essence of your whole procedure.

E: But I would not say, "I will tell you when to breathe in and out," because then you would be making her consciously aware of her rhythm! A child with whom I worked had a father who used medical hypnosis. When her father asked her about the differences in our approaches to hypnosis, she replied: "Daddy, you tell me to sleep, but Dr. Erickson breathes me to sleep." You adopt the child's rhythm of breathing, and then you start altering your rhythm and let the child now follow you. We all have a lot of rhythms, and rhythm is a very powerful force. [See Vol. I of *The Collected Papers of Milton H. Erickson on Hypnosis* for a detailed account of the Rhythm Breathing Induction.]

R: We can thus utilize rhythm as a method of inducing trance or of deepening trance. It is particularly potent because (1) it is indirect, in that the subject does not know it is being utilized, and (2) rhythms all have a natural biological grounding within us. When we get in synchrony with a subject's rhythm (whether it is breathing, movement, a verbal pattern, etc.), and then by degrees succeed in altering it, we are changing a very deep function and may be thereby capable of effecting deep therapeutic change.

Implied Directive to Reinforce Hypnotic Learning

E: When your right hand is off, you *will have learned a great deal* about hypnosis.

R: Here you subtly capitalize on her eagerness and motivation to learn hypnosis by saying she "will have learned a great deal" when her right hand has lifted. This is a form of the implied directive that reinforces a covert internal state of learning. Some learning certainly will have taken place by the time her hand does lift off her dress—not much, but some—and however little it is, it will be strongly reinforced by your rewarding her with the statement, "you will have learned a great deal." Thus emphasized and rewarded, the little bit she has learned will serve as a foundation for later learning

Disguising Authoritative Suggestions

E: *Only you won't know* what it is you have learned. But it will be a sizable amount with which you can work. If you want to know something of how to that's *right!* A nice *jerk!* Soon there will be another. [Pause]

R: You make this statement "Only you won't know" to keep the new learning experience of hypnosis safe from the neutralizing and destructive influence of the doubting sets of consciousness.

E: Yes, and that is a direct authoritative statement, only it isn't heard as such. The word *only* takes off the authoritative sound. Even when you make a direct suggestion, you typically disguise it with casual diminutives (only), probabilities (it may, perhaps), and subtle use of negatives (it will, will it not) to disarm the usual doubts so characteristic of the patient's learned limitations.

Immediate Reinforcement of Involuntary Jerks

E: Your head is going a bit lower. Hand lifting [Dr. Z's hand gives a noticeably stronger upward jerk.] *That's right! Another jerk!* [Pause] Wonder why there would be jerky movements? There are always jerky movements as part of physical learning. [Pause]

R: A very nice immediate reinforcement of an obviously involuntary upward jerk takes precedence over anything else you may be saying, so you break right into your own stream of verbalization here.

E: Yes, I may be saying something to her, but I immediately change the subject to her behavior.

R: This phrase "That's right" whispered with intense interest and conviction has become a catch phrase among members of the American Association of Clinical Hypnosis who have observed your work and learned from you first hand. When I experienced that phrase while in trance with you on one occasion, I felt a burst of pure energizing joy that motivated me to a point where anything seemed possible.

E: Yes, that's the power of reinforcement utilized at the right time. This jerkiness of her movements is characteristic of all learning—it helps patients to actually tell them that.

Slowness of Normal Learning and Clinical Retraining

E: Learning smooth movements and slowness is not anything to be distressed by. [Pause] That's right. *Lifting!* All of its own, up it comes. And now it extends to your forearm and elbow. [Pause]

E: [Describes the importance of allowing learning to take place slowly, as it does naturally. Children with stuttering and speech problems, for example, can learn to speak normally by going through a period of retraining during which they are taught to speak very slowly.] The problem in learning to speak well is in your willingness to learn slowly. All little kids can learn to speak because they are usually willing to take a year or two to say "drink of water" instead of "dink a wa-wa."

R: Normal learning in speech, walking, reading, arithmetic, spelling, etc. actually requires the coordination of an indescribable number of neurones, muscles, and sensory organs. Reorganization is constantly taking place in the synaptic connections of the brain throughout our entire lifetime (Hubel, Torsten, & LeVay, 1977; Changeaux & Mikoshiba, 1978; Greenough & Juraska, 1979). That is why such skills usually require years to develop. In clinical retraining we must therefore emphasize that a normally slow and patient period of learning will enable a genuine organic growth and reorganization to take place. This patience is sometimes required for hypnotic training as well. I remember the first time you used a hand-levitation induction on me—it

actually took an hour before my arm got all the way up. But a lot of genuine learning about trance experience took place in that hour that served as a foundation for our further work.

Tension for Hand Levitation

E: And the tension will increase in the elbow. [Pause]

R: This reminds me of the fact that some tension in the arm is required for successful hand levitation. Dr. Robert Pearson actually builds in this needed tension in a variation of hand levitation—he has the patient begin by resting the fingertips lightly on their thighs. In this variation there is naturally more tension in the forearm, which must hold up the hand, so only the fingertips touch the thigh.

E: I know, I taught him that.

Depotentiating Conscious Sets with Suggestions Only the Unconscious Can Carry Out: Occupying the Conscious and Unconscious on Their Respective Tasks

E: Now it isn't necessary for me to speak to you. You've heard what I had to say. [Pause] Your experience of learning to retain the spoken word, and you can repeat this on and on through your mind. [Pause] And make your response fit your *memories* as my words flow through your memory. [Pause]

R: In this section you're instructing her to internalize your suggestions and associate your words with her own "memories" of how responses are made. Actually, of course, she probably does not know consciously how to fit her responses to her memories. You are giving her a suggestion that only her unconscious can carry out. In this way you again indirectly depotentiate her habitual conscious mental sets in favor of unconscious or autonomous processes. This is to take place while her conscious mind continues to reverberate your words in her memory. Thus, you have given a task to both her conscious and unconscious mind.

Coping with Consciousness and Depotentiating Habitual Conscious Sets: The Inserted Command to Enhance Learning

E: In that way you are going to *enhance your learning.* [Pause as a little hand jerk is noticeable.] That's right. [Pause as another very little hand jerk is noticed.] That's right. [Pause]

E: This is an example of an *inserted command.* I've made a general statement there about learning, but I've used the word *enhance,* which makes it into a command.

R: It is actually your vocal emphasis on the word *enhance* together with a slight pause before it makes the command "enhance your learning." It is really incredible how such slight vocal changes can lead to such great shifts of meaning. These shifts of meaning are so swift and unexpected that consciousness usually cannot follow them; it usually cannot grasp their implications and then debate or negate them. This is the essence of your art of coping with consciousness: Suggestions are presented in such a way that they quickly slip through conscious defenses without ever being picked up. The suggestions finally come to rest within the subject's preconscious, unconscious, or memory banks, where they can now interact with other associations to effect their therapeutic work. The conscious mind is then presented with a fait accompli from within—without ever knowing quite how it happened.

Covering and Reinforcing All Possibilities of an Hypnotic Response: Unconscious Association and Therapeutic Suggestion

E: *Now soon* you will tie the movement of your hand to the recognizable movement of your head. [Long pause] That's right. You are trying to orient your entire forearm, elbow, and hand. [Pause] And I can see the action, and I can feel it. [Pause]

R: This is a fascinating juxtaposition: "Now soon" means a response could take place *now* or *soon,* depending on the readiness of the subject. In two words you've again managed to cover all possibilities and reinforce behavior whenever it happens.

E: "Now soon or later, or sooner than you think," would be another one. With that you've really covered all possibilities. You've also given them full permission to "think," though they don't notice that you've given them that permission to think. They are paying attention to the "now" or "soon" or "later." They ignore the "think."

R: This subtle inserting of "think" would be another example of your technique of associating your suggestions with what they are naturally doing in such a way that their consciousness does not recognize it. This unnoticed association, however, builds a strong connection between your words and their unconscious, so eventually your words will trip off processes within them on an unconscious level. At a later time you might be able to use this association to have them "think" about something for therapeutic purposes that they might not ordinarily think about.

Catalepsy in Blind and Sighted: The Failure of Hand-Levitation Cues

E: Be *unconcerned and uninterested* in what I do. [Erickson now moves closer to Dr. Z and begins to touch the lower edge of her slightly levitated hand with his. He is giving a tactile signal for lifting without actually lifting.] I do not need any assistance. [Pause] What I do is my responsibility, and you do not need to correct it or alter it in any way. [Pause] It will not be an interference with you. [Pause] It will be an effort by me to let you become aware of certain things that have happened in your physical orientation. [Pause] Keep on with that effort to lift your hand at the unconscious level without concern for what I do. [Pause. Dr. Z's hand apparently does not accept his tactile cues to remain up and lift further; paradoxically, it drops down after he gives hand-levitating cues.] I'm putting your hand here. [More firmly, Erickson places her hand in a cataleptic pose about midway between her lap and head and holds it there lightly for a moment, then, as imperceptibly as Possible, he removes his support. Most subjects, whether in trance or not, usually take this as a cue for the hand to remain suspended in that position. Dr. Z does not seem to pick up Erickson's nonverbal cues to maintain that position, however, and in several attempts her hand either flops back to her lap or descends within a moment or two] *I'm not putting it in any other place, just here.* And you are not to correct it or alter it. You are slowly beginning to understand [Pause] that you don't know what I mean by *altering it.* [Dr. Z's hand continues to drift down to her lap after Erickson positions it. Then there is another pause as Erickson again positions her arm, and again it rapidly drifts down.] Now that was a correction, an alteration. [Pause] And now I'm leaving the fingers there. [Erickson now contents himself with leaving two or three of her fingers lifted, even though the remainder of her hand rests on her lap. . . . Pause. Even the fingers lose their position so that Erickson has to reposition them.]

R: Why do you ask her to be "unconcerned and uninterested" at this point?

E: When you touch a blind person, it isn't the same as when you touch a sighted person. The blind are obligated to try to place a meaning on that touch. You don't look an Arab in the eye when you talk to him because he considers that an insult. In certain

parts of South America people stand so close to you that you're belly to belly, but you don't move away or they take it as an insult. Blind people also have their own culture; the sighted person has no awareness of what touch means to the blind.

A touch to the blind means, "do something." And what is that something you are to do with your hand? Your hand has been touched for a purpose. But what is that purpose here? She can't find any purpose. I've learned from working with a lot of blind subjects that catalepsy is an awfully hard thing to achieve. Catalepsy in a sighted person who does not understand a word you say is easily achieved.

R: You feel this is because in the blind person, hand positions and movements always have an object orientation—a purpose orientation. And yet you are trying it [catalepsy] here even though you know it probably won't work.

E: Yes, this session is for didactic purposes. Anybody doing therapy ought to get to know the range of human behavior.

R: When you say firmly, "I'm not putting it in any other place, just here," it seems to be as direct a suggestion as you could make without saying, "Please hold your hand in this position." But true to form, you make your suggestions as indirect as possible so that the conscious mind will have as few cues as possible to do things in its own characteristic way.

E: She really doesn't know what I mean by saying "altering it."

The Failure of Direct Authoritative Suggestions as a Paradoxical Indication of Trance

E: There, right there! *Right there!* [Erickson makes repeated efforts to have her maintain that arm in the air.] It's contradicting your total education, but keep it right there up, up, up! Up, up, up up! You are learning! [Several of Erickson's dogs are barking loudly outside the office, but at least Dr. Z doesn't seem to be paying any attention to them. Only Dr. Rossi silently mourns their disruption of the tape recording.]

R: *In extremis* even Erickson is capable of fairly shouting a direct, authoritative command, "Right there!" But all to no avail! The hand flops haplessly back to a flaccid resting position on her thigh. The very fact that she cannot follow a direct command for the voluntary maintenance of her hand in the air indicates that she is in an altered state of consciousness.

You have made a shift from an indirect and permissive mode to very direct, authoritative commands, but she cannot follow you now with a voluntary response. This peculiar rigidity of not being able to respond even on a voluntary level may be an indication of the psychomotor retardation that is characteristic of trance. Actually, a kind of pandemonium is taking place with the loud barking of the dogs, your unusually assertive intrusions, and the air conditioner clicking on and off just above her ear, but she ignores it all, as is characteristic of trance behavior. Those dogs have never been such a bother. I wonder it they picked up your loud voice and are trying to come to your defense?

Utilizing Natural Mental Mechanisms and Limitations

E: You may not know you have yet learned anything about hypnosis. You may not feel you have learned anything. Your unconscious mind may know that it has learned. [Pause]

R: This is highly characteristic of your approach for bypassing the doubting attitudes of consciousness. Consciously, the patient may not realize that something has been learned. Consciousness is typically unaware of latent learning, the formation of unconscious associations, etc. You use this basic fact about human learning, this basic truism, as the foundation to facilitate an acceptance attitude toward her training for involuntary signaling that occurs in the next section. You take advantage of natural limitations of consciousness to introduce a set for involuntary or hypnotic responses. I believe this is the fundamental basis of the effectiveness of your work: *You utilize natural mental mechanisms and limitations to channel responsiveness in ways that the conscious control system cannot yet do.*

The Double Bind in Hypnotic Induction: Criteria for Valid Ideomotor Head Signaling

E: So I'm going to pose a situation, and in the situation we will both wait for the answer. If your unconscious mind knows that you have learned something, your head will slowly nod Yes. If your unconscious mind thinks No, it will slowly shake No. Now we will wait for the answer. Has your unconscious learned something about hypnotic response? [Long pause] Now a positive answer is a nod of the head. A negative answer is a shake of the head. So far what you have attained has been a slight nodding and a slight shaking, meaning: I don't know. Now the unconscious mind does have a lot of repressed knowing. That's why we call it the unconscious. Now slowly move your head down, down until your chin touches your dress. Not rapidly, just slowly. [Pause] Now I want to point out to Dr. Rossi things he should notice. But you need not pay attention to what I say to Dr. Rossi. It will be without meaning to you.

R: You use a double bind to introduce involuntary head signaling with your suggestion, "If your unconscious mind ... it will shake No." This is that neat situation that actually induces a hypnotic state or deepens it. Your double bind tends to evoke an autonomous or dissociated (involuntary) response from the unconscious. When the answer comes, it really doesn't matter whether it is Yes or No. The mere fact that an involuntary response occurs means that the subject has entered trance—even if only momentarily to make the involuntary response.

E: Yes. A head can nod for Yes, shake for No, and make all sorts of movement in between for "I don't know." You accept such movements as valid only when they are (1) *slowly* and (2) *repetitively* done. When they are done quickly and not repetitively, that means they are from the conscious mind. The Yes of trance is a repetitive movement that may last for a minute.

There is no need to terminate it because there is nothing else going on in the trance state. In the waking state there is something else going on that stops and replaces the Yes response.

The blind have no possibility of relating a visual value to a nodding of the head; only the sighted person can have that understanding. Therefore, the blind person who knows what a nod and shake means can do it, but does it without any conscious understanding of what is taking place because of never having acquired the visual associations.

In this patient a nod of the head came slowly and imperceptibly because it was not necessary to become consciously aware of it. Only the viewer needed to see the slight, slow movement because only the viewer could place a meaning on it. The fact that it took place meant that the unconscious did understand but did not know how to nod the head to meet visual requirements.

A sighted person can lower her chin to touch her dress. That can be seen as a meaningful thing. A polite bow can be seen and understood, but it can't be understood at all by a blind person. It is totally without meaning. Asking her to touch her dress with her chin is asking for a performance that has no visual meaning of any sort. The only conscious meaning is to feel the dress with the chin.

R: That is the only cue she has, touch, but no visual meaning.

E: Now, when the only cue for understanding is a touch of chin against cloth, how far down do you bend the head to touch? She has no cues until she gets to the goal. It is going to seem long.

Depotentiating Conscious Sets: Tasks with No Conscious Referents

E: [To Dr. R] Location is undefined, *lost.* The need for exploratory activity is [To Dr. Z, regarding her head's micromovement downward] down and down and down. [To Dr. R] Now, the slow smoothness of the movement there is not possible by the conscious mind. This indicates there is a lack of the guidance of the conscious mind. [To Dr. Z] Down further. [To Dr. R] There is an altered time sense. [Pause] [To Dr. Z] Down still further. [To Dr. R] I would judge it's contracted time.

R: Yes.

E: [To Dr. R] Though sometimes it is expanded time. You have to learn that from the subjects later. [To Dr. Z] Down still further, and keep on going till your chin touches your dress. [Pause] It seems so long and far away, the dress does, but you can get your chin on it eventually.

E: The movement is undefined, and the purpose is lost. I'm getting something done by her for me that I can understand, but it has lost all significance for her conscious understanding. Her conscious mind has no referents for it, and she does not realize.

R: This is another way of depotentiating conscious sets. Patients may have awareness in trance, but by having them do tasks they cannot understand, by having them engage in behavior for which they have no conscious referents or orientation, you are temporarily rendering their left-hemispheric consciousness incapable of its habitual modes of action. Perhaps that is a way of understanding what trance is: *Trance is a state of awareness wherein the normal organizing and structuring function of left-hemispheric consciousness or the ego is minimal.* In keeping with recent research, we would hypothesize that it is typically the organizing functions of the left hemisphere that are depotentiated (Erickson & Rossi, 1979; Watzlawick, 1978). In this less organized state awareness can maintain its receptive function and sometimes its observer function as well. I wonder if this is similar to the state of "no-mind" which the Zen Buddhists strive for. It is in this receptive state that the patient's defenses and erroneously limiting conscious sets and attitudes are in abeyance. In this state the mind is open to receiving the seeds of therapeutic suggestion, which must then sprout in the medium of its own unconscious associative processes.

Gaining Control by Giving Permission

[Long pause as Dr. Z's head begins to lift with an almost imperceptible micromovement.]
E: And slowly now the head begins to lift up *without requiring any permission* from me, a little bit to the left, and lifting a bit easier and comfortable, much easier, much more comfortable. * * *

R: The head movement spontaneously changes direction in a manner you had not anticipated. Yet you immediately approve of it with your mentioning that it moves "without requiring any permission" from you.

E: You wait for that movement, and then you mention it so the blind person knows you are attending to them. That is the only way they have of knowing. Mentioning it also gives "permission" for it.

R: By giving "permission" you also gain control over it. You gain control over symptoms by the paradoxical procedure of giving the patient permission for them (Watzlawick, Beavin, & Jackson, 1967).

Indirect Generalization of Hypnotic Effects by Implication: Shifting from the Known to the Unknown: Facilitating Creativity

E: By sensing your hand or your forearms or your neck or your thighs or your calves, by paying attention to first one part and then another part of your body. And last of all, [Pause] feel the comfort in your head. [Pause] And feel the sense of being rested. *Now in learning hypnosis it is not important to know what you have learned.* [Pause] What is important is the acquisition of the knowledge, and having it ready to utilize when the proper stimulus conies.

E: I previously emphasized hand levitation and head nodding, and now I'm mentioning all the other parts of her body— apparently to generalize, but specifically I'm relating them to my hypnotic suggestions about hands, arms, elbows, head. And yet I'm not telling the subject, "There will be an association." When I say, "I see you've lost two fingers of your right hand," I'm also saying (implying), "but you haven't lost your fingers of your left hand."

R: So here you are actually generalizing your hypnotic work with her head and hands to other parts of her body without giving her any conscious cues to that effect. The generalization of the hypnotic effects takes place on an unconscious level because consciousness does not grasp the implications of your associations.

Next your truism, "Now in learning hypnosis it is not important to know what you have learned," tends to depotentiate her habitual conscious sets by implying that it's more important to be able to respond appropriately to a proper stimulus than simply to know. This tends to shift functioning from the knowing conscious system to the unknown processes by which the unconscious mediates responses. This continued shifting of emphasis from what is known to the unknown is highly characteristic of your approach. You do not presume to know yourself. By continually evoking the unknown, however, you are constantly breaking through the limitations of a patient's conscious sets and setting the stage for unconscious creativity.

The Patient's Cues Signaling the Wish for Trance Termination

E: Now I know that you would like to awaken, so very slowly come awake. Not all over. I want you to learn to enjoy, [Pause] sensing what trance feelings are in various parts of your body.

R: How do you know when a subject wants to awaken? Do people get fidgety?

E: Experience can be very informative. [Erickson here gives an analogy with toilet training. Mothers soon sense that youngsters begin to look up and all around in a certain way, it's time to put them on the pot. "Is he looking for the chamber pot?" R asks. "No, no," Erickson answers, "the child is looking all around wondering where that pelvic pressure is coming from. It takes some time and life experience for the child to locate its own bodily sensations—the location of internal functions tends to come later."]

Hypnotic subjects like trance up to a certain point the first time, and then by their movements and alterations of facial expression, alterations in sound of voice, altered tension of the body, altered breathing rate, they let you know in some way they want out. You see two people talking, suddenly you notice one losing interest, you can see their interest evaporating.

Ratifying Trance: Learning to Maintain the Body Sensations of Trance

E: You won't get all the feelings in all the parts all at once. It is a learning process. [Pause] I would like to have you as soon as you are ready in your own way to speak and say, "I am awake," when you *feel* you *are* awake.

Z: I am awake [spoken in a low whisper as she reorients to her body].

E: How do you know that?

Z: Well, as far as I know I always was, but I, uh, know for instance that this hand [Pause] it had a feeling like it was raised up. *But I didn't dare move my fingers to tell if it was or not because I didn't want to spoil the illusion that it was.* And then you said that the fingers were leaving the dress, so apparently it was.

E: You don't learn all at once. You learn in segmented fashion.

R: You are going to learn you have lost a certain part of your body: That is, a certain part of your body is heavy, anesthetic, or it has a "pins-and-needles" feeling. All those altered sensory responses are indicators of trance, and different parts of the body will pick it up at different times. The therapist must make sure that patients know that whatever alterations they feel are aspects of trance.

E: Yes, that is the purpose in having them describe the sensations. It ratifies the trance.

R: When she says that she "didn't dare move my fingers . . . because I didn't want to spoil the illusion," she is undergoing a very characteristic experience of highly intellectualized subjects who are learning to experience trance. She wants to maintain her body immobility, her catalepsy, to experience the altered sensations of trance. The catalepsy maintains a slightly dissociated condition of not knowing that is necessary for trance experience. She is now voluntarily blocking her own left-hemispheric mode of orientation to give the more curiously interesting right-hemispheric experience an opportunity to assert itself. The subject of Section IV, Dr. Q, illustrates this phenomenon of learning to experience trance in more detail.

The Spontaneous Discovery of Altered Sensations in Trance

Z: Later, after you tried to make it stay, it wouldn't stay up, but it did stay like that, [the heel of her hand resting lightly on her lap with her fingers uplifted] perfectly comfortable. Until you told me to feel perfectly comfortable, and *all of a sudden it was tired and went down.*

E: "All of a sudden it was tired ..." That is an important learning. Anything else that you can recall?

Z: Yes. The going down of my head, which I would have said was voluntary except that you said it was going more slowly than it could voluntarily. Maybe it was, and it was sort of turning itself with my breathing. I mean, I wasn't trying to say anything with it, really. I started it down voluntarily, I suppose, because you told me to. But *I don't know why it went smoothly.*

E: **It was so very unimportant for you to know *why* it went smoothly. It was very nice that you had the idea that you timed your head movement to your breathing.**

Z: And the breathing I did notice—at the beginning you said it had changed, but *I did not notice* it had. But I did notice later, when the head was going down, that *the breathing was sort of more like sleep breathing.* I mean, it was a more relaxed kind of breathing.

E: This section contains many beautiful statements from a blind person. She is trying to tell you what movements mean to her and how she senses reality.

R: You did not know that your request for comfort would have the effect of flaccid relaxation, but that was her own unique and individual response. Perhaps that is why her hand wouldn't levitate or maintain a catalepsy—she was too relaxed. But was that an important learning?

E: "All of a sudden" means that she suddenly noticed the violent contrast of sensations in her hand between a trance condition and being more awake.

R: I see, it is a ratification that a trance effect was experienced-it is a self-ratification of trance!

E: A ratification independent of my words! You don't normally associate the turning of your head with your breathing, but blind people do. You look around to see if someone else is in a room; the blind listen for breathing. When she says, "I don't know why it went smoothly," she is again verifying the trance condition. She did not understand an altered movement. She knows her movements, but here is a brand-new movement.

R: Her not understanding an altered movement, movement that is alien to her habitual pattern, is described by you as a trance condition. This supports our analysis of trance as a condition wherein the patient's habitual and familiar mental sets—the structuring function of their left-hemispheric consciousness—is minimal.

E: Her recognition that "the breathing was sort of more like sleep breathing" is another ratification of trance.

The Problem of Ratifying Trance for Modern Consciousness: Altered Experience and Time Distortion

E: That's right. And you're sure you are wide awake now?

Z: Yes.

E: No doubts!

Z: Do you? You did not know whether time was contracted or extended, but *I don't know* if it was either one, but of course I don't really know.

E: What time do you think it is right now?

Z: What time did I get here, do you know?

E: Yes.

Z: Well, I would say it's been half an hour.

E: How are you in noting the passage of time ordinarily?

Z: Sometimes very good, and sometimes I can be two hours off. I think it usually depends on whether I am doing familiar things. When I'm doing familiar things, particularly if there has been something like an interesting discussion or playing with the kids and there aren't any time units—then I can be way off.

R: In this section and the previous one you are both involved in the interpretation of experience that is so characteristic of the initial session of many highly intellectualized patients. Her left hemisphere, with its characteristic limitations, tried to point out how it was awake in its normal state at all times. You try to cast doubt on that appraisal by searching for evidence of time distortion. I believe you both may be right, each in your own way. Her left hemisphere is correct in the sense that it was present and "normal," at least occasionally, in its observer function. Her left hemisphere does not realize, however, that in suspending some of its ordinary directing and controlling functions during "trance," other modes of functioning (all the classical phenomena of hypnosis) may have become manifest in ways that its observer function could not recognize. Your task as the hypnotherapist is to somehow ratify that altered experiences have taken place without so alerting her left hemisphere that it prevents these altered experiences from happening again. You make a move to this end by attempting to ratify trance via an altered time sense in trance.

E: Yes. A blind person cannot tell time visually. They do it by the amount of movement, exertion, the amount of tiredness or the lack of it. This can also be equated with interest and pleasure. You can expand time by being bored and contract time by being interested. A blind person can never use visual cues for time experience, so it is a totally different thing. Time is measured by breathing, just as you measure a drink on a hot summer day automatically by the number of swallows. Only you don't know it.

Altered Sensations in Trance: Touch

E: Now, without changing anything, I want you to notice the difference in sensations, the sensations will be different in your hands. [Pause] Can you describe that difference?

Z: We obviously know there is a difference with the position of the hands. The left hand has a *certain odd feeling in the left finger.*

E: That's right.

Z: Sort of the kind of lack-of-sensation feeling.

E: That's right.

Z: Except *it also feels as if there is something wrapped around them.* It is hard to describe it.

difference between your left and right hand. How long has that unusual sensation been present?

Z: *I don't know. I* didn't pay attention. When one hand was supposed to be going up, it was not there. But there is no question that the hand decided to rise up, except it really couldn't make it.

E: That's a blind person's description. She first mentions a position of the hands in terms of geographical location before she can attend to feeling in the hand. A sighted person can see where his hands are. He doesn't have to locate his hands; he sees them. And that visual orientation is so rapid he doesn't know he has made it. A blind person has to locate the hands physiologically.

"A certain odd feeling in the left finger"—what is she saying there? How does a blind person feel things? I have to note the feeling in this finger. This finger, and this finger, and this finger. A sighted person doesn't pay any attention to the sensation between one finger and the next; he doesn't need to. A blind person has to. How does your hand feel if you are blind? The hand is a feeling, sensory organ receiving things. How would you feel if your hand was "wrapped" up?

R: That then is another trance effect. If it feels "as if there is something wrapped around" your hand, you are not feeling or receiving normally. So her very important organ of touch was sealed off as a result of trance.

E: Only roughly sealed off because she can feel the wrapping, but there was an altered sensation due to trance.

R: But even with a sighted person all these alterations in feeling, sensation, and perception are verifications of the trance condition for you. That is why you don't have to give challenges or other kinds of tests, because you have learned through experience that these altered sensations are all indications of trance.

Language as a Clue to the Sensory-Perceptual Differences Between the Blind and Sighted: Healing and Love

Z: The tension was there and the elbow, and the coolness was there in the Palm, and that told me that that part of the arm had gone up. But the arm wouldn't go up.

E: AH right. Now, what do you think is odd about that lifting?

Z: Nothing. I mean, apparently it didn't happen, but that's how I felt it happen.

E: Ordinarily, when you feel your arm lifting, it is lifting.

Z: Not always. I've *occasionally had to wiggle a finger to find out where my hand was for sure,* because I have played around to see if I could hypnotize myself. And if I put that hand out there and concentrate on it or something, *I cannot know for sure* whether it is or not [levitating],

E: All right, now. Let me state one problem that you are going to face. You have learned to rely on your ears to detect the direction of, let's say, a moving car, the presence of a person, the direction in which a voice comes. That geographical orientation is going to control you to a large degree if you don't know how to make spontaneous movements such as the sighted person makes. But you can make them. You just did.

Z: You mean I just nodded my head?

E: Yes.

Z: *I don't know* that you would call that *spontaneous,* actually.

E: It was not called for.

Z: No, it wasn't called for.

E: That's spontaneous. And you are extremely aware of bodily movements.

E: This is the language of a blind person. Tension in elbow and coolness in palm; no sighted person is ordinarily that sensitive to sensations. Notice that she "occasionally had to wiggle a finger to find out where my hand was for sure"! That's a clear example of movement in the blind to determine position. That's why I tell you language means a lot!

R: This whole session is an example of the different meanings words can have for different people. How sensitive and skilled the hypnotherapist must become to deal with these different meanings for people with handicaps, special talents, social and cultural differences! We all seem to have our own special language: The Tower of Babel is here and now. I'm coming to believe that the ordinary everyday conversation wherein we do not pay attention to these differences may be a comedy of errors in which we continually bounce off of each other's projections and idiosyncratic meanings. A real relationship is hard to find. When it does develop, however, we do have those special moments of communion that permit surprisingly effective responses to take place— healing as well as love.

Developing New Induction Techniques: Hypnosis Defined as a Technique of Communication Utilizing Automatic Responses

E: But that really isn't important because it is *a new kind of learning going into a trance.* And you don't have to know any of the learnings that you need. You can get knowledge without depending on a conscious understanding of what it is. * * * A child's body tells him how many swallows for a good drink before he has a chance to absorb much of that water. Do you understand? So you don't need to be any more aware of your learning than a child is of the number of swallows of water. * * *

R: It's the hyperawareness and extra training in body movements that make hand levitation a rather inappropriate technique to use with blind subjects. This throws an added light on the development of new induction techniques. Induction techniques usually center around the operator making contact with a response system within the subject that usually takes place in a more or less involuntary or spontaneous manner. The subject does not have too many associative connections between his conscious mind and the unconscious that usually controls the more or less involuntary system. Yet there are some connections that the operator can pick up and utilize much to the subject's surprise.

E: Yes, I think that's right. The blind person is oriented to movement and touch and no visual cues. The sighted person relies on visual cues and disregards movement and touch.

R: So movement and touch are more autonomous in the sighted, and the hypnotherapist can gain control over them more easily. That's why you find that hand levitation and the approaches to catalepsy are so effective in inducing trance in normally sighted individuals.

E: You search out for those things that are peculiar to the person. For example, with a stutterer who is not interested in speech therapy (he has accepted his stutter), you will have a much more difficult time using free speech to put him in a trance than if you stutter yourself.

R: If the therapist stutters, he gains better entry into the stutterer's own associative patterns.

E: That's right! Though you have to be sure you make the stutter not too apparent. You make it look as if you are not quite sure of what you are going to say or how to say it. But you are not *trying* to stutter.

R: Likewise with the obsessive-compulsive person?

E: You phrase things obsessively and compulsively, and that will facilitate induction. In other words, you adopt the individual style and culture that you recognize in the patient. For a farmer you throw in a few country words; for a lawyer a few legal terms. But never obtrusively.

R: You adapt yourself to the patient's mental milieu.

E: *Hypnosis is a technique of communication whereby you make available the vast store of learnings that have been acquired, the usefulness of which lies primarily in the way of automatic responses*. In hypnosis we make a direct call on these learnings that have been dropped into the area of automatically available learnings.

R: *Therefore you could develop any number of new techniques of hypnotic induction by learning how to recognize and utilize in a subject past learnings that now function in an automatic or semiautonomous manner*.

Structured Hypnotic Amnesia via Questions

E: Now what time do you think it is?

R: Did you slip in this question about time here to distract her from the subject at hand? She seems to be in a bit of a restless mood, so you make an important statement and then actually distract her before she can dispute it. In this way your statement remains within her—without her conscious biases having an opportunity to debate and possibly negate it.

E: Yes. That's the way you change a subject quickly: Ask a question. There is something else involved here. You ask a question, and then before an answer can be given, you say a lot of meaningful things, and then you go back to the original question. You've thereby drawn a blanket over the meaningful material; you've put a parenthesis around it. This is a very important principle of producing hypnotic amnesia in order to prevent the patient's consciousness from negating meaningful suggestions.

R: Since it is so carefully structured by the therapist, we call this a *structured amnesia,* in contrast to the spontaneous or suggested types of hypnotic amnesia that are usually discussed in the literature.

E: When I ask her what time it is the second time in this section, she has to go back to the original asking of that question several sections back. (See section entitled "The Problem of Ratifying Trance for Modern Consciousness: Altered Experiences and Time Distortion.") So everything that occurs between the two identical questions is as if covered by a blanket.

Dynamics of Questions and Answers: Confusion Facilitating Creative Flux

E: Now, your chin didn't touch your dress, did it?

Z: No. I was curious, I *didn't even know* if it could!

R: You didn't let her answer your question from the last section. Why?

E: You're keeping them off balance by asking and not answering questions. You are keeping them reaching out hopefully.

R: You are keeping their conscious biases off balance, and you keep an expectant and receptive attitude so you can deposit important suggestions they will then seize upon.

E: Yes, they will retain them better.

R: You don't give people a chance to experience closure by answering their questions.

E: That's right! Because once a question is answered, that closes and disposes of it.

R: No more learning can take place. You keep all questions open and keep learning at a high pitch. This is an aspect of your use of confusion: to keep a patient's learned limitations in flux so there is a greater possibility of the unconscious intruding with a new and more creative response (Rossi, 1972a, 1973b).

Ratifying Trance via Amnesias

Z: Then I wanted to ask you, *which chin?*

E: I mentioned amnesia there to Dr. Rossi.

Z: Yes, you mentioned conscious amnesia, and I presume that you meant I would not remember, but *I don't know* for sure if that is what you meant.

R: Again you don't answer her about "which chin?"

E: She is self-conscious there. She doesn't know really what she looks like, what her weight is, she doesn't really know. She is telling you in that question, "I don't know what my chin looks like. I have heard of double chins, triple chins. But I don't know." It is an unconscious question, a betrayal of a lack of physical knowledge of herself.

Then I go back to the subject of amnesia. All along I want her to develop as many amnesias as possible.

R: Why?

E: Because the more of my communications that are in her unconscious, the better she will be as a hypnotic subject.

R: The more amnesia you are able to obtain, the better the subject. So amnesia is not only a criterion of trance, but it facilitates future trance work. Because it is a function of autonomous or involuntary behavior?

E: Yes, and it is being elicited by you and named by you, and it is becoming a part of their personal experience. A patient no longer has any doubts about the trance.

The "I Don't Know" Set Facilitating Amnesia: Voice Locus to the Conscious and Unconscious: Indirect Trance Induction

E: Now you had lost your body sensation, and you vacillated from right to left in the downward movement of your chin.

Z: Did I? This *I did not know.*

E: And you shifted your way of breathing—sometimes more on the right side, and then more on the left. So I knew that you did not know your exact physical orientation. Right now, move your chin down and touch your dress.

R: Since the termination of trance she has been saying "I don't know" more and more. I wonder if you were aware of having this effect on her. [The "I-don't-knows" are placed in italics for the convenience of the reader.]

E: Yes, you get them to say "I don't know" by telling them they don't know and asking questions they cannot answer. They get a set for "I don't know."

R: Why is that of value?

E: We develop an "I don't know" set to facilitate hypnotic amnesia. It is a request for the subject *not* to know, but she does not consciously hear the request as such. It is not desirable to say, "You will forget that." They would come back with, "Why should I forget it?" But you can say, "You may not remember it, you may not know it." That gives permission, but it is not a command—nor is it a demand. It is a mere observation, but the focus words are spoken.

R: You can facilitate trance as well as amnesia by breaking up the knowing and orienting aspects of consciousness.

E: Yes, I seem to bifurcate the individual into the conscious and unconscious. When I say something, I may say it to the conscious or I may say it to the unconscious. I change the locus of my voice; I tilt my head to one side to speak to the conscious and another side to speak to the unconscious.

R: When the subject is in trance?

E: When inducing trance as well as while the subject is in trance.

R: You use a different head location in speaking to the conscious and unconscious, and people gradually become conditioned to that.

E: Yes, without knowing it—because it is so subtle they don't notice it. At most it might be taken to be a mannerism of the therapist. A subject could watch you hypnotize someone else and just think you've got a certain mannerism of turning your head from side to side. This observing subject then does not know why he is suddenly becoming sleepy, but he begins to sense hypnotic effects. It is the things I said to the other person's unconscious that makes the observing subject sleepy, because it gets right to his unconscious, too. You see, communication is not just words, it isn't just ideas. It is vocal stimulation, auditory stimulation, and it is apparently leading somewhere (e.g., dangling phrases, repetition, and then a complete sentence), causing the patient to reach out.

R: Those dangling phrases, for example, would lodge in the patient's unconscious, would they not?

E: Yes, because *there is no meaning that can be given to them by the conscious mind to close the door, to close the chapter on them.* You can use shaggy dog stories; they are a marvelous technique. The person does know that you will come to an end of that damn story.

R: He wants that damn ending!

E: Yes, he wants it! Even if the ending is in him going to sleep. There is a desperate desire for an end, a closure. And maybe the closure is "Close your eyes." I have used shaggy dog stories as a trance-induction technique.

Trance Ratification on an Unconscious Level: Distractions and Amnesia

Z: Now you want me to move it down normally. [She does so.]

R: She shows here that she is sensitive to the difference between her trance and normal head movements.

E: Only she doesn't know she told you that. She shows by the difference in behavior that there *is* another category; there is a horse of a different color, which is trance.

R: You do this very indirectly without getting her conscious mind to openly acknowledge that this proves she was in trance. Why? Why not take the advantage—tell her this is a proof of trance?

E: I'm getting away from her conscious acknowledgment. *I'm not going to let her conscious mind grab onto anything that she can dispute!* You move away from dispute.

R: I'd have felt frustrated at the end of this session because she did not feel she was really in trance. But you do not feel frustrated when a patient betrays evidence of trance and yet does not acknowledge it.

E: If there is evidence of trance, their unconscious knows it. I don't have to prove it! Too many operators try to save face. I take one look at you, and I know you are a man. Do I have to prove to you that you are a man? That is a sheer waste of time, and it arouses a patient's hostility.

R: By trying to give consciousness proofs of trance you only give it more ammunition to later fight against the idea of trance.

E: That's right.

R: How deep was this trance, by the way?

E: Light to medium. The fact that she made no response to the barking dog—you did and I did, but she did not.

R: You are not bothered by distracting stimuli? E: No. The important thing is the trance. If the patients want to listen to traffic on the highway, fine. They are still within hearing distance of me. So I don't have to compete with my voice against those barking dogs, the sound of the traffic, the sirens that go by—they do not elicit a change in my voice level. You remember a siren better when the professor had to raise his voice than when he did not. There may be a commotion out in the hall, but you do not raise your voice or give any evidence of noticing the commotion. At the end of the lecture hour you ask the students individually, "Do you know what that commotion was outside the lecture room?" They respond, "What commotion?"

R: They have an amnesia for it because they had to attend all the more closely to you.

E: That's right. You did not give them a chance to see or respond or think about it, since they had to attend to you. The commotion only made it more imperative that they pay attention to you. That means they have to go through a process of shutting out that commotion. So you have produced an amnesia without ever having verbally suggesting it in any way. Your behavior to the commotion is a negative behavior.

R: It is an absence of behavior that leaves an amnesia. You did not let the outside commotion have any energy of attention, so it could not be impressed upon memory.

E: Yes, you have many opportunities to test that out when you are aware of it.

Depotentiating Conscious Sets with the Thumb-Dominance Question: Difficulties in Learning the Indirect Approach

E: Are you right-thumbed or left-thumbed?

Z: I'm right-handed somewhat, but *I don't know* about thumbs.

E: Put your hands above your head, and put them palm to palm, and then interlace your fingers. Bring your hands down. Now, you notice that your left thumb is on top. You are left-thumbed.

Z: Okay?

E: But I knew that because you were sitting in that position with your thumbs that way.

Z: It is the normal way I do it, but *I did not know* what defined right- and left-thumbed.

E: That's right. I know Dr. Rossi looked for it.

R: Yes, I did.

E: I'm training him in observation.

R: Yes, Dr. Erickson is carefully training me to watch. [Some friendly conversation takes place between Dr. Z and Dr. R as they become acquainted with one another, and so the session ends. During the closing remarks Erickson manages to mention casually that Dr. Z was about a half-hour off in her time estimations.]

E: I've shifted her here to an entirely different frame of reference far removed from trance, from amnesia, and it is interesting, too. She accepted orders previously, and now she is still in high gear for accepting orders. She is still receiving orders, and she is interested!

R: This question about whether one is right- or left-thumbed is the closest you get to a standard operating procedure. The patients' conscious minds usually do not know the

answer, but their unconscious minds know—as evidenced by the interlocking of their hands and fingers without looking. Your silent implication is that their unconscious does know more than their consciousness, and their own behavior proves it. You don't bother to belabor this implication by a discussion of it. The unconscious implication is more effective as a means of dethroning the hubris of consciousness.

E: Yes. I hope you are starting to get an idea of what hypnotic communication is.

R: Well, if I'm not getting it, it is because of my own limitations, and not due to any lack of effort on your part. It is a strain for me to shift gears from my psychoanalytic training, where I only learned to receive messages, to your approach of actively communicating with others on an indirect level. It is hard work learning to facilitate changes in patients' frames of reference, rather than simply dealing with the contents of their consciousness. You are constantly operating on an indirect level, where you help patients reframe the contents of their consciousness. Conventional therapists usually only deal with the contents of consciousness rather than the procedures for reframing those contents. They ask and answer questions in a perfectly straightforward manner on the object level, rather than engaging the patients on a metalevel in order to make more of their potentials available to them. The effectiveness of this approach is very much dependent on your subtlety. It would not work if the patient knew what you were doing.

In my initial efforts to use this approach I've come off rather badly because I was not natural with it. Patients immediately sensed that I was not answering their questions. I was, for some reason or other, proposing riddles, talking in metaphors, etc. Rather than reframing the contents of their consciousness, I only accomplished the reverse: They became alerted (and some alarmed), wondering what was up.

Postscript: Indirect Trance Learning to Rely on Unconscious Mechanisms

E: Dr. Z really did learn a sizable amount in this first session, even though it was not apparent to her at the time. A week or so later she casually remarked to Mrs. Erickson that for some unknown reason she was able to walk on the street more easily—walking down the street was different in some way. It was easier!

R: She had learned to rely on unconscious mechanisms more. She learned to let go of conscious controlling. So you got through to her in this session after all!

E: I got through! She was so pleased to have a totally new experience of walking on the street.

R: She really learned to let go. Now, you did not know in what way she was going to experience her new hypnotic learning, but you knew *something* would happen.

E: I wanted her to learn to use her unconscious. I did not know where or how, and I did not try to tell her where or how.

R: You let her unconscious figure out its own way.

E: And she was so surprised that she wanted to share it with us. She also remarked that that chair in which she sat was somehow different.

R: Actually, her body was responding differently to it, with more spontaneity. As I recall, she did have a fairly rigid way of holding herself, but that is all beginning to soften now.

E: That's right, she was experiencing sitting and walking more in the sighted way.

R: She now has more of a casual spontaneity, relying more upon unconscious mechanisms rather than consciously directing every movement. She did not know that is what she was coming for, but that is what she was getting. This is an excellent example of *indirect trance learning:* The occurrence of

optimal learning in trance, whereby the hypnotherapist loosens the inhibiting influence of the patient's overly rigid conscious sets, which then leaves the creative unconscious free to change behavior in its own way and in areas that are most appropriate for the patient at that time.

SECTION III

Ideomotor Signaling in Hypnotic Induction and Therapy

A. IDEOMOTOR MOVEMENTS AND SIGNALING IN HISTORICAL PERSPECTIVE

The mystery of ideomotor movements and signaling has been discovered, forgotten, and rediscovered in many forms throughout human history. That the mind could signal answers or responses that were apparently outside the control of consciousness has always been a mystery. Being a mystery, it has usually been associated with the occult, magic, or those with "special powers" in relation to the gods. We cannot write a complete history of ideomotor movements and signaling because the necessary scholarship has not yet been done in this field. However, we can outline three salient periods of this history.

PHASE ONE: The Ancient and Medieval Period of Prophecy Divination and, magic

PHASE TWO: Chevreul and the Ideomotor Movement: Theories of Hypnosis in the 1800s

PHASE THREE: Clinical Investigations of Ideomotor Signaling in the 1900s

PHASE ONE:
The Ancient and Medieval Period of Prophecy, Divination, and Magic

If we consider all the historical forms in which apparently purposeful movement and behavior were carried out without normal awareness, we would find ourselves with an inventory of most of the classical forms of hypnotic behavior. These are the so-called automatisms—apparently purposeful behavior that is carried out without normal awareness. Since ancient times phenomena such as somnambulism (sleepwalking), visions (visual and auditory hallucinations), prophecy and "speaking in tongues" (automatic speech), spirit writing (automatic writing), possession (multiple personality), mystical rituals, and dance (automatic body movements) have been regarded with fascination. Frequently they have been associated with healing on the physical as well as the spiritual plane. Some force, agency, or knowledge outside of man's usual range of awareness was found to have therapeutic value when all the regular channels of conscious behavior were found wanting.

These approaches to healing were well developed in ancient times before the birth of Christ. The Papyrus Ebers, written 1500 B.C., describe magical incantations and rituals that placed patients in altered states for healing. The Egyptian sleep temples of Isis and Serapis as well as the sleep temples dedicated to Asclepius and Apollo in Greece about 400 B.C. utilized somnambulistic states to realize healing.

In the Middle Ages the "healing touch" was used as a method of faith healing when the physical medicine could offer no help. Albertus Magnus (12067-1280), Paracelsus (14937-1541), and Robert Fludd (1574-1637) utilized incantations, faith, and magnetism to effect cures. The common denominator of all these approaches, however, was recognized by numerous authors throughout the Middle Ages to be the *imagination* (Ludwig, 1964). Today we can recognize *ideomotor and ideosensory responses* as being the basis of these effects of imagination: An idea can give rise to motor (behavioral) and sensory responses to which it is associated. The idea of moving a part of the body actually gives rise to unrecognized but measurable motor responses in that part of the body; the idea of falling can activate anxiety

responses of the autonomic nervous system; the word *lemon* easily conjures up an image and sensory responses in most people.

Physicians, priests, and prophets who possessed the necessary self-conviction regarding their ability to act as channels for divine or metaphysical forces were able to activate this conviction within their patients. In turn, the patients' unconscious processes were frequently able to find and facilitate the necessary internal symbolic and ideodynamic processes to effect a cure. The rational left-hemispheric mind did not understand how such cures came about. We would say today that the cures were mediated by unconscious processes of the right hemisphere that have a close relation to bodily and psychosomatic processes. The imagistic, mythopoetical, symbolic, astrological, nonrational, and seemingly fantastical belief systems that become associated with these unconscious cures appear totally erroneous to our modern scientific mentality. It is just possible, however, that these early symbolic systems are reflections or projections of nonrational forms of right-hemispheric mentation that effect psychodynamic transformations that can result in genuine cures. Jung's studies of alchemy and the early gnostic and mystical systems seem to be the only modern, systematic investigations that take this possibility seriously (see Jung, *Collected Works,* Vols. 8, 9, 12, 13, 14, 18).

PHASE TWO:
Chevreul and the Ideomotor Movement Theories of Hypnosis in the 1800s

The first phase, wherein ideomotor and ideosensory responses were taken as a manifestation of "special powers," began in ancient times and ended only tentatively in 1854, when Chevreul published his experimental critique of the exploratory pendulum and divination devices. In this critique he provided a correct interpretation of ideomotor movements as minute muscle responses set in motion by the unrecognized thoughts of the subject. We say that this first phase "ended only tentatively" because even today, of course, many people still hold an essentially magical view of these movements whether their source be from a special spiritual inspiration or an all-knowing and infallible "unconscious." From the time of Chevreul on, however, educated workers have understood that the mechanisms of ideomotor and ideosensory responses reside within the subject, though unrecognized because the responses are autonomous in their functioning.

This second period of our history of ideomotor movements is the classical period of mesmerism and early hypnosis in the 1800s. The work of Chevreul prepared the Zeitgeist for clinical investigators like Braid and Bernheim, who recognized that the essential nature of trance and suggestion could be explained as ideomotor and ideosensory action. Bernheim's formulation (1886/1957) is as follows (italics are ours).

> The one thing certain is, that a peculiar *aptitude for transforming the idea received into an act* exists in hypnotized subjects who are susceptible to suggestion. In the normal condition, every formulated idea is questioned by the mind. After being perceived by the cortical centres, the impression extends to the cells of the adjacent convolutions; their peculiar activity is excited; the diverse faculties generated by the gray substance of the brain come into play; the impression is elaborated, registered, and analyzed, by means of a complex mental process, which ends in its acceptation or neutralization; if there is cause, the mind vetoes it. In the hypnotized subject, on the contrary, the transformation of thought into action, sensation, movement, or vision is so quickly and so actively accomplished, that the intellectual inhibition has not time to act. When the mind interposes, it is already an accomplished fact, which is often *registered with surprise,* and which is confirmed by the fact that it proves to be real, and no intervention can hamper it further. If I say to the hypnotized subject, "Your hand remains closed," the brain carries out the idea as soon as it is formulated. A reflex is immediately transmitted from the cortical centre, where this idea induced by the auditory nerve is perceived, to the motor centre, corresponding to the central origin of the flexion. There is, then, *exaltation of the ideomotor reflex excitability, which effects the unconscious transformation of the thought into movement, unknown to the will.*

The same thing occurs when I say to the hypnotized subject, "You have a tickling sensation in your nose." The thought induced through hearing is reflected upon the centre of olfactory sensibility, *where it awakens the sensitive memory-image of the nasal itching, as former impressions have created it and left it imprinted and latent. This memory sensation thus resuscitated, may be intense enough to cause the reflex act of sneezing.(*This passage contains the essence of the senior author's utilization theory of hypnotic suggestion*)* There is also, then, *exaltation of the ideo-sensorial reflex excitability, which effects the unconscious transformation of the thought into sensation, or into a sensory image.*

In the same way the visual, acoustic, and gustatory images succeed the suggested idea. . . .

The mechanism of suggestion in general, may then be summed up in the following formula: *increase of the reflex ideo-motor, ideo-sensitive, and ideo-sensorial excitability. . . .* The ideo-reflex excitability is increased in the brain, so that any idea received is immediately transformed into an act, without the controlling portion of the brain, the higher centres, being able to prevent the transformation (1957, pp. 137-139).

In his *De la Baquette Divinatorie* (1854) Chevreul documented many forms of ideomotor phenomena, but it is difficult to say where they all originated. It is said, for instance, that in the Black Forest of Germany, during the Middle Ages, it was traditional to detect the sex of a child in utero by having the expectant mother hold her wedding ring suspended on a string over her abdomen. An apparently spontaneous movement in one direction indicated one sex, while a movement in another direction indicated the opposite sex. This, of course, was a precursor of what we today know as the Chevreul pendulum.

Alexander Dowie was an itinerant preacher in the colonial days of America who would enter the major saloon of a town and offer to detect thieves and murders. He would have all present place their hands palm down on the bar. He would mention a recent local crime and then exhort them to the effect that the guilty one would not be able to keep his index finger flat on the bar. Or perhaps it would be the thumb or the little finger that would give away the guilty person. This procedure easily qualifies as the neatest early low-cost lie-detection device on record and, of course, is a precursor of the finger-signaling approaches we use today.

The "thought-reading" games of Victorian England, which are even today a part of the stock and trade of magicians and "psychics," also fit our category of ideomotor signaling. The "psychics" claim that they can read minds. One might ask all those present in a room to decide on an object to be concentrated upon. He then enters the room and selects one of those present to act as his guide. The "psychic" gently grasps the guide's wrist and lets himself be led about the room. By being sensitive to the involuntary ideomotor movement of the guide's wrist, hand, and arm, the "psychic" soon is able to establish the area of the object of his search. By weaving back and forth with the guide's involuntary micromovements (unrecognizable to the guide or any others present) as his detector, the "psychic" is soon able to make an accurate guess about the object. He claims to have read the thoughts of the group; actually, he read the ideomotor movements of his guide.

Ideomotor movements, of course, are responsible for such phenomena as the Ouija board. The operator's unconscious or partially conscious wishes are transmitted by unrecognizable ideomotor movements from the fingertips that are gently placed on the board's surface to the movable pointer that spells out a message by pointing to different letters or words written on the board. In a more arcane way the fall of yarrow sticks or the flip of coins are also ideomotor components; together with the process of psychological projection, they facilitate the use of ancient oracles such as the I Ching.

Such procedures have survived for hundreds and even thousands of years precisely because they can, under proper circumstances, facilitate the evocation of interesting and valuable ideas—Ideas that are unconscious or only partially understood, but which can be projected by such procedures into full conscious understanding. The problem with such procedures is that the responses obtained are sometimes accepted uncritically as some sort of ultimate "truth"—whether from God, the occult powers, or the modern notion of the creative unconscious. Ideomotor responses are in fact simply another response system of the individual. There is no a priori reason for regarding ideomotor responses as more valid than any other response system (such as logical thinking, intuition, feelings, dreaming, etc.).

In many individuals, however, ideomotor responses can provide information that is "surprising" to that individual's consciousness. This simply means that the "surprising information" was within the individual's system but not fully recognized or considered by consciousness. The surprising ideomotor responses, therefore, provide individuals with access to sources of information within themselves that they were unaware of or blocking out for one reason or another. The ideomotor responses are not necessarily more valid than other response systems, but they represent another source of information that can lead some individuals to make a more educated choice on some important matter because they now have a more complete inventory of information from their systems.

Ideomotor signaling, then, cannot be used as the only source of information for important decisions. It is simply one of many sources of information that can contribute to a decision. When the individual *does not know,* however, or when the individual's *consciousness is confused,* ideomotor responses can make a more important contribution. When rational thinking, intuition, feelings, etc. all fail an individual, then ideomotor signaling may be the only clear and incisive source of information for decision-making. But even under these circumstances information from ideomotor responses should be checked and balanced by the common sense and overall understanding that a therapist has of the individual being questioned.

Just as rational thinking, intuition, feeling, dreaming, etc., may each have unique sources of information for response, so ideomotor signaling may come from sources within the individual that are not tapped by any other response system. We do not at present know exactly what these sources are, just as we obviously do not know all the sources contributing to other response systems (rational thinking, etc.). Because of the high probability that ideomotor responses have unique sources of information within the individual, however, it is important that we continue to explore them and develop new procedures for receiving them more sensitively and accurately and with adequate means of validating them.

PHASE THREE:
Experimental and Clinical Investigations of Ideomotor Movements and Signaling in the 1900s

The ideomotor and ideosensory formulations of trance and suggestion of the 1800s carried over into the 1900s and provided the basis for much modern experimental work. The senior author began his studies of hypnotic phenomena as an undergraduate in 1923, working in Hull's laboratory at the University of Wisconsin (Erickson, (1964b). These studies helped initiate a program of research that eventuated in the publication of Hull's important book, *Hypnosis and Suggestibility—An Experimental Approach* (1933). That effort was to investigate hypnotic phenomena experimentally with the developing methods of experimental psychology and to integrate the concepts of hypnosis with those of basic learning theory and behaviorism. For example, ideomotor movements actually provided much of the foundation of behaviorism when it was postulated that subvocal or "implicate speech" was actually the motor basis of thought (Watson, 1919). Weitzenhoffer (1953) has reviewed the experimental work on ideomotor movements and hypnosis of this period. A portion of his summary is as follows:

> The psychophysiological basis of suggestibility is *ideomotor action,* itself a form of conditioning.
>
> The physiological bases of hypersuggestibility are *(a) neuromotor enhancement* (homoaction), and *(b) abstract conditioning* (generalization or heteroaction).
>
> The psychophysiological basis of the hypnotic alteration of awareness is a combined selective inhibition and excitation of various cerebral regions leading to a dissociation of awareness *from* all stimuli except the voice of the hypnotist, unless otherwise specified by suggestions.
>
> Through hypersuggestibility and dissociation of awareness, the words of the hypnotist acquire the value of actual stimulus objects. His voice becomes an extension, so to speak, of the subject's psychic processes. This opens the way to a large variety of perceptual alterations (p. 259).

It will be recognized that these views are remarkably similar to those expressed by Bernheim almost 100 years ago. The terminology has changed slightly, but the essential understanding of ideomotor movements as the basis of hypnotic phenomena is the same.

Ideomotor *movements* were intensively investigated because of their importance to the basic theories of behavior and hypnosis. But ideomotor *signaling,* which is of such great significance for modern clinical work, was not investigated by, or apparently even known to, the academic and laboratory workers of the early 1900s.

The senior author reports that his earliest awareness of ideomotor signaling developed when he was a boy on the farm. A cat's tail would swish back and forth slowly and broadly when the cat was playing but would then make a series of quick, short jerks when the animal became serious. A moment before the cat pounced on an unfortunate mouse, it would stop movement altogether, cataleptically poised in totally fixed concentration. Erickson also noticed that the same sort of thing happened with fish such as pike: the normal, rhythmical beat of their gill fins would suddenly cease a moment before plucking a morsel. The ideomotor signals of the animal world seem almost too common and numerous to mention—the point of a good hunting dog, the gesture of a primate, etc.

These ideomotor signals range from the purely reflexive and unconscious—as is undoubtedly the case with those of fish and cats mentioned— to those with "conscious intent," such as the gestures of primates, who can even learn the value of tokens, gesture-speech, and perhaps more when trained in the laboratory.

The evolution of the senior author's development of ideomotor signaling from automatic writing to hand levitation and then ideomotor signaling proper can be traced in his paper, "Historical Note on the Hand Levitation and Other Ideomotor Techniques" (Erickson, 1961). Relevant portions of this paper will be quoted in our later section on facilitating ideomotor signaling, which can serve as an introduction to current work. This paper indicates that by 1938 the senior author had a firm grasp of the dynamics of *head* and *hand* signaling and used them both experimentally and clinically. The earliest written record of such ideomotor signaling in our possession consists of transcripts made in 1945 of Erickson's "Informal Meetings with Medical Students," which took place at the Wayne County Hospital in Eloise, Michigan. Portions of these transcripts will be presented in our later section on the utilization of ideomotor signaling.

The earliest written record of the use of ideomotor *finger* signaling in our possession is the transcripts of the 1952 and 1953 seminars in hypnosis held in Los Angeles, where Erickson, LeCron, and Bordeaux, among others, were instructors. On these occasions LeCron introduced his use of finger signaling to determine when anesthesia had taken effect (1952 seminar) and to detect psychological traumas (1953 seminar). He then published his views as "A Hypnotic Technique for Uncovering Unconscious Material" (LeCron, 1954).

B. RECOGNIZING SPONTANEOUS IDEOMOTOR SIGNALING

We have reviewed how the senior author's early observations of naturalistic ideomotor signaling provided a foundation for his later development of head and hand signaling in hypnotic work. His observations of animals as a boy on the farm led to the formation of a mental set for detecting nonverbal forms of signaling behavior in his early experimental subjects in Hull's laboratory, in his students sitting in a classroom, and finally in his patients in therapy. If we now outline the general literature on nonverbal forms of communication, it is only for the purpose of facilitating readers' study of these phenomena as a way of training their perception of the natural and spontaneous forms of ideomotor movements and signaling that are taking place in all human interactions. As readers train themselves to look for these nonverbal signals in daily living, they will develop the appropriate mental set for understanding them in experimental clinical situations.

In everyday life we can observe a rich panorama of nonverbal signs that accompany any conversation or transaction. Many of these signs have been studied in the form of the new science of "kinesis" by Birdwhistell (1952, 1971). These range from apparently reflexive movements to meta-acts whereby one uses gestures and body behavior to qualify, comment on, or change one's verbal meanings (Bateson, 1972, 1979). The vast literature that has developed around the concept of "body language" (Fast, 1970; Goffman, 1971) in recent years actually has its roots in Darwin's early study, *The Expression of Emotions in Man and Animals* (1872/1955). The hypnotherapist can study this literature to learn more about the different response systems that signal important forms of communication from patients. From this perspective it will be seen that the traditional form of verbal communication that has played such a major role in psychotherapy is actually only the tip of the iceberg. All the forms of body language can be understood as systems of ideomotor signaling. These signaling systems come from sources other than those involved in traditional verbal communication and thus provide new sources of information about the total system of the patient.

In everyday life behavior is rich in many forms of ideomotor signaling. Some of the more obvious forms of ideomotor signaling that can be recognized and utilized in the clinical situation are as follows.

A. In everyday life head-nodding and -shaking frequently proceeds in an automatic and entirely unconscious manner. A newlywed is surprised to discover that her husband, still only half awake, is agreeably nodding and shaking his head in an imaginary conversation as he shaves in the morning. A salesman watches his customer carefully: when the customer unconsciously nods his head Yes, however slight it may be, the salesman continues with his line; when the customer shakes his head No, the salesman quickly changes his spiel. Every speaker looks to those in his audience who nod in agreement. The wise politician accepts questions only from those seen nodding in agreement.

B. From the early days of grammar school onward, the lifting of a hand and its associated movements of the face and body have been ingrained as a signal of Yes or of wanting to respond or ask a question. As we get older, these movements become more abbreviated and automatic in their functioning. When getting ready to speak, people lift their heads, wet their lips, incline the body forward, focus their gaze, etc. The parent, teacher, or leader of panel discussions readily recognizes these signals and acknowledges the would-be speaker. Most lovers can recognize at a glance whether the object of their desire is about to say Yes, No, or Maybe.

C. Ideomotor signaling plays an important role in sports. It is to great advantage if a batter can spot ahead of time some ideomotor signal from the pitcher indicating what kind of a pitch he will make. Much advantage in any competitive sport can be gained by learning to "read" the body movements of the opposing team as a signal of their future play.

D. In everyday life we automatically move our bodies the way we want things to go, even if there is no hope that our movements can actually help. Thus a passenger in a car will put his foot on an imaginary brake, bowlers will tilt their body the way the ball should go, and spectators at a boxing event will make incipient punches with their own clenched hands.

E. The senior author believes that, on a number of occasions when watching the preliminaries of sporting events, he was able to predict who would win and lose by observing the unconscious ideomotor signaling behavior of the athletes as they entered the field and prepared for the contest. The potential winners were those who appeared to have their own inner focus and sense of self-direction; the potential losers were those who appeared to fall in step behind the winner(s) or in some way to follow the lead of others during the preliminary warm-up exercises.

C. FACILITATING IDEOMOTOR SIGNALING

The senior author's review of his gradual discovery of ideomotor signaling provides a fine introduction for learning how to facilitate it in the clinical situation (Erickson, 1961):

"During that summer of 1923, among other things, the writer became interested in automatic writing, first secured from subjects in a trance state and subsequently by posthypnotic suggestion. This gave rise to the possibility of using suggestions conducive to automatic writing as an indirect technique of trance induction for naive subjects. Although successful, it proved to be too slow and laborious an induction technique in most instances. It was modified by suggesting to the subject that, instead of writing, the pencil point would merely move up and down on the paper, or from side to side. The vertical or horizontal lines thus secured were later found to be an excellent approach to the teaching of automatic writing to difficult subjects.

"Almost from the first trial it was recognized that the pencil and paper were superfluous and that the ideomotor activity was the primary consideration. Accordingly, the writer, using his younger sister Bertha as a subject for the first time, induced a somnambulistic trance by a simple hand-levitation technique. Thereafter many variations of this original technique were devised until it became apparent that the effectiveness of many supposedly different techniques of trance induction derived only from a basic use of ideomotor activity, rather than from variations of procedure, as is sometimes naively believed and reported. Perhaps of all the many variations of ideomotor techniques of induction that may be devised, the more generally useful are (1) simple, direct hand-levitation, because of the possibility of visual participation, and (2) the slightly more complex rhythmical hand levitation, in which visual and memory participation frequently lead to the ideosensory response of auditory hallucinations of music and the development of a somnambulistic trance. . . .

"At the time of this work, there was no recognition by the writer of kinesthetic memories and images as a trance-induction technique, but it led to a systematic and profitable investigation of the possibility of using any sensory modality as a basic process in inducing hypnotic trances. . . .

"Approximately 15 years after these earlier studies on ideomotor techniques had been reported to the seminar group at the University of Wisconsin, another study was begun. This was initiated by the observation that, especially at lectures on controversial topics, there are those in the audience who will unconsciously slowly nod or shake their heads in agreement or disagreement with the lecturer. This observation was further enhanced by noting that certain patients, while explaining their problems, will unwittingly nod or shake their heads contradictorily to their actual verbalizations. These informative manifestations suggested the possibility of utilizing this type of ideomotor activity as an hypnotic technique, particularly for resistant or difficult subjects, although it can also be used readily on naive subjects.

"The actual technique is relatively simple. The explanation is offered to the subject that an affirmative or a negative answer can be given by a simple nod or shake of the head. Also, it is explained that thinking can be done separately and independently by both the conscious and unconscious mind, but that such thinking need not necessarily be in agreement. This is followed by asking some question phrased to require an answer independent of what the subject may be thinking consciously. Such a question is, 'Does your unconscious mind think you will learn to go into a trance?' After being asked this type of question, the subject is told to await patiently and passively the answering head movement which will constitute the answer of the 'unconscious mind.' A rapid or forceful response signifies a 'conscious mind' reply. A slow, gentle head movement, sometimes not perceived by the subject, constitutes a direct communication from the 'unconscious mind.' With the response catalepsy develops and a trance state ensues rapidly.

"Or, as a simple variation, one can suggest that the levitation of one hand signifies the answer 'yes,' the levitation of the other, 'no,' the levitation of both, 'I don't know' and then ask the above or a comparable question. The development of a trance state is concurrent with the development of levitation, regardless of the significance of the reply.

"These techniques are of particular value with patients who want hypnosis, who could benefit from it, but who resist any formal or overt effort at trance induction and who need to have their obstructive resistances bypassed. The essential consideration in the use of ideomotor techniques lies not in their elaborateness or novelty but simply in the initiation of

motor activity, either real or hallucinated, as a means of fixating and focusing the subject's attention upon inner experiential learnings and capabilities." (pp. 196-199)

The senior author believes that for such ideomotor signaling to be truly autonomous and unconscious, patients should be in trance or distracted in one way or another so they will not have an opportunity to observe their own movements. Because of this he frequently prefers to look for automatic head-nodding or -shaking where patients are least likely to observe themselves. It is surprising how often patients will nod or shake their heads to contradict their own verbal statements even without any formal instruction about ideomotor signaling. Frequently it is a *very slow and slight but persistent head-nodding or -shaking* that distinguishes the movements as coming from an unconscious level. These slow, abbreviated movements are to be distinguished from *larger and more rapid* head movements, which are more consciously used as a way of emphasizing what is being said verbally.

The senior author prefers to utilize a patient's own natural means of ideomotor signaling whenever possible. Whatever natural and automatic movements a patient makes in ordinary conversation can be studied for their metacommunicative value. Besides the more obvious head and hand movements, eye-blinking (slow or rapid), body-shifting, leg movements, arm position (e.g., crossed over one another as a "defense"), lip-wetting, swallowing, and facial cues, such as frowning and tensions around the mouth and jaw, can be studied for their commentary on what is being said verbally.

LeCron's corresponding use of finger signaling and the Chevreul pendulum is described by him as follows (LeCron, 1954):

> The hypnotized patient can be told that questions are to be asked and that the unconscious can reply to them by lifting or wiggling the right forefinger to indicate a "yes" answer, the left forefinger for a "no" answer. (If the patient is left-handed, this should preferably be reversed.) If a question is asked to which the answer is not known by the unconscious mind, the right thumb is to be lifted. If the question is one which the unconscious does not wish to answer, the left thumb is to be moved. This last is very important as it will usually eliminate resistances which might prevent any response otherwise. . . .
>
> In addition to the suggested finger responses, conscious finger movements made to falsify and conceal can be made known to the therapist by means of some unconscious movement. This can be accomplished by suggesting that one hand, perhaps the right, will lift if at any time a false answer is given by the fingers (or verbally). It should be stated that such a hand movement will occur without the patient being aware of its being made.
>
> An interesting variation of this questioning technique is the use of Chevreul's pendulum, using a light ring or other object tied to an eight- to ten-inch thread. The thread is to be held between the thumb and forefinger with the pendulum dangling, the arm either fully extended or with the elbow resting on the knee or arm of the chair. Replies by movements of the pendulum can even be obtained in the waking state, though it is better if a trance is employed. Two out of three people, or even more, will respond in the waking state. The variation is advantageous because hypnosis is unnecessary. Therapists not familiar with hypnosis will find they can employ it very successfully.
>
> There are four possible movements of the pendulum. These are a circle clockwise or counterclockwise, a swing back and forth across the body, and a swing at right angles away from the body. It is best to permit the unconscious mind of the patient to select the movements it will use in answering according to its own choice. This is done merely by asking the unconscious to choose one of the four movements for "yes," then another for "no," a third for "I don't know," and the remaining one can then signify "I don't want to answer." (pp. 76-79)

Other details of the use of the Chevreul pendulum can be found in Weitzenhoffer (1957). It is rare to find anyone who cannot use the Chevreul pendulum successfully. When there is difficulty, it is usually because the pendulum's movements are not entirely clear in any one response pattern. Research indicates that it is important for the subject to see the swing of the pendulum to get a clearly defined response pattern. This suggests that the Chevreul pendulum finds its sources of response closer to consciousness than head, hand, or finger signaling, where awareness is not important for a clear definition of response.

The Chevreul pendulum and finger signaling do not require any formal induction of trance. In fact, the focused attention they require is itself a means of inducing trance. Even with new subjects, finger signaling usually proceeds easily after a few moments of concentration. However, a certain degree of learning and rehearsal is usually necessary. The

movements that appear are usually slow and hesitant initially. Frequently the finger trembles slightly, and sometimes it moves curiously to one side, toward the middle finger. These movements can be taken as a criterion of the genuine autonomy of the response. Fingers that move up quickly with seeming conscious purpose should be questioned by the therapist. Subjects are enjoined to take their time and allow the fingers to move up by themselves. Occasionally, however, a subject will be found who is so highly responsive that the fingers do in fact pop up quickly in startlingly large movements.

When movements do not appear after a few moments, the therapist may notice that there is nonetheless some trembling or twitching on the back of the hand. This should be pointed out to the subject, who is enjoined to relax and learn to let the finger go. Sometimes the subject may have to "help" the finger lift by moving it voluntarily the first few times, when it feels as if it wants to move up by itself. In their learning of finger signaling, subjects often first feel an ideosensory response in the finger that "wants to" lift. These ideosensory responses can be encouraged as an initial stage of learning finger movements.

A curious but by no means uncommon occurrence in finger signaling is when the other fingers that have not been given a response significance (yes, no, etc.) move in response to a question. What can such responses mean? Obviously a response other than the designated possibilities (yes, no, etc.) is being expressed. Cheek and LeCron (1968) have reported that such responses may mean perhaps or maybe, or that the question is not understood, or that it cannot be answered positively or negatively. Frequently it means the question is ambiguous and must be rephrased in such a manner that double meanings or literalisms are avoided. Sometimes the subject will have a hunch about what this extra, idiosyncratic response means. Subjects have reported that such responses sometimes coincide with an important shift in their feelings or thoughts. It is therefore valuable for the therapist to seek out the meaning of such responses. If the subject has no ideas, further ideomotor questioning may help uncover their meaning. Frequently such extra responses will have a persistent and consistent meaning for certain individuals; they may function as a signal for deepening trance, the onset of a dream, an important memory, a related thought or insight not being uncovered by the therapist, etc. The spontaneous appearance of such individual response systems—as surprising to the subject as to the therapist—are another indication of the genuinely autonomous aspect of ideomotor signaling.

Once a form of ideomotor signaling has been established, the observant therapist will notice that ideomotor responses sometimes begin to function spontaneously on other occasions, even when they have not been asked for. Later in the interview or in later interviews patients may not even realize that they are giving the therapist ideomotor responses along with verbal interaction. There is thus a *generalization of ideomotor signaling* that takes place just as naturally as any other form of learning. Patients will sometimes report with some amusement that they found ideomotor signaling taking place unexpectedly when they were daydreaming, reading, listening to a lecture or music, driving their car, falling asleep, etc. That is, spontaneous ideomotor signaling tends to take place on those occasions when people experience throughout the day those short periods of self-absorption that we have called the "common everyday trance."

D. FACILITATING IDEOSENSORY SIGNALING

Ideosensory responses constitute a unique signaling system that can be utilized in interesting ways. They can appear in any part of the body and can be experienced in a number of different forms—warmth, coolness, pressure, tingling, prickliness, itch, etc. Ideosensory signaling can be used by the patient for self-knowledge, but by its very nature this signaling does not communicate to the therapist. Thus, ideomotor signaling can be of distinct advantage when patients want to explore something privately or when they are not yet ready to communicate to the therapist. When ideosensory responses occur in place of ideomotor signaling, however, the therapist can interpret this to the patients and encourage

them to continue their inner exploration in a private manner. Patients will later be able to make their own choices about how to communicate this material to the therapist.

Ideosensory signaling can thus be understood as middle station in the communication process. Ideosensory responses may be the first, primitive somatic signals coming from an unconscious level. Once recognized, they help the individual become aware of something that is in the process of reaching consciousness. These signals help individuals recognize that something important is happening even if they don't know exactly what. Thus, the person should pause for a moment and be receptive to new feeling or cognitive processes that require attention. From this point of view it can be seen how ideosensory signaling merges into the province of emotions, on the one hand, and psychosomatic response, on the other. All the somatic indications of anxiety, for example, can be taken as forms of ideosensory signaling. Blushing is a paradoxical ideosensory response that may signal to others even before the self.

E. UTILIZING IDEOMOTOR SIGNALING

Ideomotor signaling is without doubt the most useful indicator of trance experience that has ever been developed. It is very easy to establish in practically everyone, and it can be applied to exploring practically any circumstance of interest to patient and therapist. Here we will simply outline the range of its applications.

1. Inducing Trance

Simply requesting ideomotor signaling of any sort requires the subject to fixate and focus attention in a manner that is trance-inducing. The beginning therapist can find no better way of learning to recognize the subtle indications of trance development—body immobility; the relaxation of facial muscles, giving an "ironed-out" or flaccid look to the face; a fixed gaze; retardation of respiration, pulse, and certain reflexes like blinking and swallowing; literalism; comfort; etc.—than by calmly studying subjects requested to allow ideomotor or ideosensory signaling of one sort or another to take place. If no other form of formal trance induction has been used, the therapist will note that many of the signs of awakening from trance tend to occur as soon as the period of ideomotor signaling has ended. Thus, most subjects will tend to reestablish their *generalized reality orientation* by body movements that provide the kinesthetic feedback associated with the awake state. They will tend to readjust their posture, flex and clinch their fingers, stretch, refocus their gaze, look about, adjust their legs, and so on. Subjects may then report having spontaneously experienced any one of a number of the classical hypnotic phenomena (amnesia, regression, analgesia, time distortion, dream states, sensory perceptual changes, etc.) in a more-or-less attenuated form.

2. Trance Deepening

With subjects who are receptive and properly prepared for exploring trance or inner experience, it is but a short step from ideomotor signaling to a state of deeper trance. The therapist can simply ask if the subject would like to go more deeply into a comfortable state of relaxation or inner absorption. If a positive signal is received, the therapist tells the subject to continue going more deeply until the unconscious is satisfied with the state of comfort and to give a positive signal when that state is reached. The therapist can then utilize any of the other classical approaches to deepening trance (hand levitation, eye closure, a ride down an escalator, heaviness or warmth of limbs, etc.) and use ideomotor signaling to monitor the effectiveness of each procedure for deepening.

In the past few years the junior author has adapted a form of hand signaling for trance induction and deepening that is well suited for therapists learning to use the hypnotic modality and indirect suggestion as well as for their patients who are experiencing hypnosis for the first time. The special value of this "moving hands" approach is that it allows the patient's own unconscious to play an important part in determining trance depth as well as signaling what is being experienced. Since this approach lends itself so easily to practically any contingency the beginning hypnotherapist may encounter, we will detail some of the ways it can be used in the following section.

3. A Double Bind Induction with the "Moving Hands" Approach to Ideomotor Signaling

The junior author originally adapted the hypnotic experience of "moving hands" (Weitzenhoffer, 1957) for creating a double bind approach to hypnotic induction because a great deal of research had already established that this phenomenon was very easy to experience. When it is evoked by direct suggestion as one of the items of the *Stanford Hypnotic Susceptibility Scale,* for example, it is "passed" by 70% of the subjects. Moreover, the observable aspects of how it is accomplished have diagnostic value regarding the quality of the trance that is being established. Hilgard (1965) has described some of his observations as follows: "It is characteristic of the more susceptible subject to move his hands with a slow and somewhat jerky movement. The response may be rapid or extreme; for example, the hands may move apart until the arms are stretched out on either side of the body. The less susceptible subject often shows considerable delay before the arms start to move, or a movement is arrested after a very short distance. These quantitative aspects are of course subject to study; even without study the experienced hypnotist soon detects aspects of the movement related to an established trance state." (p. 104)

In the following we will present a generalized paradigm of the junior author's approach to facilitating the experience of many classical hypnotic phenomena via the use of indirect suggestion carefully monitored by ideomotor signaling to enable the therapist to tune into the patient's experience at all times.

Truisms Leading to Hypnotic Induction Via an Ideomotor Form of the Double Bind

R: Place your hands like so with the palms facing each other about eight inches apart. [The therapist demonstrates with his hands held about a foot or so in front of his face. Arms and elbows should not be touching anything so the hands and arms can be freely mobile.] Now we know the human body has a magnetic field. I don't know if you really will be experiencing that magnetic field between your hands, or whether your feeling will come from your imagination—but let yourself be sensitive to that magnetic force you will begin to sense between the palms of your hands—as if you have magnetic hands.

> R: Everyone has experienced the curious phenomenon of magnetism. Being a "curious" and invisible force that works mysteriously by itself, the metaphor of magnetism is associated with all sorts of ideodynamic processes that may evoke autonomous unconscious forces within the subject. This is a use of *indirect ideodynamic focusing:* an indirect form of suggestion that utilizes not the semantic or cognitive meaning of words, but rather their associated, concrete, ideodynamic values.
>
> While the subject's conscious mind (left-hemispheric rational processes) is a bit confused, fixated, and focused on the curious cognitive concept of "magnetic hands," the subject's unconscious (right-hemispheric ideodynamic processes) is automatically

evoking all sorts of concretistic *body experiences* associated with the words "magnetic" and "hands."

In general, many of the subject's life experiences with autonomous unconscious forces tend to be activated and placed on stand-by, ready for expression; in particular, many life experiences with automatic unconscious movement of the hands are primed for expression. The subject is unaware of all the unconscious, ideodynamic forces that have been set in motion because the conscious mind is still puzzling over what could be meant by "magnetic hands.

Everything the therapist said is true, but what does it all mean? This obvious inner question is itself another indirect hypnotic form that binds the subject's consciousness to the induction process and arouses *expectation.*

Implication and the Negative Building Expectation

R: But don't let those hands move *yet!* Just let yourself experience the forces between them. [Pause]

R: The unconscious requires time for the full experience of many ideomotor and ideosensory phenomena. In asking the subject to delay any actual hand movement and then pausing, the therapist is allowing time for these ideodynamic processes to maximize themselves. But notice that we have subtly introduced another indirect hypnotic form: *implication.* By saying, "But don't let those hands move *yet!"* we are implying that they will move. The senior author has emphasized that implication is something the listener must construct within himself. The therapist does not directly tell the subject to move his hands, but the implication indirectly evokes the necessary ideodynamic processes within the subject that will move the hands in an autonomous manner. The hands are now primed to move, if only the subject will let them move.

In saying "don't let those hands move" we have interspersed a negative that may indirectly discharge any resistance the subject has about following the therapist's suggestion. Ambivalence is characteristic of all hypnotic work; the subject wants help and wants to follow suggestions, but of course there are doubts and fears about following any fool doctor. For many reasons the subject both wants and does not want the hypnotic phenomena to work. If the therapist continually insists that the phenomena will take place, naturally the subject is polarized and burdened into carrying out the opposite possibility that the hypnosis will not work. By expressing the negative "don't let those hands move," the therapist takes over this negative possibility so that it need no longer reside within the subject, and he need no longer act it out. The subject is thus left with nothing else but his curious positive *expectation* about when the movement will be permitted. It is no longer a question of will there be movement. The only question is, if not yet, then when?

Nonverbal Expectation and Preliminary Oscillations: Displacing and Discharging Resistance

R: In this pregnant pause the therapist simply watches the subject's hands with avid interest and expectation. This *nonverbal expectation* is another indirect hypnotic form that tends to evoke responses automatically within the subject. But the therapist cannot fake this avid interest and expectation because the subject's unconscious will sense it and be put off by it. The therapist is able to manifest genuine expectation because he knows that in fact unconscious ideodynamic processes have been set in motion, and he is indeed curious about how they will become manifest. He knows that acute and careful observation is necessary for the successful art of hypnosis so he eagerly watches the subject's hands for the first manifestations of movement.

When the patient sees the therapist's genuine interest, he too usually *focuses and fixates* his gaze on his hands. If not, the therapist makes a slight nonverbal head movement in the direction of the subject's hands to direct his gaze there. If the subject still does not focus his gaze on his hands, the therapist points at the hands to direct the subject's gaze nonverbally. The nonverbal direction tends to potentiate right-hemispheric processing while allowing left-hemispheric words to remain in relative quiescence.

With the subject's gaze now focused on his own hands, both he and the therapist can enjoy a few moments of expectation and careful observation. How will the subject's individuality process and manifest the autonomous forces that have been set in motion? No two subjects or sessions are alike. Each subject experiences it a bit differently each time. When the therapist notices the first slight micromovements, he sighs contentedly and comments on the movements however they begin to take place.

Reinforcing Ideomotor Movements: Creating a Therapeutic Milieu

R: That's right, letting that happen. Some fingers move a bit by themselves and that's OK, but don't let the hands move very much yet. Just experiencing, letting it happen by itself.

R: In commenting on the minute, tremulous movements that can usually be seen by this time the therapist is, of course, reinforcing them. In feeling and nonverbally manifesting satisfaction the therapist is modeling and indirectly reinforcing satisfaction and contentment within the subject for experiencing autonomous movements that in most other contexts might seem strange and frightening. In being able to experience such an unusual and potentially frightening phenomenon with contentment, without quite being aware of it the subject is being conditioned to experience and express other repressed and potentially frightening material that may be of therapeutic value later on when it can be easily and safely elicited. The therapist is thus creating a safe milieu for future therapeutic experience.

The sentence, "Just experiencing, letting it happen by itself," is a subtle *indirect compound suggestion.* The first part, "Just experiencing," is, of course, a truism. How could the subject deny he is experiencing? Since he must agree that he is experiencing, the first phrase of the compound suggestion establishes a "yes set" for the acceptance of what follows, "letting it happen by itself." There are at least two levels of meaning confused in this phrase that funnel into facilitating autonomous ideomotor movement of the hands. On one level, the experience is going on by itself; all experiencing has an autonomous quality. On another level, the therapist is also directly, but subtly and permissively, telling the subject to let the hands move by themselves. Even if the subject is consciously aware of only one level of meaning, the ideodynamic principle of mental functioning indicates that all levels and possible associations will be activated even if they are not overtly manifest. When many levels of meaning and association are focused in one direction, however, an autonomous movement does tend to take place.

Introducing the Double Bind for Ideomotor Signaling

R: We know a magnetic force can pull things together or push them apart, and it's the same with the unconscious. When it wants to say "yes" it pulls people together; when it wants to say "no" it pushes people or things apart. So we can use that hand movement to ask your unconscious an important question. If your unconscious wants to say yes, you will feel those hands pulled together. If your unconscious wants to say no, you will feel those hands being pushed apart. You simply let your unconscious move those hands either way. And what will that question be? [Pause]

R: The double bind is that whichever answer is given, yes or no, an ideomotor response will become manifest, and autonomous ideomotor movements are by definition a form of hypnotic response. The subject is usually so fascinated with the incipient movements he is experiencing and the possibility of his unconscious answering a question that he does not recognize the double bind. Even when the subject does recognize the nature of the double bind and comments humorously about it (usually fellow professionals who have studied the double bind and know of its applications in hypnosis), the ideomotor experience continues. Sometimes a skeptical subject will be so unbelieving that he will consciously stop the movement, clinch his hands a bit as if to wake them up and reposition them to test the phenomenon again.

The Double Bind Question

R: What is the question that the unconscious is getting ready to answer with a yes by moving the hands together, or a no by pushing them apart? [Pause] The question is, "Will it be okay for the unconscious to allow you to experience a comfortable therapeutic trance?" [Pause] That's right. Allowing the hands to come together for yes, apart for no.

R: The hands usually do begin moving slowly together at this point, sometimes with that slightly jerky movement so characteristic of unconscious movements. The subject frequently smiles at this movement; it is a pleasant surprise to experience it.

Eye Closure via Contingent Suggestions

R: That's right. And as those hands continue moving very slowly together you can wonder what is happening to your eyelids. Are they blinking? Are they getting ready to close comfortably as those hands continue moving together? [Pause] Will they close before those hands touch?

R: Associating eye closure with the ongoing hand movement is an indirect form of *contingent suggestion:* we hitchhike a new suggestion to an ongoing pattern of behavior so that the yes of the ongoing behavior carries the new along with it. We introduce the new suggestion in the form of a question so that the subject's own internal dynamics can be responsible for the eye closure. The phrasing of the suggestions in question form is always associated to whatever behavior the subject is actually manifesting. If the subject does blink the therapist comments, "That's right, it does seem to be happening, doesn't it? And how soon will those eyes actually close?"

If the eyes do not close at this point, or if the hands actually move apart or not at all, it means we are encountering resistance. This resistance can be explored and utilized somewhat as follows.

Displacing and Discharging Resistance: Many Contingencies, Many Opportunities for Hypnotic Response

R: That's right, those hands are actually moving apart, meaning the unconscious would rather not go into a therapeutic trance just yet. And that's because consciously or unconsciously there is some difficulty with it. So those hands can continue to express that difficulty by very slowly moving apart. And as they continue moving apart, does the reason for that difficulty come into your conscious mind? Does the unconscious require some time to work things out before trance can take place? [Pause]

Let's just watch those hands. Can the unconscious deal adequately with that problem right now without even telling me about it? And start moving those hands together when it has dealt with the problem? [Pause]

Can the unconscious stop that movement for a moment as it deals with that issue? Will it keep your eyes open, or will it allow your eyes to close in order to focus more intensely and adequately on resolving that problem? [Pause]

Does the unconscious want you to speak about what you are experiencing even as you continue to experience it? How easily can you let yourself talk while that continues?

R: The above are only a few of the possible ways of exploring and resolving whatever is behind the negative ideomotor signal of the hands moving apart. The therapist deals with the so-called resistance by (1) continually commenting on how it is being manifested and by (2) associating the resistant behavior with another hypnotic suggestion designed to deal with and possibly resolve the resistance via a series of questions that are answered by (3) yet another ideomotor response. As long as some movement is taking place the hypnotic modality is being manifest and the therapist can enjoy the process of exploring the patient's patterns of responsiveness. In the very rare case of no hand movement at all the therapist can proceed somewhat as follows.

Converting No Response into Catalepsy

R: And what is happening to those hands? Are they really not moving? How long can you hold them rigidly there with no movement at all? That's right, try as hard as you can not to let them move at all. The body is usually always in a state of constant movement even if we don't notice it, but in the hypnotic state we can get paradoxical responses—the opposite of what we ask for—and the body can become completely immobile and still sometimes for quite some time. Or one part of the body can become quiet while another part of the body experiences the movement. What will happen in your case?

R: Thus no movement can be converted into a passive form of catalepsy with the subject staring wide-eyed at his hands and not moving at all. While so transfixed, the therapist can go on with further indirect suggestions about how the unconscious can continue to work on its problems very intensely within as the body remains completely quiet and immobile—just as in a dream or in a deep state of concentration.

Time Distortion and Awakening: A Subtle Posthypnotic Suggestion

R: And the unconscious can continue working on that problem in that special trance time when every moment in trance can be equivalent to hours, days, or even years of ordinary clock time. [Pause] And the interesting thing is that the conscious mind may or may not really understand just what is happening if the unconscious needs to keep it private. You can remain just as you are until the unconscious completes that unit of work and you'll know it's finished when you have that urge to move and stretch and come fully awake again.

R: What has happened here? The original lack of ideomotor movement has been converted into a trance experience wherein the subject deals effectively with whatever resistance there was to oppose the ideomotor movement. It could even be that there was no active resistance at all. The subject may simply have no talent for ideomotor movement. In this case the passive catalepsy is the more ideal way of permitting trance experience to take place.

How do we know that trance has in fact taken place? The very quietness and immobility of the body frequently with a flattened facial expression are the basic signs of trance. Perhaps the eyes blink and eventually close as permission is granted to remain immobile. At certain moments the observant hypnotherapist may notice that the pupils of the eyes dilate with interest and recognition that something is happening.

Another obvious indicator of trance is that the subject will usually follow the subtle posthypnotic suggestion to "move and stretch" as he comes awake. Sometimes the therapist can reinforce this posthypnotic suggestion by stretching and moving about himself. On awakening the subject may be rather blank and essentially amnesic about what was experienced. This of course is yet another indication of a genuine trance experience and the therapist should not press the subject to talk about it. The situation is that an interesting hypnotic experience has just taken place which lays the foundation for future trances. The next time the therapist and subject meet the experience of this first trance can be brought up again as an ideodynamic approach to initiating the next trance.

If on awakening the subject does want to talk about the experience, the therapist can carefully collect the phenomenonological data regarding the subject's experience, and then utilize it to facilitate the next trance experience which can take place immediately or later.

But let us return now to the more typical situation where the subject responds positively to the original double bind question by allowing the hands to move together indicating that a comfortable therapeutic trance is being experienced. There are innumerable directions that suggestion can take once the hands are moving slowly together. Here are a few that are typically explored by the junior author because of the valuable information they provide about the subject's response abilities.

Demonstrating Conflict Between the Conscious and the Unconscious

R: That's right. And as those hands continue slowly moving together indicating that the unconscious is moving you more and more into a comfortable state, you may wonder what would happen if you try to oppose it with your conscious will. What if you took some time out just for a moment and tried to oppose that force? Is it possible for your conscious mind to oppose that unconscious force? [Pause]

R: The pause gives the subject a conscious opportunity to counter the magnetic force. It is interesting and informative to note how the subject uses this opportunity. If the hands continue moving together without interruption even as the subject makes a somewhat hopeless facial grimace, or perhaps a wee smile, it may mean that he is so possessed by the ideomotor movement that he cannot oppose it; this is possibly a right-hemispheric type of individual who has a special talent for hypnotic suggestion and may be able to experience most of the classical hypnotic phenomena with ease.

With another subject, the hands may continue moving together without interruption and with no facial cues of an opposing effort being made. This may be an individual who is so comfortable with the ongoing experience that he would rather not bother to make any effort to oppose it. This subject may also be ready to experience most of the classical hypnotic phenomena but he may be particularly successful with those that permit him to remain passive rather than active: ideomotor inhibition, ideosensory responses, and imaginative processes; successful suggestion may be best phrased in a manner that allows him to remain passive and simply receive from his own unconscious or the therapist rather than suggestions that require an active engagement of some effort.

Yet another subject will pounce upon the opportunity with relief and eagerness to test the strength of the conscious will against the ideomotor movement. The therapist will now observe all sorts of testing behavior: Most of the time there is an oscillation between the obviously conscious pulling of the hands apart and then a pause as they slowly begin moving together again autonomously; infrequently a subject will pull his hands apart, drop them, and become apparently awake thus ending the experience for the moment. This subject should then be questioned to determine if there are any serious objections to further trance experience.

All these diverse and informative ways of opposing the ideomotor movement have one common denominator: It is invariably disappointing to the subject when he finds he can, in fact, stop the ideomotor movement. Subjects usually say later that they were sorry to sense that the "magic" or "trance" was gone for a moment; they did not want their ordinary conscious mind to interfere with the interesting potentials of the unconscious. It's not as comfortable when the conscious mind imposes its will.

In this disappointment reaction the junior author sees further evidence for the special state theory of hypnosis: trance does involve a special state of consciousness or being that most subjects can distinguish as different from ordinary everyday consciousness, even when they have difficulty in verbalizing the difference. This shift from the hypnotic to the ordinary modality may be either (1) the perceived phenomenological shift from right- (or minor) hemispheric dominance to left- (or major) hemispheric dominance, (2) a shift from the dominance of the parasympathetic system to that of the sympathetic, or, (3) perhaps an actual shift in the relative utilization of different neurotransmitters, endorphines, or other psychobiological systems. Whatever the underlying biological source of this perceived phenomenological shift, it can help people to recognize an altered state and be used to introduce a valuable bit of self-understanding somewhat as follows.

Recognizing Altered States: Posthypnotic Suggestion Facilitating Therapeutic Modes of Being

R: That's right, it is a bit disappointing to force yourself out of that comfortable state where things happen by themselves. It's rather disconcerting because it always does feel better to let the unconscious do the things it knows how to do best, by letting it work without interference from the conscious mind. You're now experiencing that difference and learning how to allow the unconscious to do things. Letting the unconscious move those hands again either together or apart. It really doesn't matter, the only important thing is that we allow that creative part of the unconscious to determine just what it will be. And it's nice to know that just as you allow those hands to move again you can use this new sensitivity throughout the day to occasionally tune into yourself when the unconscious wants you to take a few minutes out, to rest, and let it do the important things that will help you in more ways than you can consciously realize. Tuning into the body carefully throughout the day and letting the unconscious have the time and energy it needs to deal with those problems that are so important to you.

R: We know that in fact the body is on a ninety-minute cycle throughout the day and night (Hiatt & Kripke, 1975). Every ninety minutes while asleep we go through a dream cycle. And every ninety minutes while awake we go through a period of parasympathetic dominance when we actually do need to take a break from work and left-hemispheric thinking. Every ninety minutes throughout our waking hours we do get a bit hungry and are prone to fantasy. This, of course, is the ideal time to go into self-hypnosis, giving our unconscious the permission to do everything necessary to facilitate our lives while we give our conscious intentionality a rest for a while. The junior author is currently exploring the clinical hypothesis that many states of *unease*

and psychosomatic *disease* are the result of the stress that arises when consciousness does not allow this natural ninety minute cycle to operate. Anxiety, mental blocking, errors and fatigue tend to occur when the conscious directed thinking of the dominant hemisphere attempts to usurp the balancing and compensating functions of the minor hemisphere as they naturally take place throughout this cycle.

To associate a posthypnotic suggestion of sensitivity to this cycle, then, is to *tie a posthypnotic suggestion to a behavioral inevitability.* That tends to reinforce the suggestion while utilizing and facilitating a natural life process.

Exploring Hypnotic Potentials: Body Immobility and Anesthesia

R: And as those hands continue coming together you can tune into what else is happening. Are those hands getting a bit stiff and wooden? Is there a pair of thick, soft magnetic gloves on those hands so that they don't feel anything? So thick that the padding of those gloves stops the hands so they can't get closer than an inch or two together? [Pause]

R: If the subject responds and the hands do in fact stop an inch or two apart (assuming the subject's eyes are open at this point; or, if the eyes are closed phrasing the suggestion so that it becomes contingent on the eyes opening to witness this blocking, stiffness, and numbness of the hands), the therapist has an excellent basis for now wondering aloud just how stiff and numb those hands have become so that the subject can experience a glove anesthesia. The anesthesia can be tested later when the hands are allowed to drift to the lap and not feel anything. For many subjects, of course, it will be impossible to feel anything because by remaining consistent to the glove suggestion their hands will not quite touch their lap because the thick magnetic gloves will interfere. Along with anesthesia, or in place of it, one could also explore ideosensory responses.

Ideosensory Responses

R: And as that continues you can tune into the sensations on your face. We all know the warmth we sometimes feel on the face and parts of the body when flush with emotion. And you may not know exactly why but your unconscious knows how to feel that warmth. Can you feel that warmth now? [Pause] And as you feel that warmth, will those hands drift apart to let me know, or will your head slowly begin to nod yes? [Pause] Or will your head shake no all by itself?

R: There are innumerable ways of evoking ideosensory responses but certain principles always help: (1) mentioning a life history of situations when the body could have experienced the sensation (the flush of emotion, the coolness of the wind) tends to initiate an inner search on an unconscious level that primes the sensations to be experienced; (2) using the pause to allow adequate time for the response; (3) setting up a behavioral ideomotor signal to let the therapist know when the response has been experienced. These principles are, in fact, basic for facilitating any hypnotic phenomenon in the permissive manner. At this point the therapist can introduce and explore whatever range of hypnotic responses he feels is necessary to facilitate future work.

Trance Deepening and Preparation for Further Therapeutic Work

R: That's right. And if the unconscious is now ready to allow that trance to deepen, for the comfort to deepen just as in going to sleep, you will feel those hands and arms getting a little bit heavy—and then a bit heavier. [Pause as therapist looks for the

slight bobbing motions that signal the greater weight that is being experienced.] And as those hands continue drifting lower that comfort deepens more. But those hands won't come to rest on your lap until the unconscious is really ready to rest and then learn other hypnotic skills that can be useful for your purposes.

R: At this point the subject is usually ready for further work. The junior author now typically introduces ideomotor finger signaling that can be used to monitor the course of whatever procedures there are to follow.

4. Measuring Trance Depth

The concept of trance depth has been a controversial matter in the history of hypnosis. Our modern *utilization theory* would define depth as the state of concentration or absorption in relevant associations and mental processes that allows the subject to experience a particular phenomenon of interest. "Depth" may thus be understood as readiness to respond in a *particular* way rather than as a *generalized* readiness to experience any hypnotic phenomena. The notion of a generalized readiness to respond with a graduated scale of trance depth correlated with the various hypnotic phenomena (from easiest to experience in a light trance to those phenomena requiring deeper trance) is well established, however, and offers a practical guide. Tart (1972) has reviewed many self-report scales of hypnotic depth which suggest that subjects can be trained to give accurate verbal responses about their current depth of trance. It is found that depth varies continuously, so that it is of value to monitor it when doing important trance work. Individual differences between what is actually experienced at the various stages of "depth" are so great, however, that no universal scale exists that can be used with all subjects at this time.

The senior author has used finger signaling as an individual index that is gradually developed for each particular subject. With patients' hands resting comfortably by their sides, out of their line of vision, Erickson will suggest that the digits of the hands can signal the depth of trance by moving a bit all by themselves. The use of the thumb is excluded because the senior author believes there is more consciousness associated with thumb movement than with other finger movements. He uses the impersonal term *digits* because it has less conscious associative strength than terms like *forefinger, index finger, ring finger,* and *little finger.* The same digit on either hand can designate trance depth. This tends to bypass learned associative patterns specific to one hand or the other, but there are great individual differences in this matter. Some patients will use the hands interchangeably; others are very consistent in using either the left or right hand.

In working out an index of trance depth, the first digit (however the patient interprets "first digit") can be used to indicate the lightest stage of trance, while the other digits can indicate depth on a scale somewhat as follows:

First digit (0-25%): Light trance wherein relaxation, comfort, ideosensory, and ideomotor signaling is possible.

Second digit (25-50%): A comfortable state of receptivity to inner experience wherein feelings, thoughts, daydreams, colors, etc., flow autonomously. An agreeable receptivity to the therapist's suggestions so that familiar trance phenomena can be experienced easily, with the subjective experience of their taking place automatically when the therapist suggests them (e.g., hand levitation, heaviness, warmth, sensory-perceptual alterations, etc.).

Third digit (50-75%): A state of established receptivity where the subject has "passed" all familiar indicators of trance experience and feels capable of exploring new trance phenomena or unfamiliar areas of personal dynamics (uncovering memories, partial age regression, etc.). Trance events take place autonomously, though the ego may observe them and may or may not recall them upon awakening. Subjects are frequently enthusiastic upon awakening because they feel their trance was deeper or more therapeutic than usual, and they spontaneously experienced other hypnotic phenomena not even suggested by the

therapist. They have a deep sense of the autonomous or dissociated nature of their experience.

Fourth digit (75-100%): Subjects report that they lost consciousness at times. They were either asleep, dreaming, far away, or "out" somehow. They cannot recall hearing the therapist's voice, even though they responded appropriately, though slowly, to it. They cannot explain or recall much of their experience.

Some people may experience the plenary trance, which is relatively rare and usually requires several hours for induction. It is a state akin to suspended animation, with greatly retarded respiration and pulse, requiring an extended period of time (30 minutes or more) to recover the generalized reality orientation.

5. Replacing Challenges

Perhaps the greatest value of ideomotor signaling for modern hypnosis is that it permits the therapist to do away with the authoritarian "challenges" of yesteryear ("you cannot open your eyes, unclasp your hands," etc.), which were a somewhat traumatic method of gauging trance depth and a most disheartening way of relating to patients. Ideomotor signaling permits the patient's own system to indicate when it is ready to respond and what help it requires to make an adequate response. This permits a closer rapport and more enlightening cooperation to develop between patient and therapist. Ideomotor signaling opens up the subject's trance experience so that the clinician and the researcher have an adequate tool for exploring the nature of any altered state of consciousness.

6. An Indicator of Response Readiness

The shift from the older authoritarian approach to the more modern permissive approach pioneered by Erickson is nowhere more evident than in the use of questions to subjects regarding their readiness to experience a particular response. The senior author continually offers subjects a series of truisms regarding their ability and motivation for experiencing different phenomena. Even when he believes a subject is ready for a particular experience, he will first ask a question about it to activate the proper associations and response potentials within the subject. Questions and ideomotor responses are thus a way of priming an individual to make certain responses.

An example of the senior author's recognition of a spontaneous and automatic head-nod at the appropriate moment made by a person attending his 1945 "Informal Meetings with Medical Students" illustrates how he utilizes unconscious ideomotor signaling as an indicator of a person's readiness to experience trance.(Taken from unpublished stenographic records of Erickson's "Informal Meetings with Medical Students," 1945)

E: Actually, there isn't a volunteer here tonight. I have been looking the group over very carefully and there isn't a volunteer. ... By the way, does anyone know who nodded his head just then?

LeJ: It seems I did. I had already said I would try to go into a trance, and then the fact that you said you didn't see a volunteer in the group seemed significant and it seemed it must have been me. ... I didn't know it. It might have been because I was rocking the chair.

LeJ's head-nod came in response to the senior author's verbal remarks about searching for a volunteer. Erickson might have (1) arbitrarily picked out a volunteer or (2) asked for a volunteer. But he might have picked a person who was not ready, and even if a subject volunteered, it may have been only a response from the conscious level. By spotting an

ideomotor signal, the senior author was fairly certain of finding a subject who was ready on a deeper level.

LeJ's introspective remarks are instructive. He had previously said (outside the immediate group situation) that he would try to go into a trance. That is, he was ready to make a response to trance induction. He needed Erickson's verbal remarks about the need for a volunteer as a stimulus to trip off the automatic head-nod, however. Having made the head-nod, LeJ admits that he did not know he was making it (he had no forethought of nodding his head), and he even tries to rationalize his way out of it by suggesting his head nodded because he was rocking his chair. On a conscious level LeJ was thus ambivalent; he said he would like to try trance, yet he tries to rationalize his way out of it. This ambivalence is highly characteristic of patients, who have problems precisely because they are poised between conflicting forces within themselves. Erickson's verbal remarks and questions allowed an ideomotor response to take place as a way of tipping the ambivalence into a constructive direction.

Other investigators such as Le Cron began to use ideomotor signaling in a more consciously directed form. In the 1952 Los Angeles Seminar on Hypnosis, taught in association with Erickson, Le Cron described his beginning use of ideomotor signaling as follows (taken from L. LeCron's unpublished tape transcriptions of the 1952 Los Angeles Seminar on Hypnosis.) :

> In inducing anesthesia, you do not know when your suggestions are taking effect until you test the anesthesia and the subject says he feels nothing. I avoid the use of the word "pain," saying "discomfort" instead. The word "pain" is a negative suggestion—the word itself. I make a suggestion that when anesthesia has become complete or almost complete that a designated finger will twitch. When it does, you can take it that you have at least a good partial anesthesia. That finger twitch is an indication of acceptance by the subject. When he feels the finger twitch, his thought is "well, the hand must be anesthetized."

This approach is certainly applicable in evaluating the patient's readiness to experience other phenomena as well as anesthesia. What if the patient's ideomotor responses indicate that he is not ready to experience the desired response? This is an indication that the patient's understanding, motivation, or internal readiness is not yet sufficiently developed to sustain the required response. The patient can then be questioned about the source of the difficulty. The therapist then helps the patient resolve these problems with understanding and motivation, then provides the appropriate associations that will enable the patient to approach the required response with more security and internal preparedness. The therapist mentions all the past and partial experiences the patient has had in making the response automatically, as a part of everyday life experience. These associations encourage the patient on a conscious level while (1) providing the unconscious with appropriate cues about how the response may be made and (2) actually activating the relevant response sets that can facilitate the appropriate behavioral response. Examples of this procedure will be provided throughout the following chapters.

6. Uncovering Unconscious Material

Ideomotor signaling can be used as a procedure for uncovering unconscious material in a much shorter time than the traditional psychoanalytic approaches. An early illustration was provided by Erickson in his "Informal Meetings with Medical Students" (1945). Upon recognizing the presence of covert hostility in Mrs. W, Erickson proceeded to use both ideomotor signaling and automatic writing to help her recognize it. This example is particularly instructive because he begins by working with two subjects, both of whom make an identical response on a conscious verbal level indicating that they do not want to say anything unpleasant. Ideomotor signaling supports Miss H's verbal statement but does not support Mrs. W's. Erickson then proceeds to utilize *ideosensory* signaling (when Mrs. W's

hand "feels a little light"), which then merges into a genuine *ideomotor* signal a few moments later, thus helping Mrs. W. Recognize her ambivalence.

E: Let's put it to a test. Suppose you put your hand in this position. If unconsciously you would like to say something unpleasant about him, your right hand will lift up. If you have nothing unpleasant to say—if there is no need to say something unpleasant—the left hand will lift up. Which hand will you bet on?

Mrs. W: My left one. [No hand lifting]

Miss H: My left one. [Left hand lifts up]

E: Nothing unpleasant. Is there anything unpleasant you would like to say about anybody here?

Mrs. W: No.

E: Does your right hand feel different?

Mrs. W: My right hand feels a little light, but does that mean I want to say something unpleasant to somebody?

E: Does it?

Mrs. W: I can't think of anything.

E: If you would like to, let's see your right hand lift up.

Mrs. W: [Right hand lifting] It did, though. You're going to get me into trouble.

E: Do you know what it is?

Mrs. W: No.

E: There's no awareness or conscious state. There is a movement of the hand. Something occurred within her to make her realize that there must be something unpleasant. I haven't persuaded her or directed her, one way or the other. I have just created the situation and raised the question, and she found her right rising, and she is aware of the face, "Yes, If I am to believe my hand, I want to say something unpleasant, but I can't think of anything."

Mrs. W: It's all Greek to me. My hand lifted, and I was trying to keep it down.

E: Would you like to have the fun of finding out what it is you want to say?

Mrs. W: I can't imagine want it is.

E: I can tell you very easily and quickly how to find out.

Mrs. W: Go back to sleep again?

E: No, no. Suppose you pick up the pencil, and your hand is going to write somebody's name.

In the process of doing automatic writing the name of the person she wants to say something unpleasant to finally pops into Mrs. W's mind. This is highly characteristic of the ideomotor-response approach to uncovering unconscious material. There is an interplay between *entirely autonomous ideomotor responses,* which come from sources outside the patient's awareness, and *conscious recognitions* (thoughts, feelings, etc.), which become available suddenly. It is as if the therapist's persistent questions activate many patterns of association and sources of response within the patient. The patient's responses may then come by way of ideomotor signaling alone, through a combination of ideomotor signaling with conscious recognition (which may come just *before, during,* or *after* the ideomotor response is made), or by conscious recognition and verbal report alone.

A question naturally arises regarding the validity and reliability of ideomotor signaling in these applications. All of these applications of ideomotor signaling to date have been developed in clinical work and have depended upon the clinician's skill in detecting valid from invalid results. No systematic studies of the validity and reliability of ideomotor signaling have ever been done under standardized laboratory conditions with proper controls and statistical analyses. Erickson admits that the results are only as valid as is the clinician's capacity to understand the total situation. He discusses this as follows (edited from audio recordings made with the junior author during the 1970s):

"What is the validity of ideomotor signaling? A great deal has been said about asking the unconscious to lift the right hand if the answer is Yes and to lift the left hand if the answer is No, to seek further information from the patient's unconscious as an entity that can give reliable information. The question is asked, how valid is that? It is only as valid as is your capacity to understand the situation that you are dealing with.

"A patient came into my office and said that she had a tremendous complex over the fact that she had had seven affairs over a period of several years. She very willingly gave me the names, dates and places, and situations of each of those seven affairs. The patient was so communicative and so free, so direct in describing all of those things, describing her feelings. But having some psychiatric experience, I wondered what she would tell me in the trance state.

"In the trance state she gave me literally the same account of the same seven affairs with minor corrections. I mentioned the possibility of her unconscious giving answers: Yes with the right hand or with the right index finger and No with the left hand or with the left index finger just as one would nod the head Yes or shake the head No. I gave this as a simple incidental explanation, not telling her to do that but just to mention that it was one of the things that could be done presumably by some other patient. In the trance state, when she finished relating the first affair, she said, 'My first affair was in 19xy,' but her left hand said No. I made a mental note of that. Then I think it was the fourth affair she introduced by saying, 'My next affair,' and her hand again said No.

"Ideomotor movements contradicted her words three times: Once her hand said No, once it was her finger that said No, and once it was her head saying No. But she didn't notice any one of those movements. She was as unaware as could be. Later I found out that her first affair didn't occur at age 17, as she said. It occurred at the time of puberty, when she became very aggressive and undertook to seduce an older man, but had tremendous guilt reactions and a complete repression of it. That was her first affair which she had forgotten. She had forgotten who the sixth one was also. Another repression. She gave that information only through ideomotor signaling. And yet I could ask her, 'Did you give me an account of all your affairs?' and she would answer verbally, 'Yes.' Well, she had given me an account of all her affairs, but only those that she was aware of consciously. She did not at all mind knowing that it was an incomplete account when I later suggested that to her. She was willing to learn about the affairs first disclosed via ideomotor signaling that were repressed from consciousness.

"So when you deal with patients, you ought to bear that in mind. You cannot force them, but you can get them to disclose more completely when you provide an ideomotor outlet for responses that are not available to consciousness. I certainly didn't try to force that woman to tell me about the missing accounts until she got ready to. She was tremendously surprised when she found out about those repressed affairs later in therapy."

LeCron (1954, 1965) has utilized ideomotor signaling to uncover early memories of light trance states. He outlines his approach to questions in his early 1954 paper as follows:

> Questioning should usually be carried out on a permissive rather than a commanding basis. Cooperation at unconscious levels will probably ensue if this is adhered to, for resistance may be provoked if there is an attempt to force information.
>
> With practice and ingenuity in asking questions a great amount of valuable material may quickly be obtained. For instance, if a trauma is involved, the exact day when it occurred can be ascertained by a bracketing method of questioning. A query may be made as to whether the event happened before the patient was 15 years old. If the reply is "yes," the next question could be "was it before you were 10

years old?" If the answer is "no," the date was then between 10 and 15 years of age. The year can then be ascertained and further questioning can even locate the exact day, though it is seldom necessary to establish the time so closely.

Having learned the age or date, the patient can be instructed to regress to the time of the experience. The regression need not be of the revivification type, the subject merely relating the experience as though reliving it but recognizing also that he is in the present. Such a regression can be with all five senses functioning as the incident is relived—seeing, hearing, etc.—and with abreaction and discharge of emotion.

In this way information can be obtained as to almost anything involved in the patient's difficulty or neurosis. It is, of course, infinitely more rapid than the usual method of free association. Questions can even be diagnostic—"Are there psychological or emotional causes for this symptom?" And sometimes it will be found valuable also to ask questions as to prognosis.

To the patient it is most impressive to have this information come from within himself. The nonvolitional movement of the fingers demonstrates to him most effectively a direct action of the unconscious mind. Not infrequently a patient will remark that a "no" answer was expected when the fingers actually responded with "yes." This serves as an excellent indication both to the patient and therapist as to the validity of the replies. Sometimes a subject may try experimentally to prevent the fingers from moving. Perhaps he can do so, but frequently they will move in spite of such an effort.

Of course the wise therapist will take all replies with a grain of salt and will show, however, that it is exceptional for a false reply to be given, though of course it is possible. Even with deeply repressed material the answers usually are accurate and perhaps easily obtained. This is not always true if the repression is great or if the material is too emotionally charged, but the method seems to break down repressions. Avoidance of answering a question by the signal with the left thumb [I don't want to answer] is an indication of danger. Carefully handled, objections may be overcome with reassurance and discussion, or a suggestion may be given that the subject will be able to summon ego strength enough to bring out the material at a later session. Questions may here bring out the reasons for the avoidance of an answer and also if there is danger to the patient as to being overwhelmed.

Care should be taken in the wording of questions so that they do not suggest either an affirmative or negative answer. The operator can mention at the beginning of the questioning that he does not know the correct answers and that the patient probably does not consciously know them, but that his unconscious mind does know and is able to reply with the correct answers, (pp. 76-78)

Cheek and LeCron (1968) have systematized many paradigms for questioning patients to obtain ideomotor signaling to uncover sources of psychological trauma and psychosomatic illness. Cheek, in particular, has developed a number of ingenious ideomotor procedures for uncovering unconscious material. These include the removal of subconscious resistance to hypnosis (Cheek, 1960), the unconscious perception of meaningful sounds during surgical anesthesia (Cheek, 1959, 1966), the significance of dreams initiating premature labor (Cheek, 1969b), and communication with the critically ill (Cheek, 1969a). In an important paper, "Sequential Head and Shoulder Movements Appearing with Age Regression in Hypnosis to Birth" (1974), he has made interesting observations on ideomotor responses that take place on unconscious levels. His papers represent truly pioneering efforts on the part of a clinician and therapist. His work points the way toward much systematic research that needs to take place under controlled laboratory conditions in order to establish the validity and reliability of ideomotor responses and signaling.

F. SUMMARY

The useful clinical art of ideomotor signaling has evolved out of an extensive and ancient history of automatism. While automatisms were regarded as mysterious, God-inspired, or magical in ancient and medieval times, we understand them today as an interesting manifestation of response systems outside the usual range of awareness. These ideomotor and ideosensory responses are now understood to be the fundamental building blocks of the automatisms that gave rise to the classical trance phenomena and the establishment of hypnosis in the 19th century. New forms of ideomotor signaling have been explored during the past few decades, primarily by clinicians interested in uncovering unconscious material and facilitating hypnotic responsiveness. These modern forms of ideomotor signaling,

developed by Erickson, LeCron, and Cheek, are providing *permissive* clinical approaches to understanding and facilitating hypnotic and therapeutic responses that are replacing the older *authoritarian* forms of command and "challenges." Systematic and controlled laboratory investigation is still required to establish the validity and reliability of ideomotor responsiveness and signaling.

G. EXERCISES IN IDEOMOTOR SIGNALING

1. Ideomotor Signaling and the Indirect Forms of Suggestion

The use of ideomotor in conjunction with the indirect forms of hypnotic suggestion (Erickson & Rossi, 1979) provides the therapist with a creative array of approaches to facilitating hypnotic phenomena and working with unconscious material. In his 1960 paper on the removal of resistance to hypnosis, for example, Cheek provided an excellent illustration of the use of the Chevreul pendulum with questions and the implied directive to help a subject recover a traumatic memory. The subject, Dr. R. (not the same Dr. R. of this volume), had an unusual reaction to his first experience with the Chevreul pendulum and apparently froze with fear. Following is an excerpt from Cheek's account; the italics are ours, indicating where Cheek utilized a series of two implied directives in successive sentences to evoke the critical material.

> Dr. R grasped his pendulum more tightly. Beads of perspiration appeared on his forehead. His face and hands turned an ashy-gray color. I asked him to open his eyes and let the pendulum answer some questions. I asked him:
>
> Q: Have you ever felt like this before?
>
> A: Yes.
>
> Q: Was this before you were 20 years old?
>
> A: Yes.
>
> Q: Before you were 15?
>
> A: No.
>
> Q: Does your subconscious mind now know what that was?
>
> A: Yes.
>
> Q: Let your eyes close now, and *if your inner mind will let you know what the experience is it will pull your fingers apart. As the pendulum falls to the table, the noise will bring that memory up to a conscious level where you can talk about it.*
>
> I remained silent for about 20 seconds. As his fingers released the chain, he appeared disturbed. A split second later, as the plastic ball of the pendulum struck the table, he lifted his left hand to the side of his head, opened his eyes and said: "I know now. I was in gymnasium exercises and I was the top man in one of those pyramids. The man below stumbled, and I landed on the side of my head on the cement floor."
>
> There seemed to be no further comment. I asked him to pick up the pendulum and answer this question:
>
> Q: Do you now think you can enter hypnosis comfortably, and be free of the reaction you had a little while ago?
>
> A: Yes. (p. 106)

The reader can now explore how each of the indirect hypnotic forms can be used with ideomotor signaling to effect significant therapeutic responses.

2. A Basic Paradigm for Ideomotor Signaling

In recent years the cybernetic hypothesis that conceptualizes *information* flowing along a *feedback loop* as the basic unit of learning and behavior has provided interesting models of psychological functioning. Of these, the *Test-Operate-Test-Exit* (TOTE) Model (Miller,

Galanter, & Pribram, 1960; Pribram, 1971) provides a useful paradigm for experimental and clinical work with ideomotor signaling. This paradigm outlines the use of a series of *test* questions and psychological *operations* that can eventuate in the solution of a given psychological problem.

After establishing ideomotor signaling via head, hand, or finger responses, a five-state TOTE paradigm that theoretically could be used to investigate and resolve most psychological problem runs as follows: The *tests* are usually a series of questions or instructions that the therapist addresses to the subject, while the *operations* are the inner psychological processes the subject must undergo to give an ideomotor response. This paradigm is actually a generalization of the lines of investigation developed by Cheek and LeCron (1968). In the following outline the "no," "I don't know," or "not willing to answer" responses all indicate a need for further inquiry at that level to resolve whatever difficulty the patient is experiencing.

1. TEST: Is there a psychological or emotional reason for your problem? OPERATE: Inner review on an ideomotor level (with or without conscious awareness), giving rise to an ideomotor response:

"YES" "No" ➧ TEST: Further inquiries

2. TEST: Series of age-bracketing questions and/or a request to reorient to time the problem began.
OPERATE: Inner review on an ideomotor level, giving rise to an ideomotor response:

"YES" "No" ➧ TEST: Further inquiries

3. TEST: Is it okay for consciousness to know it? OPERATE: Ideomotor response:

"Yes" "No" ➧ TEST: Further inquiries

4. TEST: Discuss the source of your problem.

OPERATE: "No" ➧ Unsatisfactory verbal discussion TEST: Further Inquiries
'Yes": A satisfactory discussion

5- TEST: Is it now okay to give up the problem?
OPERATE: Inner review of the problem on many levels summarized in an ideomotor response.
"Yes" "No" TEST: Questions about other sources of problem or when problem can be given up.

EXIT: Posthypnotic suggestions supporting resolution of the problem.

The first test question regarding a psychological or emotional reason for the patient's problem initiates the operation of an inner review on an ideomotor level. Such inner reviews always tend to deepen trance; consciousness is fixated and focused within, while an autonomous or semiautonomous process is allowed to make an ideomotor movement. If a Yes signal comes forth, the therapist can go on to the second test question. If a No response is obtained, then further inquiries are indicated. It may well be that the problem does not have a psychological or emotional basis. It may be that the patient does not accept the words *psychological* or *emotional* and that the question needs to be rephrased in terms acceptable to the patient's understanding.

A No response at this initial level could also indicate transference problems. The therapist may need to question patients about their willingness to let the therapist help them, and so on. At this level "I don't know" may mean that the patient needs more education regarding the nature of psychological or psychosomatic problems. "Not willing to answer" may mean that there are important secondary gains associated with the problem that need to be investigated. People use their signaling system in their own unique ways, however, so the

therapist must closely study each person's style and personal system of meanings. In any case this first question initiates a process of inner review regarding the nature of the problem. This activates many associative processes that may be utilized to identify sources and potential solutions to the problem.

The second test question is actually a series of bracketing queries to localize the source of the problem in time. Erickson has always emphasized that hypnotic responses take time. This series of bracketing queries provides time for a series of inner reviews. In addition trance is usually deepened whenever we have a serial task (Erickson, 1964b). Frequently the sources of the problem will pop into the patient's mind as soon as the bracketing queries are initiated. It is well to continue an entire series of questions, however, to provide the patient's associative process with an opportunity for a more thorough review than the patient probably has ever done before. Other sources of the problem may be uncovered and valuable connections made between different age levels.

Having located the time when the problem began, the therapist then asks if it is okay for the consciousness to know it. In truth the therapist does not always know where the patient's consciousness is. It may be present, quietly watching the ideomotor responses, or it may be far on, relating to other matters and entirely unaware of what ideomotor responses are being made. There may be a total, partial, or complete lack of dissociation between the ideomotor level of responding and the cognitive system of awareness. When there is no dissociation, the patient's consciousness is theoretically aware of the significance of a particular ideomotor response. Even when this is the case, however, there is every likelihood that there are associations available at the ideomotor level that are not shared with consciousness. Because of this we ask whether these associations can be shared with the patient's consciousness. A Yes response usually means that the inquiry can proceed, but there is still no assurance that all the relevant associations will be shared with consciousness at this time. Many reviews (sometimes dozens) of the same ideomotor process relating to a problem may be required before certain associations reach consciousness.

An "I don't know" or "unwilling to answer" response at this level requires further inquiries regarding why a dissociation (or unconsciousness) needs to be maintained. The conventional view of most forms of therapy requires that the unconscious be made conscious. Erickson, however, has pioneered the view that many if not most neurotic problems can be handled more adequately at an unconscious rather than a conscious level. A No response at this level could mean that consciousness is not necessary to resolve a problem. A line of inquiry can be used to test this possibility (can the unconscious solve this problem without your conscious mind knowing anything more about it?). This possibility gives rise to the fascinating prospect of problems being resolved at an ideomotor or unconscious level without either patient or therapist knowing the what, how, or why of it. Much research is needed to explore this possibility. It may be that certain patients and certain problems are more effectively resolved without the intervention of consciousness.

In the typical course of inquiry test question #4 invites the patient to talk about the material stirred up by the questions thus far. What is or is not a satisfactory discussion of the problem depends on something more than the therapist's preconceptions and theoretical views. Ultimately the only criterion of a satisfactory discussion of a problem is the pragmatic one of whether or not it leads to a Yes response to test question #5, regarding the patient's willingness and actual ability to give up the problem. There is a wide range of possible responses when patients are invited to talk about their problems at this level. There is the usual uncertainty about the degree of dissociation that may be present. Patients may talk with seeming normality, yet be in a somnambulistic state so that an amnesia would be present for everything said when they awaken later. Usually, however, the dissociation is only light or partial; the patients speak and may undergo a catharsis more freely than when awake, but they retain a fairly complete memory of the discussion when awakened later. This memory has actually been facilitated by any efforts to secure a Yes response to test question #3, regarding the appropriateness of consciousness knowing.

Test question #5, regarding the patient's willingness and ability to give up the problem, is the main objective of the entire proceeding. Again it is well to recognize that psychological

processes continue to develop over time. Sometimes a patient will gain a clear insight about a problem and definite prospects for its immediate, confident resolution. Many "emotional" and "identity" issues can be resolved in this manner. Habit problems with ingrained patterns (smoking, nail-biting, overeating, etc.), however, may require more time. It is always valuable to have the patients "see" a date when the problem will be finally resolved. It is then valuable to have the patients pseudo-orient themselves in time future to that date. When the ideomotor responses indicate the patients are there, the therapist can have them review all the things they had to do to finally resolve the problem (Erickson, 1954). This provides patients with a series of tasks or steps their own system needs for problem resolution. In this manner, a patient's individuality has an opportunity to create its own patterns of problem solving. Patients are usually impressed when they realize that modern hypnotherapy thus facilitates their own creative abilities rather than attempting to impose some arbitrary solution from the outside.

The final stage is to EXIT from the therapeutic encounter with a few indirect posthypnotic suggestions to facilitate the solutions just found (and created!). The patient usually awakens spontaneously when the ideomotor situation is ended by the therapist simply adopting a conversational manner that requires responses of normal attention and behavior. The therapist can recognize the spontaneous awakening by the patient's reorientation to his body, etc. If the awakening is not obvious and spontaneous, then the therapist can request that the patient close his eyes, rest comfortably for a few moments, and then awaken completely, feeling refreshed.

3. The TOTE Model and Psychological Change

The TOTE Model was developed to account for central control of receptor mechanisms (which Sherrington's conception of the reflex arc cannot do). Central processes within the brain are continuously modifying sensory input from the environment. This central control is necessary for the organism's continuous adjustment between internal states and the outer environment. If this central control is important in integrating sensory and motor processes, consider how even more important it is in the psychological realm, where input from a social scene is continuously modified by the person's central control over that input—that is, the person's interpretation of that social scene. What we have termed "interpretation" or "bias" in clinical psychology is actually the person's "central control" over input. When the person's central control of "bias" is rigid—that is, not sufficiently or appropriately modifiable by changing external realities—we have psychological maladjustment. When the central control (bias, interpretation) changes appropriately as a function of real-life changes, we say the person is "well oriented to reality," "adjusted," or "growth-oriented."

The most significant factor involved in changing central processes or biases is the organism's motor interactions with the environment. Central control does not change unless the organism has a chance to modify itself by way of an actual interaction with external reality. A kitten needs to actually walk in order to organize its visual perceptions; being carried about in a special cart does not allow it to develop the requisite perceptual-motor coordination to move with grace and accuracy. Thus we can expect that modifying inappropriate central control of social situations (bias) will also require actual interaction with those social situations— simple interpretation or understanding of one's bias is not enough. One needs to interact or actively change one's responses to a social situation in order to change the bias or maladjustment.

4. Levels of Response in Ideomotor Signaling

It is evident from the preceding discussions that the sources or levels of response in ideomotor signaling remain a fascinating puzzle. Cheek and LeCron (1968) have indicated,

"Deeply repressed information of a traumatic sort will be indicated first by physiological indications of distress, then by an ideomotor response, and finally by verbal reporting" (p. 161). The results of their clinical investigations thus indicate that there may be at least three sources or levels of response. Actual clinical experience suggests there may be even more. Some patients respond on an emotional level, feeling something but not knowing what it is. The emotional level is thus different (dissociated from) the cognitive level. Others have an intuitive level of response about knowing something, but again they cannot put it into words. Ideomotor signaling appears to be in rapport with these emotional and intuitive levels even when they cannot be verbalized. This is a line of research that is still open for systematic investigation. Is there in fact a hierarchy of sources or levels of response that passes through the various stages—physiological, ideomotor, emotional, cognitive, verbal, etc.—or is this simply a matter of individual differences? What approaches can be developed to explore the question experimentally?

AN AUDIO-VISUAL DEMONSTRATION OF IDEOMOTOR MOVEMENTS AND CATALEPSY: THE REVERSE SET TO FACILITATE HYPNOTIC INDUCTION

In 1958 the senior author gave Ernest Hilgard and Jay Haley a demonstration in hypnotic induction at Stanford University. A videotape or 16mm film of this demonstration is available from the publisher (Irvington Press, 551 Fifth Ave., New York, New York, 10017). Although both the visual and auditory qualities of this old record are poor, it is nonetheless the best visual record we have of the senior author's uses of a variety of nonverbal approaches to catalepsy and an unusually complex form of ideomotor signaling in trance induction during an exciting period of his work as a teacher. The analysis of this visual record in this section contains his commentaries on the puzzling use of a *reverse set* to confound the learned limitations of everyday thinking to facilitate the experience of mental flux, creativity, and therapeutic trance.

After being introduced to the subject, Ruth, Erickson made a few conversational remarks to initiate the idea of "automatic movement" to her and then began a hand levitation approach. As her hand approached her face, Erickson introduced another task: to discover the difference between her thinking and doing. In what follows we have a transcription of how Erickson proceeds to facilitate a dissociation between her thinking and her doing as a means of deepening trance and establishing a reverse set.

In this ingenious procedure Erickson arranges matters so that her *doing* (an initially voluntary head signaling that gradually becomes more and more involuntary) can be true or false. Circumstances are arranged, however, so that her *thinking* will always be true. Her thinking will be true even if she needs to go through a private mental maneuver of believing the reverse of what she does with her head signaling.

The outer movement of head-nodding or -shaking and the inner process of thinking are usually associated together in a body-mind pattern of agreement in everyday life. Here Erickson separates or dissociates them, so they now have a significance that is the reverse of each other. By having her head signal the reverse of what she obviously knows to be true, Erickson establishes a reverse set within her. She develops a set to think the reverse of what her head signals. The critical point comes when he has Ruth shake her head No to indicate she is not in trance; but the reverse set that has been activated within her reverses this so she must think, "I am in trance." Erickson thus arranges what she actually thinks by utilizing a mental mechanism (the reverse set) within her own mind.

This example is the clearest, verbatim illustration of the evocation and precise utilization of a mental mechanism for trance induction that the junior author is aware of. It has been analyzed in this section in almost painful detail because it is so subtle a process that it can easily be lost or misunderstood. Difficult though it may be to grasp initially, we believe *this*

process of activating and utilizing mental mechanisms is actually the essence of the hypnotherapeutic process. Erickson's 1948 paper "Hypnotic Psychotherapy" contains his original formulations of this approach of utilizing—rather than simply analyzing—mental mechanisms.

Introduction and Initial Learning Orientation to Hypnosis

Hilgard: Ruth, I want you to meet Dr. Erickson.

Ruth: How do you do, sir.

E: How do you do. Do you mind if I call you Ruth?

Ruth: No, I'd like to have you call me Ruth.

E: Please sit down. Does that light feel all right?

Ruth: Yes, it does.

E: I understand you've never been hypnotized?

Ruth: No, I haven't.

E: But that you are interested?

Ruth: Yes.

E: And I think that perhaps the best thing to do is to get right down to work. *How much are you willing to learn?*

Ruth: Well, I'm very willing. [Slight pause] I'm a little nervous, though. E: You're a little nervous? Ruth: Yes.

E: Well, really, I ought to be the one who's nervous, because I've got to do the work, and *all you have to do is let things happen, and they will happen.*

R: Upon being introduced, Erickson uses his first remark to gain access to personal contact by requesting permission from Ruth to use her first name. Requesting her permission is not only polite, it immediately gives her an active role in determining how the proceedings will go. Erickson's first solicitous remark about the light (for the movie that is being made) continues this initial effort to enlist her approval and active participation. He then asks a question to ensure her interest in hypnosis, and then another, "How much are you willing to learn?" Thus the hypnotic situation is immediately defined as a learning process. This is especially appropriate in a university setting.

In the next remarks about being nervous Erickson does a number of things: (1) acknowledges and reflects her feelings; (2) identifies with her nervousness and in a peculiarly concrete way may be relieving her of it by taking it on himself (the original meaning of transference in the rituals of early forms of healing was that the patient's disturbance or disease was transferred to the healer (shaman, witch doctor, or guru), who internalized the problem and dealt with it in his own system); (3) utilizes it to define hypnosis further as a situation where "all you have to do is let things happen, and they will happen." The ease and casualness with which all this is done contributes to its effectiveness. Casualness in a context of truisms and good rapport may be regarded as a most effective vehicle for the acceptance of suggestion.

Initial Assessment of Possible Trance

E: Uh, are you forgetting about the light?

Ruth: No, I'm not—am I supposed to look at it?

E: Oh, no.

Ruth: Oh.

E: You can forget about it, you know.

R: In this innocent questioning about the light, Erickson is boldly but indirectly assessing her response attentiveness and potential for hypnotic responsiveness. If she had given some indication that she had already forgotten the light in the intensity of her concentration on him (e.g., a slight startle as she reoriented to the light or a frank admission that she had indeed already forgotten it), Erickson would have had rapid evidence of her tendency toward somnambulism. She indicates to the contrary, however, that she is in fact aware of the light. She is a subject who likes to hang onto her generalized reality orientation. She does not like to admit altered states. It will not be easy to ratify her trance experience. This turns out to be true, as we shall see later; even after experiencing a number of classical hypnotic phenomena during this session, she tends to question them at the end. Nonetheless, Erickson ends the interchange at this point with the direct suggestion that she can forget the light. The casualness with which this suggestion is made, however, tends to make it indirect and acceptable without challenge. He then rapidly goes on to initiate a formal hypnotic induction by hand levitation.

Modeling Hand Levitation and the Conscious-Unconscious Double Bind

E: And I'm going to take hold of your hand in a moment or so. [Pause while E puts her hands on her thighs.] Now, as you watch your hands, they're resting there. And do you know about the feelings you have when you are feeding a baby and you want the baby to open its mouth, and you open yours instead of the baby? And did you ever put on the brakes when you were in the back seat of a car?

Ruth: Yes.

E: Well, I would like that same kind of automatic movement. Now look at my hands. You see very, very slowly, without it being a voluntary thing, my right hand can lift and it can lower, and the left hand can lift and lower. [E models this slow lifting and lowering with his own hands.] Now what I'd like to have you understand is this: that you have a conscious mind, and you know that and I know that, and you have an unconscious mind or a subconscious mind, and you know what I mean by that, do you not? [E is leaning forward in his chair toward her, engaging intense eye contact.] Now you could lift your right hand, or your left hand consciously, but your unconscious mind can lift one or the other of your hands. And I'd like you to look at your hands, ***and I'm going to ask you a question and you do not know the answer to that question consciously, and you'll have to wait and see what the answer is. I'm going to ask you which hand is your unconscious mind going to lift up first? The right hand or the left, and you really don't know. But your unconscious knows.***

R: Erickson begins a hand-levitation approach by giving an everyday analogy of automatic movement that is especially appropriate for a young woman (feeding a baby). This analogy tends to initiate an unconscious search for those unconscious processes that can facilitate the automatic movement of her hands. Erickson models this automatic movement with his own hands and then uses the conscious-unconscious double bind to further facilitate the unconscious search for automatic movement (Erickson & Rossi, 1976, 1979).

Voice Locus Cue for Hand Levitation

E: That's right, and it's beginning to lift one of your hands. *Lifting, lifting, lifting,* [E slowly moves his body backward and his head upward as he says this] *lifting up,* and now watch it. That's right. Watch it lifting, lifting, lifting, up it conies, lifting higher. And watch it. Soon you'll notice it, and keep watching your hand and watching it. And if you wish, you can close your eyes and just feel your hand lifting higher and higher. That's right. Lifting still more. That's right, elbow will start bending and the hand will come up, that's right. Lifting, lifting, and now close your eyes and just feel it lifting, and it's lifting higher and higher.

R: As you intensely intone "lifting, lifting, lifting, lifting up" you move your body backward and your head upward. Your voice locus is moving upward in the same direction you want the hand to levitate.

E: Yes, that's an auditory cue that may facilitate hand levitation on an unconscious level. The patient doesn't know why the hand lifts.

R: In the next section you again use voice locus as a cue several times by lowering your head and deepening your voice when you tell her that her hand is coming down and she will "go way deep asleep."

Tactile Cues for Hand Levitation and Catalepsy: Amnesia for Tactile Cues: The First Apparent Awakening

E: *And I'm going to take hold of this hand. [E* signals the levitation of her left hand by lightly sliding his thumb on its underside.] And it's lifting)

lifting, lifting, lifting, that's right. And the other hand is lifting, lifting up. [E guides her right hand up with some lingering touches to signal that it is to remain up in a cataleptic position.] That's right. Now, I mentioned before that the hand could lift, and it could go down. And now I wonder if you know which hand is going to go down first? One or the other is going to go down, and down it conies. [Her right hand begins to come down slowly.] That's right, that's right, down it conies, down it comes, and coming down still more, still more, down it comes, down it comes. [E lowers his head as he says this.] And as it conies down, I want you to go deeper and deeper into the trance. I'd like to have you enjoy going deeper and deeper, and when your hand reaches your lap, you'll take a deep breath and go even deeper into the trance, because you're beginning to learn how now. That's right, coming to rest there. That's right. Now, take a deep breath and go way deep asleep. [E lowers his head and deepens his voice.] And now let it seem to you as if many minutes had passed. And I'd like you slowly to arouse and look at me and talk to me. [E lightly touches the underside of her still levitated left arm.] And slowly *rouse up* now, slowly rouse up, rouse up now. And open your eyes. [She opens her eyes and looks at E.] That's right. And you're beginning to learn to go into a trance. Do you realize that?

Ruth: I think so.

E: When I tell her, "I'm going to take hold of this hand," I actually just lightly touch her right wrist with my hand, giving slightly more pressure with my thumb on the underside of it. My touch indicates that I'm going to lift her arm, but I don't lift it! I just gently slide my thumb a bit up the underside of her wrist to indicate lifting, but she does most, if not all, the lifting. I try to give continuous cues for lifting until she takes over and does all the lifting.

R: This is a way of initiating a kind of semiautomatic hand movement that seems to take place without the patient realizing it is a step toward fully autonomous hand movements. As you ask her to "rouse up," you gently touch the underside of her left wrist as a nonverbal cue that that arm is to remain levitated even after she awakens.

E: Yes, if you do this at exactly the right moment between trance and awakening, the patient will awaken and stare with curiosity at that arm in a cataleptic position.

R: The patient tends to be amnesic for the tactile cue that was just given in the trance state?

E: Either the patient is amnesic or she has lost the tactile cue altogether, because it was given between the trance and the awake state and actually belongs to neither.

Assessing Trance Experience: Sensory and Perceptual Distortions

E: You think so. And how does your hand feel?

R: Um—a little—heavy.

E: A little heavy; and can you see your hand plainly?

Ruth: The one in my lap, yes.

E: And this one?

Ruth: Yes.

R: You apparently awaken her, but her left arm remains levitated, and she reports that her hand is heavy. This suggests that she is still experiencing trance effects. Your questions are to assess just what sensory and perceptual distortions may be spontaneously present at this point. Your unusual questions can evoke unusual responses in the unusual situation of a trance induction.

Implied Directives for Automatic Movements and Trance Deepening: Sensitizing for Minimal Cues

E: Now watch that hand as it gets closer and closer to your face. That's right. That's right. And I would like to have you pay full attention to the sensations of the movement of your arm, the bending of your elbow, and the way that hand is getting closer and closer to your face. And very shortly it is going to touch your face, but *it's not going to touch your face until you are ready to take a deep breath and to close your eyes and go way deep, sound asleep.* That's right, almost ready, almost ready. That's right, that's right, and it's moving, moving. That's right, and you're waiting for it to touch your face and getting ready to take that deep breath. Getting ready to go way deep, sound asleep in a deep trance. Almost touching now, that's right, almost touching now, and yet *it isn't going to touch until you are ready to take that deep breath and your eyes will close.* That's right, getting closer and closer and closer. That's it, elbow bending more, fingers move up to touch your chin. That's right, that's it. Almost there, almost there, and now your head starts bending forward. That's right, and you'll take a deep breath and go way deep asleep. That's right. [E arranges the fingers of her right hand into a cataleptic position.] Go way deep, and now slowly [E gives her left arm a signal touch to go down.] this arm will come down to rest on the arm of the chair. That's right. Slowly and then just a bit more rapidly. And now your right arm is going to start lifting up, and the elbow will start bending. That's it, and the left arm is coming down, [E waves his hand to motion her right arm down.] more and more. That's it. And your right elbow is bending, and your wrist is lifting up. That's right, lifting, lifting, lifting, lifting, lifting. [E is giving the underside of her right hand light touches to signal lifting.] That's it. Lifting, lifting, lifting, lifting, lifting, lifting, lifting. That's it. Elbow bending, and this arm is straightening more and more.

R: You're reinducing deeper trance by focusing and fixing her attention on the sensations of movement in her arm, etc. This kind of unusual task tends to

depotentiate her usual conscious sets so that she more readily accepts your implied directive not to let the hand touch her face until she is ready to close her eyes and, in effect, go into a deep trance. You gave her many directive touches in this section both to speed up the procedure and to increasingly sensitize her to the minimal cues you're giving her as well as the minimal cues from her own inner processes that are usually ignored in the everyday awake state.

Paradoxical Challenges to Facilitate Hypnotic Responsiveness: Implication and Hand Gestures as Nonverbal Cues for Right-Hemispheric Involvement

E: And now, Ruth, I would like to have you discover something more. I'd like to have you slowly, very very slowly open your eyes and look at your right hand and then look at your left hand. That's right. And notice the difference in the movements. That's right. And now I want you to try, just try to stop the downward movement [E makes a broad sweeping gesture downward, as if directing the left hand downward.] of the left hand. That's right, that's right, and down it comes. And now I want you to notice that you can't stop it from lifting up. [E now makes a slow upward movement to direct her left hand upward.] Watch it. Now watch the right hand lifting up toward your face, and try hard to stop it, but up it conies, up it comes, up it conies, and keep watching that. Up it comes.

R: Are you using challenges here to deepen trance when you ask her to try to stop the downward and upward movements?

E: You can't try to stop a downward movement unless there *is* a downward movement. The patient thinks I'm challenging her to stop something. She doesn't see the implication for downward movement to continue.

R: A patient could be hesitating on a downward movement; you apparently challenge her to stop it. She doesn't realize that this challenge actually implies there is movement and facilitates that movement.

E: Yes, because you have to have a thing in reality to be able to stop it. I reinforce the reality of the movement with my own hand movements that direct her nonverbally. By this time she has been conditioned to follow my nonverbal cues, so she finds that she cannot stop the lifting or lowering of her arms.

R: So the paradoxical challenge to stop a hypnotic behavior that is on the brink of taking place is actually a way of facilitating and strengthening it. You then reinforce the movements with your nonverbal hand gestures. The patient's right hemisphere is probably picking up these cues and processing them automatically, so that she follows your hand gestures even though her left hemisphere may be puzzled, since it only hears your verbal challenge to do the opposite. This opposition may be reinforcing the more autonomous processes of the right hemisphere, which we associate with hypnotic behavior, and depotentiating the verbal controls of the left hemisphere, which we associate with the normal generalized reality orientation.

E: Yes, and you can tell the patient, "Try hard to stay awake." R: You thereby set in motion a process to go to sleep.

E: Yes, and she knows she's been trying to stay awake! It's been a difficult job to stay awake. Therefore by implication, it's easy to lapse into sleep or trance.

Multiple Tasks to Depotentiate Conscious Sets and Facilitate Following Behavior

E: And I'd like to have you watch, look at my finger now. [E points upward with his left hand for Ruth to focus on. With his right hand he slowly moves her left hand to her face. While doing this, he points his left hand down, so that Ruth's eyes gradually close as he lowers his hand toward the floor.]

And I want you to notice something that happens to you. **Take a deep breath, close your eyes. That's right. And all the time you are beginning to feel that you are learning more and more. [E touches the underside of the fingers of her right hand to signal an upward movement.] And it's moving up toward your face, and as soon as your right hand touches your face, you'll take another deep breath and go deeper asleep. The closer your right hand gets to your face, the more your left hand will move away from it. [E signals a downward movement with a light touch on her left arm.] And up goes the right hand. That's right. Up it goes, and the left hand is moving away. A little bit faster, and a little bit faster, that's it, and faster yet, and still faster, and still faster, and faster and faster, that's it. And now, while your hands are busy doing that, Ruth, I'd like to have you open your eyes and look at me. And now I want to teach you something of importance, as soon as your right hand touches your face. And it'll start moving away, and so we'll have that alternate movement. [E demonstrates by alternating his hands up and down.] Do you understand? And Ruth, I want you to discover something else. It is rather hard for you to guide your hand. [E guides her right hand toward her face.] That's it.**

R: You continue your learning frame of reference, continually enjoining her "to notice something that happens to you." You are hereby reinforcing her hypnotic attitude of passive expectation; her conscious intentionality is to do nothing except witness unusual sensations, perceptions, movements, or whatever manifestations there may be of autonomous or unconscious processes. You reinforce her movements with nonverbal touch signals, and you give her multiple tasks that so absorb the conscious attention of her left hemisphere that the way is open for the more autonomous processes of the right hemisphere to manifest themselves (Watzlawick, 1978).

Dissociating Thinking and Doing

E: I want you to discover *the difference between your thinking and your doing.* And that is this: You know how to nod your head, [E models head nodding.] and you know how to shake your head. [E models head shaking.] And you know your first name is Ruth, and you know that you are a woman, and you know that you are sitting down, and I know all those things too.

R: Your initial statement about discovering "the difference between your thinking and your doing" sounds matter-of-fact and rational, but it is a task that is outside her habitual ideational patterns. Thus, it is a new and rather odd frame of reference that tends to depotentiate her usual conscious sets so that unconscious searches and processes are initiated. This reinforces and deepens the hypnotic modality.

You then state a series of truisms that establish both a strong yes set and the first stage of a reverse set that you are carefully developing.

Paradoxical Confusion from Ostensible Clarification

E: And no matter *what I say or you say* or anybody else says, *it won't change your name,* will it? And it won't change the fact that you are a woman. And it won't change the fact that you are sitting down.

R: Here you are apparently clarifying the difference between doing ("what I say or you say") and thinking ("it won't change your name") in a convincing way so that the above yes set is maintained and reinforced. But in actual fact your statements are so different

from the ordinary frames of reference of everyday life that what is ostensibly clarifying is in reality precipitating a paradoxical confusion that further depotentiates her left hemisphere's ability to maintain its own orientation. This is especially true since she is already in a fairly passive, receptive mode where she is not particularly disposed to do much active analysis of your abstractions. Further, even the highly abstract nature of the dissociation you are establishing is hidden behind your casual manner and the apparent obviousness and concreteness of the phrases you use—"you are a woman" and "you are sitting down." Anyone could hear and accept the obviousness of these concrete statements even if they were half unconscious. So naturally she accepts them without realizing everything else she is accepting along with them—especially the hidden implications that come in the next section.

E: [Laughing heartily] You found me out! [The senior author and the junior author have been working on the reverse set for about five years. Only now, and after a dozen revisions, does R catch on to this particular bit of paradox. E was just waiting and wondering when it would finally dawn on R.]

R: Did you actually plan this confusion while apparently clarifying?

E: Yes, of course, many times! [Breaks up in renewed laughter]

Hidden Implication for the Reverse Set

E: But I can say anything, and you can think anything. *It doesn't necessarily interfere with facts.*

R: These statements further illustrate and reinforce the difference between doing (what we say) and thinking ("it doesn't necessarily interfere with facts"). The apparently gratuitous use of *necessarily,* however, does set up the hidden implication that what we do may after all influence what we think. This, as we shall see, is the critical implication that later allows the reverse set to operate effectively.

Exercising a Yes Set

E: Now I'm going to ask you, is your first name Ruth? [Ruth nods Yes.] That's right. Are you a woman?

Ruth: Yes.

E: You just nod your head or shake your head in answer. Are you a woman? [Ruth nods Yes.] Are you sitting down? [Ruth nods Yes.]

R: You now exercise a yes set wherein Ruth establishes a habit of responding behaviorally (a head nod meaning yes) in a positive way to the questions. What she does and thinks are the same; both are true.

Dissociating and Reversing Thinking

E: AH right, now I'm going to ask you some other questions, and you will nod your head in answer. Is your name Ann? [Ruth shakes head No.] And you will nod your head in answer. [E models, nodding Yes.] Is your name Ann? [Ruth nods Yes.]

R: This is the first dissociation and reversal between her doing (nodding her head Yes) and her thinking (she thinks No, since obviously she knows her name is not Ann). Is this also a confusion technique?

E: Yes. I also sometimes tell irrelevant stories and make non sequitur remarks to induce confusion. [Erickson now illustrates a number of childhood games that amuse by inducing paradox and confusion.]

Reinforcing the Reverse Set

E: That's right. Because your thinking can be different than movement of the muscles in your neck. Are you standing up? [Ruth nods Yes.]

R: This response reinforces the same dissociation and reversal between thinking and doing begun in the above section. Her head nods Yes, while her conscious thinking, if she is consciously thinking, must obviously be the reverse.

E: That's right. And are you a boy? [Ruth nods Yes] That's right.

R: Again the same dissociation. By this time a reverse set has been established; a set for acting out a dissociation between doing and thinking. It is a reverse set because what she thinks is the reverse of what she does; she now tends to nod Yes when her thinking is No.

Reversing the Reverse Set: The Onset of Confusion

E: And now I want you to shake your head No. [E models head shaking.] Your name isn't Ruth, is it? [E shakes No; Ruth shakes No.]

R: Another dissociation is established similar to the above but with a reversal of the reverse set in doing and thinking: Her doing (shaking her head No) is now false, while her thinking is true (her name really is Ruth!). If the reader is now beginning to struggle against becoming confused, imagine the difficulty Ruth is beginning to have!

E: And *you* aren't a woman, are you? [Ruth shakes head No.]

R: Again the same dissociation between the falseness of her doing and the truth of her thinking.

E: And you aren't sitting down, are you? [Ruth shakes head No.]

R: The same dissociation establishes another reverse set: doing what is false while thinking the reverse, which is true. It is the complementary reverse set of the first that was established. She is now trained both in doing what is false while thinking what is true, and doing what is true while thinking falsely. The net results tend to be a well-established reverse set between thinking and doing; she will now tend always to think the opposite of what she does, and vice versa.

The Reverse Set Establishes That She Is in Trance

E: And you aren't in trance, are you? [Ruth shakes head No.]

R: This is the utilization of the hidden implication described earlier and the firmly established reverse set; since she shakes her head No, she must think the reverse, "Yes, I'm in a trance." Thus, the reverse set establishes within her own thinking that she is in a trance. At least that's the first implication of her head shaking No. It would be too difficult to immediately switch the reverse set that has been so long established. She could switch it if she had a moment to reflect and decide, "Well, no, I'm really not in trance." But you don't give her time to make this inner adjustment, even if she felt disposed to it.

The situation is now as follows: Since she is in fact closely following you in her outer behavior, she is evidencing what you call "response attentiveness." That is, she is in

trance whether she knows it or not. Even if she had a tendency toward inner resistance so that she would deny consciously acknowledging trance, this resistance tends to be bypassed because of her confusion and your careful engineering of the reverse set—which now prompts the inner, conscious acknowledgment that she is in trance.

Adding Contradiction to the Reverse Set: Depotentiating Conscious Sets

E: And you aren't answering me, are you? [Ruth shakes head No.] And you're not going to answer me, are you? [Ruth shakes head No.] That's right. And you can hear everything I say, can you not? [Ruth shakes head No.] And you won't hear anything I say to you, will you? [Ruth shakes head No.]

R: You now quickly shift to another question that reinforces the reverse set in a very obvious way, so that she cannot disagree with it. She continues with the same form of the reverse set as the above, which implies she is thinking (if she is consciously thinking at this point) that she is in trance. This reverse set is reinforced four times, but notice that the last two are contradictory. Since she makes the same response to these contradictory statements, she is obviously confused to the point where she is simply responding by a rote following of whatever response Erickson sets in motion. Her conscious sets and self-direction are depotentiated to the point where left-hemispheric rationality has been depotentiated.

Deepening Trance: Breaking the Reverse Set

E: All right, and you can close your eyes.

R: You suddenly switch from questions to a definite statement about something she can do.

E: You can close your eyes, can you not?

R: This is another change. You ask a positive question about something she really can control. She does not shake her head. The previous reverse set is broken.

E: And you're closing them, are you not? [Ruth closes her eyes.] That's right. And you can enjoy sleeping more and more deeply all the time. And you really are, aren't you? [E nods his head continuously.] That's right. And you really are—and just keep right on sleeping, deeper and deeper in the trance.

R: You now positively reinforce eye closure and deepening trance.

Implied Directive to Deepen Trance

E: And to let me know that you are, your right hand is going to come to rest on your lap.

R: This implied directive is used to signal, motivate, and reinforce deepening trance.

E: And in some way you're *beginning* to know that you're sleeping in a deeper and deeper trance. [Ruth's right hand slowly moves down to her lap.]

R: You emphasize *beginning* because the subject can hardly argue with that; it is experienced by the subject as true no matter how her conscious attitudes may be evaluating the situation.

E: And I'm going to talk, and you don't even need to listen to me.

R: A dissociation is encouraged between the conscious and unconscious by not needing to listen.

E: And you really don't, because you are very, very busy, going deeper and deeper in the trance as your hand comes closer to your lap. And as it comes to rest in your lap, and *as it continues to rest in your lap, you're going to be very, very busy sleeping deeper and sounder and more profoundly in the trance state, as your hand comes to rest more and more completely.*

R: This section ends with the simple contingent suggestion that as her hand continues to rest in her lap, she will be going deeper into trance. Since her hand is resting there, it would be hard to resist the suggestion that she is going deeper into trance. She would have to move her hand to deny the suggestion.

Ideomotor Signaling of Dissociation and Daydreaming

E: That's right, and that's what your hand is doing, and it is doing it very, very well. And the wrist is coming to rest, and the whole arm is going to feel relaxed and comfortable. And I can talk to the others. I can say anything to them, but you don't need to listen, and your head can shake No, that it won't listen. And it can shake No. [Ruth's head shakes No.] That's so you can go deeper and deeper and your hand can rest on your thigh. And perhaps the other hand would like to rest on the arm of the chair, and I don't know, but your hand will find out. That's right, and the elbow can straighten out. But of course it would be all right if I took hold of your wrist and lowered your hand, because that would feel all right. [E manually signals a lowering of her left hand.] That's right. And as you go deeper and deeper in the trance, it feels so restful and so very comfortable. And I'd like to have you enjoy all the learnings you are achieving. I'd like to have you enjoy that feeling of relaxation, that feeling as if you were all alone and relaxing comfortably by yourself. And you're getting that feeling. And I would like to have you enjoy the way that your head can nod in answer to questions. And it can, can't it? [Ruth's head nods slightly.] And I'd like to have you discover how easy it is, and you will discover how easy it is to feel yourself all alone, sitting in a chair all by yourself and feeling yourself at home, in an easy chair, just daydreaming, aimlessly, purposelessly, just daydreaming comfortably all alone. [E is nodding his head Yes throughout this section.] Nobody else around, and a very, very pleasant daydream. And as you daydream, you will nod your head, and as you enjoy it more, your head will nod a little bit more extensively. That's right. And a little bit more. And nodding more freely. That's right, still more freely. Nodding, nodding still more freely. [Ruth gradually nods her head very slightly.]

R: You continue your learning context, always associating it with enjoyment about achieving. You give her the internal tasks of dissociating herself to her home and daydreaming. You then give her the ideomotor signal of nodding her head to let you know when these internal tasks are accomplished. You have to do quite a bit of prodding to get that head movement. It could be that you're rushing a bit because of the time limitations in making a movie of this situation.

Assessing and Deepening Trance: The Second Apparent Awakening: Assessing the Possibility of Negative Hallucinations

E: All right, now rouse up. That's right. [Ruth opens her eyes.] That's right. And how much did you forget about the people that were here?

Ruth: Well, I didn't think of them.

E: You didn't think of them. And can you answer my next question? And I wonder if you can answer it? I wonder if you can answer it?

R: You assess the depth of trance by questioning her about amnesia and possible negative hallucinations about the other members of the group. Her answer is of a neutral sort consistent with trance experience, but it does not give any admission of deep trance experience.

Pantomime Suggestion for Further Dissociation

E: Is your name Ruth?

Ruth: Yes.

E: And now I wonder if you can nod your head? Is your name Ruth? [Ruth nods her head slightly.] All right. And this time I wonder what you'll discover. Is your name Ruth? [Ruth begins to nod her head continuously.] And keep nodding your head and see what happens. Is your name Ruth? [E begins to shake his head No, but Ruth nods Yes.] Is your name Ruth? That's right. And now it is going to shake more and more No, isn't it? And it is shaking from side to side—you can't stop. That's right. [Ruth still nodding Yes.] More and more from side to side, more and more from side to side, more and more from side to side. More and more. [Ruth continues nodding, so E makes exaggerated movements with his whole body shaking No.] And the nodding stops and the sidewise movement begins. [Ruth begins shaking her head No.] That's right, that's right, that's right, that's right, that's right, that's right, that's right, that's right, from side to side, from side to side. [E is still shaking his whole body from side to side.] And now I want you to feel comfortable and at ease, and I want you to feel rested and comfortable. And you will, will you not? [E now starts to nod broadly.] And you will, will you not? And you will, will you not? And you will, will you not? [Ruth still shakes No.] And you will, will you not? That's right. Slowly you will. That's right. Slowly you will. That's right. And now it begins, doesn't it? Up and down, more and more. [Ruth gradually converts her head-shaking to -nodding.] That's right, that's right, that's right. Up and down, and I want you to feel rested and comfortable and relaxed, and I want you to feel as if you had been resting for hours, and feeling so comfortable.

R: You continue sensitizing her to following your nonverbal head-nodding and -shaking. She seems confused at this point and becomes more and more dependent on following your behavior. Apparently you are dissociating her more and more so that she follows your behavior whether what you are saying is correct or not.

Third Apparent Awakening and a Double Bind Question

E: And I'd like to have you rouse up. And you'll rouse up as your hand lifts and lifts and lifts, [E signals a lifting of her left hand with touches.] and rousing up, your eyes are opening. That's it. Wake up feeling fine. Wake up. [She opens her eyes, but her left hand remains cataleptically suspended.] ***You think you're awake, don't you?*** **Are you really?**

Ruth: [Laughs] ***I'm not sure.***

E: Now you know the answer. You closed your eyes, didn't you? And you couldn't help that, could you? Are you awake?

Ruth: Um-hmm.

E: What did you think about that? Now, I'll ask you again, are you awake? [Ruth nods Yes, but then closes her eyes.] ***Would you like to awaken? Would you like to awaken?*** **[Ruth opens her eyes.]**

Ruth: ***No.***

R: Like the others, this third awakening is only apparent, since her hand remains cataleptically suspended. The double bind question, "You think you're awake, don't you?" provides enough confusion so that her left hemisphere answers that she is not sure. When you repeatedly ask if she wants to awaken, she finally answers, "No," meaning she is still in trance and does not want to awaken—even though she does manage to open her eyes.

Fourth Apparent Awakening with a Double Bind Question and Ideomotor Questioning to Assess and Ratify Trance Experience

E: [Laughs] You wouldn't? But you know all good things come to an end sometime. So close your eyes and take a deep breath and wake up wide awake, wake up, wake up, wide awake. Hi! How are you?

Ruth: I'm sleepy.

E: [Laughs] You're sleepy? You mean I've got to awaken you again? Well, I'll tell you the world's worst joke if I need to in order to awaken you, and if that doesn't, I'll tell you the world's second worst joke. Is that sufficient threat?

Ruth: I feel all right now.

E: [Laughs] You rested?

Ruth: Uh-hmm, very.

E: *Did you know you were a good hypnotic subject?*

Ruth: Not exactly—well—um—yes.

E: Um-hmm. Would you like to ask your unconscious the question? Now, if the right hand goes up, that means Yes. If the left hand goes up, that means No. Are you a good hypnotic subject? [Pause as her right hand goes up.] Of course. I wonder if you've noticed what's happened to this hand. And did you know you're back in a trance? And did you see the perfectly beautiful answer there?

R: You make a more serious effort to awaken her with the taking of a deep breath, your typical "Hi," and a question to evoke her conscious evaluation of her feelings. Since she is still tending to remain in trance, you utilize the situation to ratify her conscious acknowledgment of her trance experience. You do this in your typical fashion of asking a double bind question, "Did you know you were a good hypnotic subject?" Since she seems doubtful in her reply, you ratify trance further with an ideomotor questioning approach that tends to convince her, since her right hand does go up in an apparently autonomous manner.

Arrested Awareness to Ratify Trance

E: And now you've got that very, very nicely arrested awareness. [To Ernest Hilgard and Jay Haley off-stage] And you see she's very, very much out of contact with the total situation. There's a loss of the blink reflex, there's a loss of the swallowing reflex. As I mention these things, she may or may not reestablish them. But you see, I awakened her, she didn't want to awaken. I forced the issue. I shook hands with her. This way, which was out of order—and she is really going to go into a trance. And now what she's doing is the other thing, and carrying it out so very nicely, and this is going to come, and we are going to get that very nice continued maintenance of the trance state. Now, I doubt very much if she isn't much aware of the range of movement or the range of activity, and she is decidedly interested in her own experience at the present time. [To Ruth] Was I talking to anybody, Ruth? Were you listening?

Ruth: Sometimes.

R: Your description of the trance indicators she is experiencing is a way of further ratification of trance. You give this information to her in a slightly indirect way by telling it to the professional observers who are present. Speaking to them makes it more authoritative for her, since they are, after all, professional. Speaking to others about her is also a way of depersonalizing her and thus further reinforcing trance experience. Her response of "sometimes" is typical of the light to medium stages of trance, where the subject's conscious awareness or attending to the outside situation tends to fade in and out.

Doubt and Not Knowing to Ratify Trance

E: Sometimes. It wasn't really important for you to listen, was it? You're really enjoying watching your hands, isn't that right? *And actually you've forgotten where your hands are, you can just watch them,* And you really don't know how far up they move, how far down they move, isn't that right? And Ruth, now you can understand how unimportant everything else is and how important is your own experience as you continue in the trance. That's the important thing, what's happening within you and your own learnings.

R: Doubt and not knowing about her awareness and memory is implied with the subtle compound suggestion, "And actually you've forgotten where your hands are, you can just watch them." Notice how the second half of this sentence, "you can just watch them," is a simple statement of what she can do; she probably receives it with an implicit inner response of "Yes, I can watch them." This immediate Yes also tends to reinforce the associated suggestion about forgetting where her hands are. This doubt and not knowing about her own experience ratifies to her now reoriented habitual conscious sets that she has, in fact, been experiencing trance.

Fourth Awakening: Time Distortion to Ratify Trance

E: Would you like to awaken now?

Ruth: I don't know.

E: Well, suppose you look at your hands and see which one of them moves up. Would you like to awaken now? All right, so you can close your eyes and take a deep breath and let it seem to you as if you had been resting for hours and hours, as if you had been in bed for eight long, comfortable, and restful hours. And I would like to have you really rest that way and then rouse up and feel so rested and so comfortable, and willing to discuss things with this group. Will you do that? Will you do that? That's right. All right, now, slowly your hand comes to rest in your lap, and when it reaches your lap, take a deep breath and open your eyes and become wide awake. [Long pause] Lowering still more, that's right, still more. As soon as it touches your lap, take a deep breath and wake up wide awake and feeling rested, refreshed, and energetic. [Ruth makes a deep breath sound.] Wake up. Hi!

Ruth: [First, she makes an indistinct mumble or small laugh.] Hi. [Both Ruth and E laugh]

E: Well, do you mind if I change seats? You won't mind if I sit down here. Now what is the rest of the program?

Hilgard: We have a meeting in another place at 4:15.

E: Do you feel completely rested?

Ruth: Yes, I feel like more. [The group laughs heartily]

E: Do you know you are a very delightful subject to work with?

Ruth: Yes?

E: And sometime I hope Dr. Hilgard has you, or Dr. Weitzenhoffer has you—sit in and observe some other subject because you are capable of very extensive somnambulistic behavior. You have a tendency to—what should you call it?—utilize time in the way that I am particularly interested in. You show the phenomenon of time distortion. Did it seem to you that you were in a trance as long as you have been?

Ruth: No, I don't really—how long have I been?

E: Well, how long do you think?

Ruth: Well, it really seems just a few minutes.

E: That's right, it seems like a few minutes. Actually it was much longer than that. How long was it, Jay?

J: About an hour.

Ruth: Really?

J: About 50 minutes, anyhow.

E: About 50 minutes.

Ruth: Oh, that's amazing.

E: Now I bring that out because all of her hand movements tell you that she—that she is distorting time in a rather significant fashion, and if she were to watch some somnambulist do a number of things, in the tempo of the ordinary waking state, then you could have her learn that, and have her in addition show you her own spontaneous development of distorted time. Just getting technical. Now I'm supposed to go somewhere else in a few minutes. Anything you'd like to ask me?

> R: You're feeling it's time for the session to end, so you make a more determined effort to awaken her. You even change your chair in order to change the situation a bit and thus break associative connections with trance experience. You ratify trance directly by allowing her to assess the time distortion she experienced and indirectly by talking to the observers about her hand movements that were different in trance.

An Ideomotor Ratification of Amnesia and Dissociation

Ruth: Well, why wasn't I allowed to put my head back and really—I mean I wanted to—lay down and just fall asleep? I mean, and not hear anything. Do you always hear—I always hear you.

E: That's right. Some people say I'm not bad to listen to.

Ruth: No, you're very nice to listen to—but *I felt that I was in a trance, and yet I felt I wasn't.*

E: Uh-hmm. And yet you know you were, and yet you felt you weren't, and wanted to lean back. You know your picture was being taken.

Ruth: Oh, I forgot about that.

E: [General laughter] Do you mean to say that in your movie—

Ruth: —I'd rather have slept—

E: —debut, you forgot all about that? What else did you forget about?

Ruth: Oh, I don't know.

E: Didn't you forget about the presence of the audience? . . .

Ruth: Yes.

E: —more than once?

Ruth: I mean I'd—I just didn't care whether they were there or not.

E: And tell me, did it seem to you as if for awhile there you were at home?

Ruth: I could have been. I mean, I was comfortable enough to have been.

E: Yes, but could you have had a feeling there for a little while that you were actually sitting in a chair or lying on a couch at home?

Ruth: No, I don't believe so. ,

E: You don't believe so. Do you mind if we find out? Ruth: No.

E: Put your hands in your lap. Now, right hand lifting means Yes; left hand means No. Did you at some time during this afternoon's trance or trances feel yourself, sense yourself, at home in your own home? [Pause as right hand lifts] Lifting, lifting, and maybe as your hand lifts, you will have a conscious awareness of just where you were in that feeling. And so close your eyes and take a deep breath and lower your hand to your lap. Another deep breath and wake up, wide awake and feeling rested. Wake up, wake up. Hi. [Laughter]

R: You get into a bit of trouble here as you attempt to further ratify trance by having her acknowledge amnesia for the movie-making and the presence of the audience, along with a possible dissociation of place from the laboratory to her home. It would not be wise to end her first hypnotic experience with the doubt she expresses about these hypnotic experiences. You thus feel impelled to further ratify her experience with yet another ideomotor signaling. Fortunately the right hand lifts, giving a positive ratification, and you immediately awaken her on that positive note.

Doubt and Humor to Ratify Trance

E: Oh, you remember where you were in your sensation you're feeling?

Ruth: No, I just thought of—thought of being in the study. I didn't—I wasn't there, I don't remember being there. Just the thought passed through my mind.

E: Uh-hummm. [Laughter] Ruth: Oh, they're all scientists. E: Well, that's why the afternoon seemed so—brief-

Ruth: Oh, I—

E: —went home, it seems! Well, I suppose I've got to terminate this, and I want to thank you very, very much for your help. I've appreciated it greatly. Thank you.

R: Ruth gives some small acknowledgment of at least having a thought of being dissociated to the study in her home. It is in fact common for subjects to dissociate themselves to a comfortable home environment when they are in trance. That is why suggesting such a dissociation can be a good approach to deepening trance. But Ruth apparently did not dissociate in just this way on this occasion. It might have been better to ask a more general question about dissociation such as, "Was there a time during trance when you seemed to be somewhere else?" To this question Ruth might have given valuable information on just where she tends to dissociate herself. This information could then be used for deepening her next hypnotic trance.

EXERCISES AND SELF-DEVELOPMENT REQUIRED IN LEARNING ERICKSON'S APPROACHES

The preceding analysis of the reverse set is without question the most detailed approach to evoking a specific mental mechanism that we have ever presented. Learning how to evoke and utilize such mental sets could bring the process of trance induction and hypnotherapy to new levels of effectiveness. The exercises in this section are designed to help the professional reader gradually develop some facility in using this approach.

Many of Erickson's original papers in *The Hypnotic Investigation of Psychodynamic Processes* (Vol. 3 of *The Collected Papers of Milton H. Erickson on Hypnosis,* 1980) contain the basic background reading required. This is particularly true of the section, "Mental Mechanisms," where, in a number of papers written between 1939 and 1944, Erickson illustrates how he makes the transition from the typical psychoanalytic approach of analyzing to utilizing mental mechanisms. Not till several years later, in his highly innovative paper, "Hypnotic Psychotherapy" (1948), did he actually demonstrate how the utilization of mental mechanisms can be employed in a radically new kind of hypnotherapy. A patient and deep study of his paper will provide the reader with the essence of Erickson's utilization approach. The reader will find an ingenious utilization of the psychodynamic mechanisms of projection, amnesia, repression, and resistance, among others.

The greatest danger in reading some of these early papers by Erickson is that they make the work seem rather glib and easy, so that the reader feels foolish and frustrated if the techniques cannot be immediately and successfully duplicated. But these early papers do not specify the many years of patient study and effort Erickson went through in his late teens and early twenties, learning to develop his own psychological, sensory, and kinesthetic perceptions. His efforts were motivated by highly personal reasons as he sought in lonely desperation to teach himself to recover from the crippling effects of polio—despite the fact that his condition was assessed as hopeless by his doctors (see "The Autohypnotic Experiences of Milton H. Erickson," Erickson & Rossi, 1977).

In these early case presentations Erickson usually did not specify the many hours of diligent effort he spent studying and evaluating a patient's problem before proceeding with what then seemed like a quick and brilliant cure. Often Erickson would see a patient for a session or two and then ask him/her to return after a few weeks. He would then spend the time pondering what he knew about the person and how he could utilize that knowledge effectively to facilitate a cure that then seemed dramatic and surprising, but was actually based on many hours of careful and often tedious planning.

The first major requirement in learning to use Erickson's approaches would thus appear to be facilitating the personal development and clinical sensitivity of the hypnotherapist. Many of the exercises in our former volumes (Erickson, Rossi, & Rossi, 1976; Erickson & Rossi, 1979) were designed for this purpose. The second basic requirement is taking the time to undertake careful clinical studies of individual patients to determine what their dominant or preferred mental mechanisms are, and how these mechanisms can be engaged in the hypnotic process. The hypnotic work could then be organized in a systematic manner as follows:

1. How can a particular patient's own mental mechanisms and habitual associative processes be utilized to create a method of hypnotic induction that is uniquely suitable for that patient?

2. How can the patient's own mental mechanisms and associative processes be utilized to facilitate an experience of all the classical hypnotic phenomena?

3. Now, utilize this background of hypnotic training to help the patient find a uniquely suitable resolution of the presenting problem.

Although this three-stage paradigm is highly characteristic of the senior author's exploratory approach to clinical problems (Erickson & Rossi, 1979), he has long maintained that each case is unique, and he recognizes the essentially experimental nature of each clinical endeavor. But while each case has this exploratory and experimental aspect, the three-stage paradigm does provide a methodological outline of a therapeutic approach that could enable clinicians to describe and publish their work in this area on a comparable basis.

SECTION IV:

The Experiential Learning of Trance by the Skeptical Mind

Dr. Q was a young psychiatrist interested in having a hypnotic experience with Erickson. He was just passing through Phoenix and decided to call. He agreed to allow Dr. Rossi to tape the sessions for possible publication. After an agreeable half-hour in which a mutual feeling of trust and rapport was developed, Dr. Q expressed some of his difficulties and doubts about hypnosis and his wish to have Erickson facilitate his personal experience of trance. This took place in two sessions extending over two days. Of particular significance in these sessions was the emphasis on Dr. Q's experiential learning. Erickson reiterates his belief that the best way to learn trance is by experiencing it. Erickson said of Dr. Q, as he said of so many other professionals he has trained, "Now here is a trained man, skeptical! I had to meet him at that level. I had to give my suggestions in a way that would meet his needs for scientific understanding. I had to phrase what I said in ways that would appeal to his unconscious mind . . . ways he would not be able to analyze."

In this first session Dr. Q entered the beginning stages of the experiential learning of trance through catalepsy and "not doing." The experiential approach so well demonstrated in the session has important implications about Erickson's views of the nature of therapeutic trance. Trance can be most broadly defined as a state or period of intense inner absorption. The concept of trance depth is highly relative. Erickson likes to point out that a trance can be both deep and light at the same time. It can be deep in the sense that a person is so absorbed that he or she does not notice irrelevant stimuli like the traffic outside or a surgical tray dropped a few feet away. The trance is light in the sense that important and relevant stimuli like the therapist's voice are easily received.

There are some subjects, however, who have special requirements for the nature of the trance they are willing to experience. They object to the experience of trance as a kind of sleep or withdrawal from outer reality. They don't like to close their eyes or rely on automatic responses like hand levitation. Many modern subjects want to know what is going on at all times. In such cases Erickson ratifies trance by a careful questioning that heightens the subjects' awareness of any minimal alterations of their usual everyday mode of experiencing. A subject and observer might not believe a trance was experienced, but Erickson accepts *any* unusual pattern of subjective experience or responsiveness as an indication of at least the beginning stages of learning to experience trance. This is sometimes disappointing to subjects of our post-psychedelic era, who expect to experience striking alterations of awareness in trance. Striking alterations are certainly experienced in some subjects (see Chapter 9 of Erickson & Rossi, 1979), but the more basic problem for the skeptical and rational mind of our day is for the hypnotherapist and patient first to learn to recognize the minimal manifestations of altered states wherein therapeutic processes may be facilitated. This first session ends with Erickson giving Dr. Q some "rehearsal" in learning to experience the reentry into trance by following a posthypnotic cue before he can recognize what is happening.

SESSION ONE:
The Experiential Learning of Minimal Manifestations of Trance

Receptivity and Reinforcement in Compound Suggestions

E: Look at that spot there. Put your hands on your thighs. Now you do not need to talk. You do not need to make a single movement of head and hands. Just look at one spot, and I'm going to talk to you.

E: Dr. Q expressed so much skepticism and disbelief about trance. He had made his own inability to understand. Instead of suggesting something to him, I gave him simple statements with which to deal that did not seem to have much real significance. "Look at that spot there. Put your hands on your thighs. Now you do not need to talk." What he is not realizing is that in that simple way I am taking over the control of the total situation. I haven't offered anything with which he can take issue.

R: With these few simple directions you have indirectly established an acceptance set for a quiet, receptive mode of being. You don't tell him to be quiet and receptive; rather, you structure his behavior so he naturally will be.

E: That's right. "Just look at one spot, and I'm going to talk to you." There is no possible way of disputing either one of those. It is a compound statement: You do that and I do this. If he accepts my statement of what I'm going to do, he has to accept my statement to him of what he is to do. Only he does not know that.

R: This compound statement, "Just look at one spot, and I'm going to talk to you" gives two suggestions tied together with the conjunction, "and." The second suggestion that you have control over (talking) reinforces the first (he is to look at one spot).

E: Yes, it emphasizes my control in a way not recognizable in the ordinary conscious state.

The Indirect Use of Language: Depotentiating Conscious Sets and Channeling Resistance with a Casual Negative

E: But you don't need to listen.

R: Why do you begin here by telling him he doesn't need to listen?

E: It depotentiates consciousness and thereby potentiates the unconscious functioning. If there is any rebellion in his soul, it can now be centered in doing exactly what I told him: He *doesn't* need to listen. I'm taking control of any rebellion by telling him how to rebel.

R: If he is experiencing resistances, you gather them up with your negative *don't* and channel them into a resistive response *(not* listening) that can facilitate the hypnotic process (since "not doing" facilitates the parasympathetic mode of receptivity rather than self-directed activity). This is an example of your indirect use of language. You do not tell him he should not listen! That would require an active effort to cooperate. Your casual approach of merely mentioning that he doesn't need to listen has an indirect purpose that is entirely different: in this case to depotentiate his conscious sets and channel resistance into a constructive channel.

Depotentiating Left-Hemispheric Conscious Sets: Mind-Wandering and Truisms

E: You can let your mind wander because I'm going to mention to you something that happened when you first went to school. When you went to school, you were confronted with the *problem* of letters and numerals.

R: Letting the mind wander also depotentiates the conscious self-direction of left-hemispheric functioning in favor of right-hemispheric access to the personal and experiential.

E: Dr. Q and I are strangers, you know. How can I mention something that happened to him when he first went to school?

R: That is a question in his mind immediately.

E: Immediately! He is going to search his mind, and that is where I want him to be. But even you reading this could not see what I was doing! It is so indirect.

Now, what "problem" was there? He has really got to search. He has to determine that there was a problem. There is no way for him to turn away from this problem because it is true; it's a truism. Everyone has had a problem in the initial stages of learning.

R: You first lull his self-direction by permitting mind-wandering, and then indirectly nudge it into certain directions—in this case an early learning set—with a series of truisms that continue into the next section.

Intriguing Questions to Yo-yo Consciousness to Initiate Inner Search and Therapeutic Trance

E: To you at that time learning the letter "A" seemed to be an impossible task. And *how did you* tell a "B" from a "P"?

E: In response to my question he's probably thinking, "Why?" What is hard about the letter "B"? It has various shapes, sizes, even colors. Script and block printing. All kinds of forms. I've got another truism there that is within his experience. You can see how he's being played back and forth, up and down, being yo-yo'd, you might say. "How did you" is a question that gets him inside his own thoughts.

R: Your questions are taking him away from outer reality and putting him on an inner search.

E: Without telling him that! And he can't avoid what I'm saying because it is an intriguing thing.

R: By yo-yoing him back and forth between your intriguing statements and questions, you lift him out of his usual and habitual frames of reference and put him on an inner search that we have described as an essential aspect of the microdynamics of trance (Erickson, Rossi, & Rossi, 1976; Erickson & Rossi, 1979). Intriguing statements and the yo-yoing process, as you call it, are indirect or metapsychological uses of language to secure attention and initiate that intense focus of inner search and automatic unconscious processes that we define as therapeutic trance.

Utilizing Internal Reinforcement to Facilitate an Acceptance Set

E: A "Q" from an "O"?

E: A "Q," you know, is hard for every kid. An "O" is easy. So I give him the hard thing first, and then he accepts the "O" because that is easy.

R: So you have reinforced "Q" by putting an easy "O" after it. This is how you reinforce with a subtle truism right within the same sentence. You are utilizing his own already built-in internal patterns of reinforcement to continue his acceptance of what you are saying. This is another illustration of your indirect approach: When you feel one suggestion may be difficult to accept, you immediately reinforce it with another related suggestion that is easier, more acceptable, or more motivating. The second, easier suggestion also leaves him with an acceptance set for what follows.

Words Extending Unconscious Activity in Time: Posthypnotic Suggestions

E: *But eventually* you learned to form mental images. Mental images that you did not know at the time would stay with you for the rest of your life.

E: "But eventually"—how long is *eventually?*

R: Could be any length of time. It's fail-safe to say *eventually* because it is open-ended in time. Other words like *yet, until, when, sometime, henceforth,* etc., all have a time aspect that can continue unconscious activity from the past to the present and future. We know that some posthypnotic suggestions, for example, can continue over decades (Erickson & Rossi, 1979). It would be a fascinating research project to find some means of experimentally evaluating the extent to which different words and suggestions are effective in setting unconscious processes into activity over time.

E: That's right. I'm also preparing him for what takes place after this. That word *eventually* stretches from kindergarten to old age. With his training in psychology, he knows that very well.

R: That is the indirect use of a truism again: a safe statement that utilizes his own knowledge to reinforce what you are saying.

Focusing the Attention of the Modern, Rational Mind Inward with Intriguing Learning Experiences

E: You had to learn the numerals, and *how do you tell the difference between an upside-down nine and a right-side-up six?* It seemed impossible at first, and which way do you make the number three?

E: "How do you tell the difference between an upside-down nine and a right-side-up six?" Well, that is intriguing. So he is not going to be thinking about anything else. I am focusing his attention inward to his own experience.

R: That's what you are doing in presenting all these intriguing learning problems. It is not the particular content that you are interested in. It is the indirect *process* of focusing inward that is the important matter. A modern, rational mind like Dr. Q's is intrigued with learning, so you utilize this interest to focus him inward.

E: Early learning is a long, hard task, and all kids go through that.

R: So this approach is actually valid for most people who have gone through the educational process. You are focusing them on valid inner experiences you know they have had. They cannot dispute it. You move them away from external reality.

E: Very far away.

Hypnosis as Loss of Multiple Foci of Attention: Maintaining the Absorption of Trance: The Role of Poetry and Rhyme

E: But you formed mental images, and later you formed mental images of words, of *faces,* of *places,* of objects, of a great many mental images.

R: Thus far there is no question of an altered state of consciousness or trance; it is just a shift of his focus of awareness.

E: The shift of the focus of awareness.

R: Where now does the altered state of consciousness come in? Do we need the concept of an altered state of consciousness or is it just a shift in the focus of awareness that is involved? Maybe that is all hypnosis is: a shift in the focus of awareness.

E: *All hypnosis is, is a loss of the multiplicity of the foci of attention*.

R: I see. A loss of the multiplicity of the foci of attention. Is that the monoideism of Braid? You really agree with that?

E: Except it isn't just a monoidea, but all the *multiple* foci of attention; the desk, the birds, the bus have all been eliminated.

R: Okay, now would you define this loss of multiple foci of attention as an altered state of consciousness, or is this just a game of words?

E: It's an altered state of consciousness in the same sense as you experience in everyday life when you are reading a book and your wife speaks to you and you make no immediate response. You are obviously experiencing some sort of altered state involving time distortion when 10 minutes later you answer, "Did you speak to me?"

R: That's the sense in which hypnosis is an altered state of consciousness; the same as that experience of absorption in reading an interesting book.

E: *It is a lack of response to irrelevant external stimuli*.

R: That's the altered state of consciousness that constitutes trance: deep absorption on a few foci of inner experience to the exclusion of outer stimuli.

E: And to use it for therapeutic purposes, it must be maintained.

R: Part of the art of the hypnotherapist is in maintaining that trance state.

E: Yes. You deal with that altered state in any way you wish, but you are keeping that altered state.

R: That's the purpose of many of your verbal suggestions to the patient—trance maintenance.

E: I never really made up my mind whether the rhyme of "faces" and "places" was important in maintaining trance. But all these words, faces, places, and objects—there are so many in his past. In anybody's past. And I'm really enlarging that altered state of consciousness to permit the entry of words, faces, places, and objects.

R: That interesting little book, *Hypnotic Poetry* (Snyder, 1930), certainly suggests the importance of rhyme and rhythm in trance. By adding these other words you are reaching into his memory banks; you are bringing other memories and associations into the realm of the trance focus, for whatever values they may have for maintaining the trance and laying down an associative network for therapeutic work.

E: Yes, and making it possible to enlarge that altered state. But it is all within him; nothing from his outer environmental situations is important while he is focusing within during this trance work.

Indirect Suggestion for Visual Hallucinations: Constructing Implications with Time

E: And the older you grew, the more easily you formed mental images.

E: Dr. Q doesn't know that is a suggestion: The older he grows, the more easily he forms mental images.

R: What's the suggestion here?

E: He will easily be able to do whatever I tell him with regard to visual images. That's the implied suggestion. It is awfully hard to see it.

R: This is another subtle use of time to construct an implication that could be preparation for hallucinatory experience later.

E: Yes, later.

Depotentiating Conscious Sets: Structured Amnesias

E: And you didn't realize it at the time, but you were forming mental images that would stay with you for the rest of your life. Now you don't really need to listen to me because your unconscious mind will hear me. You can let your conscious mind wander in any direction it wants to.

R: Why do you repeat that phrase about forming images that would stay "with you for the rest of your life" here? You said it earlier in a previous section (Words Extending Unconscious Activity in Time).

E: It's tying that previous section with this section.

R: Oh, so that all between them falls into a lacuna and will tend to become amnesic! It is a structured amnesia.

E: Yes, all that material will fall into a lacuna. I also said that about not needing to listen to me and letting your mind wander in an earlier section.

R: That again tends to structure an amnesia while also depotentiating his conscious sets.

Ratifying Trance: Inner Focus for the Experiential Learning of Trance

E: But your unconscious mind will pay attention, you will understand. And *you are drifting into a trance. You've altered your rhythm of breathing. Your pulse rate is changed.* I know that from past experience.

R: Are you giving him a direct suggestion by telling him he is drifting into trance?

E: No, that is a statement of fact based on the alterations in his breathing and pulse that I can actually observe. I did not say, "You've *drifted"* (past tense): I just observe, "you are drifting into a trance" (present tense).

R: You observe these changes that are actually taking place and comment on them so that his own inner experience can ratify that trance is really taking place. You don't suggest trance is taking place: You prove it!

E: Yes. He has to examine his rhythm of breathing. He is still within himself! He has to examine that rhythm of breathing in terms of drifting into a trance.

R: You're keeping the focus inside of him, and you are getting him to ratify his own trance through these experiential learnings.

The Role of the Conscious and Unconscious; Left- and Right-Hemispheric Focus in Therapeutic Trance

E: And you're trying so hard to understand instead of just experiencing.

E: This implies I'm going to say things to you that you will try hard to understand instead of just experiencing. It implies you're going to do more than just experience.

R: This I find difficult to understand! I thought you were trying to turn off the conscious mind in order to facilitate the unconscious and the experiential mind. When you ask him to "understand," it sounds like an appeal to do left-hemispheric conscious work.

E: You still don't grasp it! I've already turned off his conscious mind except to a minor degree. And I'm trying to make his unconscious mind understand: You've got a lot of work ahead of you in addition to just experiencing.

R: We could formulate this as a two-stage process of trance induction and utilization. In the first stage, *trance induction,* you depotentiate Dr. Q's currently dominant left-hemispheric conscious sets. This then facilitates the release of right-hemispheric unconscious processes, which contain the experiential learnings and repertory of response possibilities that will be used as the raw material for the hypnotherapeutic changes you will evoke. In the second stage, *trance utilization,* you reactivate left-hemispheric processes to now act upon ("reassociate, resynthesize"; see Erickson, 1948) the released right-hemispheric contents in order to reorganize them into hypnotherapeutic responses.

Depotentiating Conscious Sets While Engaging Unconscious Processes to do Constructive Work: Gentle Direct Suggestion for Unconscious Work

E: ***You don't need to understand. All you need to do to drift along and feel relaxed and comfortable.*** **And I don't even need to talk to you because there is nothing that needs to be done. But you can rest comfortably while I speak to you,** ***your unconscious mind will hear me*** **and** ***do as I say, as I indicate.*** **[Pause]**

R: You again depotentiate left-hemispheric conscious sets with not knowing ("You don't need to understand") and drifting along, relaxed and comfortable.

E: That enhances the trance state and implies that he is going to maintain the trance.

R: Maintaining the comfort and relaxation of trance means that nothing needs to be done by left-hemispheric consciousness. Then you clearly indicate that the unconscious will hear you and do as you say.

E: "Do as I say, as I indicate"—that's complete obedience.

R: What? You are giving a direct suggestion for obedience! E: But it is said so gently. It is so comprehensive.

R: And you're not telling the conscious ego to obey you; rather, you're gently nudging the unconscious to respond to verbal stimuli you're providing.

Dissociating Frames of Reference to Facilitate Hypnotic Phenomena: The Art of Reinforcing Suggestions

E: ***And I can talk to you, to Dr. Rossi*** **all I wish. But you don't need to pay any attention to that.** ***You are busy with your unconscious mind,*** **looking at that mental image.** ***You just rest.*** **[Pause]**

E: "And I can talk to you"—that's one frame of reference; ". . . to Dr. Rossi" is another frame of reference. I'm separating, dividing the situation.

R: That separation and division is an essence of the approach by which you effect dissociation and set the stage for experiencing most hypnotic phenomena. This dissociation is the important hypnotic phenomena, the important unconscious work you have been leading up to in the past few sections. You tell him, "You are busy with your

unconscious mind." Let your conscious mind rest while your unconscious does the work of engaging its dissociative mechanisms.

E: That's right, there is nothing else. And it is said so gently and so acceptably.

R: You don't give him, a psychiatrist, a difficult left-hemispheric cognitive task by telling him to "dissociate" the conversation. Rather, you give him a concrete task of separating the talk to him and to me, Dr. Rossi. The right hemisphere can perform this concrete sensory-perceptual task and thereby engage its dissociative mechanisms. You evoke unconscious processes not by informing him of what mechanisms to use but rather by giving him a task that will automatically evoke these mechanisms. This is one of your favorite indirect approaches: You give a suggestion or task, not because of any inherent interest in it, but rather to evoke those mental processes that are required to carry it out.

The placement of your final phrase, "You just rest," reinforces the statement just before it, "You are busy with your unconscious mind." You do that a lot, don't you? You use one phrase to reinforce another. That is an important aspect of the art of suggestion.

Rapport and Indirect Suggestion to an Audience via Voice Locus

E: Now, Dr. Rossi here is somebody who is trained in psychology. He has been oriented to place individual meaning or interpretations on everything according to his past teachers. *He does not know very much about* looking at or *experiencing reality.* He must experience reality in terms of what he has been taught and read.

R: *Huh?!* [Pause]

R: You caught me by surprise here; although you were apparently talking to Dr. Q, you were actually beaming important suggestions to me. I was so absorbed in watching Dr. Q that I was actually experiencing what you would call the common everyday trance. I finally wake up out of it with my "Huh?!" You also shifted your voice tone and its location to provide a clue to my unconscious even before my conscious mind realized what you were doing. In fact, I did not realize it until I began going over this transcript to prepare for these commentaries. This was a typical example of how you use indirect suggestion to turn over the associative processes of someone in the audience without their quite realizing it.

E: And that different locus of voice *is* important.

R: Even though the subject is not aware of it consciously.

E: At the same time I'm adding to the rapport by pulling him closer to me and excluding you from the situation from his point of view.

R: Why do you want to exclude me?

E: I thereby increase his areas of functioning in accord with what I say, what I indicate.

R: I'm irrelevant for that, so you exclude me to focus all his mental energies on himself. At the same time he also gets the implication that he must learn to experience more on his own and not be limited to just what he learned from books and his past teachers. This is one of those peculiar situations that's so hard to analyze: Dr. Q and I both received the same indirect communication, but in different ways—each from his own frames of reference.

E: Yes.

Catalepsy to Ratify Trance

E: *Now I'm going to touch your wrist.* [Erickson touches Dr. Q's wrist and very gently provides tactile cues to facilitate a lifting of his hand and arm of about six inches.] I'm going to touch your arm. I'm going to put it in this position. [Pause as Erickson arranges a somewhat awkward position of Dr. Q's wrist by positioning his hand at an odd angle relative to the arm. The arm does not remain in the air but drifts down to Dr. Q's lap. One or two fingers touch his thigh, and the others remain poised and unmoving in the air. His hand is not really resting "normally" on his thigh, but appears to remain cataleptically suspended with only the lightest touch on his thigh.]

E: "Now I'm going to touch your wrist." So what's the big deal? There is no big deal there at all. It is a safe procedure.

R: You are setting up a catalepsy in a very innocent way.

E: Very innocent—the odd angle is the important thing.

R: Why is the angle in which you place the hand so important?

E: In lifting the subject's arm, I'm not going to tell him I'm lifting it purposefully to achieve a certain goal. But I am lifting it to achieve a certain goal. When the goal is reached, I can see it, but he doesn't even know it. And so he is behaving in accord with the tactile stimuli I've given him.

R: What does that prove? Why are you engaged in that?

E: When you lift up a person's arm, they seldom leave it up in midair, do they?

R: No, not normally.

E: And when you put it in an odd angle, they are much more likely to correct that odd angle, are they not?

R: When you do this in trance, the subject just leaves it there. Is this then a test of the trance state? Is that why you are doing this?

E: I was doing it more to prove it to you so you could have visual proof.

R: So that catalepsy was to convince me. How about to convince the patient?

E: Sooner or later he will find out his arm is still there. And that is contrary to all his past experience. He will have to investigate it, and it will be very convincing to him.

Not Doing: Catalepsy is a Form of Mental Economy Utilizing the Parasympathetic Mode: Electrodynamic Potential as a Measure of an Altered Receptivity Expression Ratio: A Proposed Definition of Therapeutic Trance

E: And I'm not Instructing you to put it down. [Pause]

Dr. Q: Umm, that—

R: Why the "not," here? Why not simply say, "hold your hand up?"

E: Whatever he does has to be on his own responsibility.

R: So he will hold it up on his own responsibility because the implication of your remark is to hold it up.

E: No, his hand was already up. The only way he can get that hand down is for he himself to undertake that task as a separate, totally separate, totally individual task. It is much easier to allow that state of balanced tonicity to remain. He doesn't have to do anything!

R: I see, it is simply an economy of mental effort to leave the hand there rather than go through the labored decision process of whether or not he should put it down in this situation.

E: That is better than telling him, "Don't put it down."

R: Otherwise, after you lift his hand, he could put it down as part of the same act; the lifting and putting down would be one total act. But when you lift his hand and say, "I'm not instructing you to put it down," that means one act (lifting) is completed, and to put it down would require another act on his part demanding a separate decision and expenditure of energy. Since he is in such a relaxed state of trance, it would simply be easier to let the hand remain there. You incisively do something (like lifting an arm) and then cut it off, limit it, so that he needs a lot of decision and energy to change it. It is harder to put it down than leave it. So there is an economy of effort in trance. Would you say in trance the parasympathetic system, the "relaxation" system of the body, is more dominant than the sympathetic?

E: Yes, it is.

R: That is why you place so much emphasis on "not doing" in trance: Not doing is natural when relaxed in the parasympathetic mode; doing things is more natural in the outgoing, high-energy output characteristic of the sympathetic system. I believe that is what the Burr-Ravitz device measures, by the way. When the Ravitz curve goes down, it means the patient is in a passive-receptive mode. I've conducted ordinary therapy sessions without the use of hypnosis while measuring a patient's electrodynamic potential (Ravitz, 1962), and when the patient is really absorbed in a moment of introspection or listening to me in a receptive manner, the potential goes down. When they are putting out energy to express, the potential goes up.

E: It is an altered state.

R: Altered in a direction of receptivity. In trance the normal alteration of receive and express is cut off in favor of continual reception. That reception can be from within—as when one is receptive to their own imagery, thoughts, feelings, sensations, and fantasy—or it can be receptive to something from the outside, like the therapist. The electrodynamic potential seems to remain low as long as one is not making the normal effort to respond actively.

E: And use the normal pattern of multiplicity of foci of attention.

R: That's right, the foci of attention have a restricted range in trance—the range being defined frequently by what the therapist suggests. This indicates that we could also define therapeutic trance as an alteration in the normal balance of receptivity and expression that is characteristic of an individual. Anything that shifts the individual to a higher receptivity/expression ratio would be a shift toward therapeutic trance. Research would be needed to determine how our proposed receptivity/expression ratio could be measured, and the degree to which it is similar to or different from some measure of the relative dominance of the parasympathetic system to the sympathetic: the parasympathetic/sympathetic ratio.

Catalepsy as Balanced Tonicity

[Dr. Q experiments very slowly for about two minutes, moving his arm a bit at the elbow and shoulder, but not the wrist and hand.]

E: ***Now, nobody knows what any one person learns first.***

Dr. Q: Ummm.

R: What is he doing, moving his elbow and shoulder about that way?

E: He knows there is something different in that arm, and he is trying to find out what it is. He knows there has been a change.

R: And that change is balanced tonicity?

E: Yes.

R: That balanced tonicity, you believe, is a different physiological state?

E: Yes, that's right.

R: The balanced tonicity means there is an equal pull on the agonist and antagonist muscles, is that right?

E: That's right. All day long you keep your head in a state of balanced tonicity.

R: That is why we don't get tired holding up our head—it is balanced tonicity. If there was a pull on one side or the other, we would get tired.

E: That's right. In other parts of your body you are not accustomed to balanced tonicity.

R: Catalepsy is introducing balanced tonicity into another part of the body?

E: Yes, into another part of the body where it is an unfamiliar thing.

R: That is what Dr. Q is investigating.

E: But he can't understand it, nobody has ever explained to him what balanced tonicity is.

R: How did you introduce that balanced tonicity? Just by those subtle tactile cues to lift the hand?

E: No. He's in a trance state, where there is balanced tonicity. And then when 1 tell him "nobody knows what any one person learns first," I'm telling him that he is learning, but I'm telling it as a truism that he cannot dispute: We really don't know what any one person learns first.

"Wait and See" as an Early Learning Set: Evoking and Facilitating Response Potentials from Idiomatic Expressions with Multiple Meanings: The Essence of Hypnotherapeutic Work

E: Wait and see. [Pause] The only really important thing out of this—

E: "Wait and see"—what on earth does that mean? There is nothing to be seen. That is an idiomatic instruction to keep on learning.

R: Without saying, "Keep on learning," and possibly arousing resistance.

E: That's right! Just "wait and see." That is so enigmatic that it arouses expectation!

R: And when a person has waited in the past, they frequently have learned something new, so you are also setting into action and utilizing a learning set that has been relied on since childhood.

E: Yes, and it is also asking for passivity.

R: Yes, the passive-receptive type of learning is another implication. You do this repeatedly: You make a general statement; frequently it is a cliché or an idiomatic expression that has many meanings, many implications. You presume you are utilizing many if not all the meanings. The patient is certainly not aware of all of them at any given moment, but these multiple meanings are evoked at some level and then focused to facilitate response potentials that might not otherwise be possible for the patient. You first evoke a plethora of associative processes and then somehow focus on one or

two that will be reinforced into overt behavior. This is the essence of your work as a hypnotherapist: to evoke and facilitate response potentials that the patient's own ego cannot quite manage yet.

The way you first evoke multiple associations and meanings is akin to Freud's idea of the multiple determination of symptoms from many different life experiences and lines of associations. With symptoms, however, we are the victim of these multiple paths of psychic determination that we cannot control. You presume to use the same principle to actually facilitate desirable behavioral responses.

E: The "this" in "The only really important thing out of this" is not defined, but it refers to the learning.

R: You don't always know what the hypnotic learning is, but you reinforce whatever it may be.

Principle of Paradoxical Intention: Memories for Inner Focusing

E: —is what I say to your unconscious mind, nothing else. Your conscious mind can tend to or attend to memories of anything. [Pause]

E: It "is what I say to your unconscious mind, nothing else." That means, Don't pay attention to the room, nothing else is important. I've excluded Dr. Rossi, the room, the floor, the sky. But I haven't told Dr. Q to disregard those things.

R: Right. If you actually mentioned those extraneous things, then by the principle of paradoxical intention he would be focused on them even though you told him not to.

E: "Attend to memories"—that is, not external realities. R: You are focusing on inner work again.

The Double Bind and Unconscious Mind as Alternative Metaphors

E: And now I'm going to give your unconscious mind some instruction. It isn't important whether or not your conscious mind listens to it. Your unconscious mind will hear it—

E: His unconscious is unreachable by him, but I can say anything I please.

R: So long as you address your remarks to Dr. Q's unconscious, you are using the conscious-unconscious double bind (Erickson & Rossi, 1979). He can only control his conscious mind, not his unconscious. Is this also a way of dissociating a person?

E: That's right. It also depotentiates conscious sets just as it does to add the phrase that it's not important whether the conscious mind listens.

R: Do you really believe that there is an unconscious mind that will hear you? Or is this all just a way of formulating a double bind?

E: I know his unconscious is listening. It has to. He's only a few feet away from me, my voice is loud enough. It will!

R: You actually operate on the assumption that any unconscious mind really exists and you can tell it what to do; others would view the unconscious only as a metaphor. My best understanding is that the double bind tends to depotentiate conscious, voluntary (intentional) control of the left hemisphere over the associative processes so that more involuntary response potentials of the right hemisphere will become manifest.

Casual Approach to Posthypnotic Suggestion

E: —and keep it in mind. From now on you can always go into trance by counting from one to 20, going into the trance 1/20th at each count. [Pause]

E: "And keep it in mind," but I didn't do it elaborately, "Now forever more you will remember!"

R: So casually put it does not arouse resistance.

E: Yes, I'm just making talk, that's all.

R: It seems to be an explanation describing how he can go into trance. But actually it is a posthypnotic suggestion?

E: Yes.

Time Distortion to Ratify Trance

E: Now I'm going to suggest that you awaken by counting silently, mentally, to yourself from 20 to one. And you can begin the count, now! [Pause for 50 seconds, and then Dr. Q begins to awaken.]

R: Why do you like to have people go into trance and come out at the count of 20?

E: Sometimes I use a stopwatch. It tells them they have had an altered experience. I can show it to them.

R: If they are far off in their estimate of how long it took them to awaken, it is a way of ratifying trance due to the time distortion.

Questions to Ratify Trance

E: *Are you fully awake?* [Dr. Q stomps on the floor and stretches a bit more.] Now the first part of the awakening was done by facial movements. Then the respiration alteration and the head and neck movements.

R: Um-hum.

E: And more facial movements and still further alteration of the respiration. You will note how rapidly. How long did it take you to awaken?

Dr. Q: About 35 seconds.

E: [To R] How long was it?

R: About 45, closer to 50. [Pause]

R: "Are you fully awake?" asked after he is moving and awakening ratifies the trance.

E: Yes, it really ratifies trance to his unconscious mind, and his conscious mind can think anything it pleases.

A Double Bind Inquiry to Ratify Trance

E: Do you know if you were in a trance?

Dr. Q: Felt like I was in a light trance.

E: What all occurred?

E: This seems to be just a simple inquiry, "Do you know if you were in a trance?" Whether the answer is Yes or No, it admits a trance: A Yes response admits a trance, but a No response also admits a trance! A No response means, "No, I didn't know I was in a trance."

R: If you said, "Did you know you were in a trance?" that would be an even clearer way.

E: But he can dispute it if you put it that way. The way I put it was just asking for information for myself, not for him.

R: What if he says, "No, I wasn't in a trance?"

E: Then I'd say, "That's fine, you really didn't know." I'm putting doubt in him, and I'm speaking the truth—he really didn't know.

R: So your question was a double bind: Any answer he gives automatically ratifies trance. The double bind is effective in this situation because it's being used to depotentiate the limitations of his doubting and skeptical mind that does not know how to recognize the reality of his trance experience. Some level of awareness within him that does recognize the reality of the trance experience is thereby potentiated into awareness, so that it may be more possible for his conscious belief system to overcome its limiting bias and accept the reality of the altered state.

The double bind is effective in altering one's belief system only when it is used to confirm a truth that is known at some level but denied because of the biasing effect of the conscious mind's learned limitations. The double bind can facilitate the recognition of a truth only when it is confirmed by something within the subject. You probably could not get away with using it to foist something on a person if this inner confirmation is absent.

Outlining Amnesias

Dr. Q: Well, the most significant thing is that you touched my arm and said, "I'm not instructing you to put it down." I *felt badly* because I—my arm should have hung there in a trance, and it didn't.

E: Ask Dr. Rossi if that is a correct memory.

Dr. Q: Is that a correct memory?

R: I'd like to have you describe your experience in more detail. Did it hang there at all?

E: What he doesn't know here is that he is outlining his amnesias. He doesn't know it, and you didn't know it. He doesn't really know what his arm did. When he says he "felt badly," it means he felt bewildered. He didn't know what to understand. Something was altered, but he doesn't yet understand what.

Learning to Recognize Minimal Indications of an Altered State: Muscle Sense and Distraction

Dr. Q: It might have done this [touches his thigh very lightly with hand that is partly suspended in air]. I felt the pressure of my fingers against my leg. *I did feel my muscles try to carry out the suggestion,* but I don't feel that I did.

R: [To Dr. Q] I noticed that your hand dropped a little bit, but I felt it was a satisfactory catalepsy.

Dr. Q: I didn't.

E: [To Dr. Q] Did you notice that your skin was touching, your fingertips were on your leg? Were they?

Dr. Q: Fingertips were on my leg?

R: One or two were touching.

Dr. Q: Something like that. Like this. [Dr. Q correctly demonstrates.] And I think you [Dr. R] wrote something.

R: Yes.

E: All right. Let's take up the question of values. How important was Dr. Rossi's writing?

Dr. Q: *I think it distracted somewhat.*

E: Did it have any value for you at all?

Dr. Q: Well, I was receiving some attention, so I think I enjoyed that aspect of it.

R: Was it a partial response here when he says, "I did feel my muscles try to carry out the suggestion?"

E: [Erickson demonstrates by lowering Rossi's arm.] Did you feel your muscles? How do you feel your muscles?

R: I did not have any particular feeling in my muscles when you guided my arm. The very fact that he is feeling his muscles means that he is in an altered state. His foci of attention are concentrated on his muscles. When patients say something like that, you know they have been experiencing trance?

E: They have been experiencing an unusual feeling.

R: Now, someone like T. X. Barber (1969) might say that you have just shifted their focus of attention, but that does not mean there is a trance.

E: I haven't shifted the focus of attention—he has! He doesn't do that consciously. What did your writing distract? He is validating that something was there that your writing distracted him from. Only he doesn't know he's saying that.

R: From Dr. Q's point of view he was not experiencing enough of trance. This seems to be highly characteristic of many modern subjects in our post-psychedelic revolution who deeply covet an altered state. But from your point of view he is just a beginner whose first task is to learn to recognize and welcome any minimal alterations that take place, however slight. Even mental health professionals today think of hypnosis as a fast key to miracles. But the reality is that learning to experience an altered state of consciousness usually requires time, particularly for professionals because of their critical and skeptical attitudes. They first need to learn to recognize these very subtle cues that imply an alteration has taken place.

Questioning to Ratify Trance and Inform the Unconscious

E: You are receiving attention right now. Since I asked that question, how many cars have passed?

Dr. Q: I have no idea.

E: That's right. Of what importance was the passing of the cars while you were answering that question?

Dr. Q: Answering whether the cars passed or not?

E: Urn-hum. I know that they didn't have importance for you.

Dr. Q: No.

E: Dr. Rossi's writing had no value for you. ... All right, now I'm going to ask you to shift from that chair to that one.

R: What is your purpose in asking Dr. Q all these questions?

E: I'm using them to ratify the trance, and I'm directing his attention to various things. And I'm not telling him! I'm just asking for information. You ask for information about all the things you want him to be aware of unconsciously.

R: They seem to be innocent questions, but actually you are informing his unconscious?

E: Yes, to make known anything that happened.

An Hypnotic Demonstration for Indirect Trance Training

The senior author now demonstrates an hypnotic induction and trance with another, more experienced subject, as a learning experience for Dr. Q. Dr. Q believes there has been a role shift so that he, as a young psychiatrist, is now being trained to induce trance in others by watching a demonstration. The purpose of this procedure, of course, is that without being aware of it, his unconscious is receiving indirect suggestions for learning to experience trance personally.

After this demonstration and a discussion of it, Dr. Q talks about himself and his professional work. He describes his uncertainty and tenseness when working with groups. Erickson draws an analogy with going to the theater. One might or might not be interested in the play being presented, but there are certainly many interesting observations that can be made on the audience: One can distinguish those who can hear and those who cannot, the man or woman who came only because their spouse insisted, etc. "You can see a lot of things, but you enter the theater not knowing what you are going to discover there. There are plenty of alternatives in any situation. . . . When you attend a session of group therapy, what on earth are you going to see? That is what you go there for." The conversation then continued as follows.

Posthypnotic Suggestion initiating the Microdynamics of Trance Induction: Therapist's Behavior in Focusing Attention for Trance Induction: Interspersal Approach and Voice Dynamics

Dr. Q: There is a lot going on at all times.

E: Much more than you can see, and you have no time for anxiety.

Dr. Q: I think my anxiety is because I feel so blind in the situation where there is so much data coming at me that I can't understand it.

E: And everybody learns to count. *First they count up to one. Then they count up to two, and five, and 10 and 20.*

Dr. Q: Hummm. [Dr. Q blinks uncertainly and then closes his eyes. He begins to raise a hand toward his face, as if to scratch his nose, but the motion slows down, and his hand finally becomes motionless after it touches his nose and makes only a preliminary movement of scratching. His hand becomes cataleptically fixed in mid-scratch. His face relaxes, and he is obviously entering trance. Erickson pauses a moment or two, observing him intently, before continuing.]

E: He is following the posthypnotic suggestion given back in the last session.

R: Even though it did not seem like a posthypnotic suggestion when you told him he could reenter trance on a count of one to 20.

E: There was no way for him to identify it as a posthypnotic suggestion.

R: You said in the last session that he would go into a trance when he counted from one to 20, not when you, Dr. Erickson, counted. Yet you count here, and he goes into a trance. Why?

E: All right, now, see what you do. [Erickson now begins to count to 20 while staring with intense interest at R, who in turn feels a strong hypnotic effect and momentarily closes his eyes, obviously responding to it.] Do you follow? You have been counting with me.

R: Oh, I see! When you count, it automatically evokes a counting response in the patient, and that is his cue for entering trance.

E: Yes. You see, it doesn't fit in with anything. It was an interspersal technique.

R: The count from one to 20 was interspersed in the normal flow of conversation.

E: Yet it doesn't belong there, so he has to think, "What?" But he doesn't know.

R: The conscious mind is startled and doesn't know why. That startle leaves a gap in awareness and allows the unconscious to fill in.

E: Yes, because whenever your conscious mind does not understand, it says, "Wait a minute, that will come to me." What are you saying? In effect you are saying, "My unconscious will help me."

R: The typical microdynamics of trance induction come into play here: (1) Your remarks about counting do not fit the context of the conversation, so his *attention is immediately fixated;* (2) the conscious mind's *habitual sets are depotentiated* by the startle effect; (3) not knowing what it means initiates an *unconscious search* that (4) locates and *processes the posthypnotic suggestion* you gave him previously so that (5) he experiences the *hypnotic response* of reentering trance. I notice that you stared very intently and expectantly at him when you gave him the posthypnotic cue. Is that searching look of yours important?

E: I couldn't let him trivialize my counting as a meaningless utterance, so I looked at him as if I was really saying something.

R: That is a problem I've had with posthypnotic suggestion. I mention the cue, but since I did not have the patient's full attention, they just ignored it.

E: When you speak to a person, you let them know, "I'm speaking to *you!"* You can speak directly with your eyes or your voice or with a gesture. You have to have the person's attention. If you have been speaking casually and then use a very *soft* voice, you immediately get the person's attention.

R: So that is another built-in habitual mode of responding that you are utilizing. Simply by lowering your voice in initiating an induction, you fixate attention, and that already accomplishes the first step of trance.

E: Yes, that narrows the person's attention. I use a soft voice because that compels attention.

R: So, when initiating a posthypnotic cue, you first try to fixate attention so that it is not running on and on in its own association patterns. You focus attention so the rest of the system is momentarily open and receptive. The unconscious can then respond.

Awakening to Ratify Trance

E: *And now* you can begin to count backward from 20 to one. [Pause for about 30 seconds, after which Dr. Q moves and apparently awakens.] I only wanted to surprise Dr. Rossi.

R: I was still listening to your stories!

E: "And now" implies that he has accomplished the trance. From that accomplishment he can proceed to the next, which is counting backward.

R: You thereby quickly ratify his accomplishment of trance.

Reentering Trance Without Awareness

Dr. Q: Yeah. It was so out of context, what you said, that it just had to have a different meaning.

E: And you didn't know what I was saying, but your unconscious mind did.

Dr. Q: I had a conscious awareness, too. I think I had both.

E: You had some awareness consciously after your eyes closed and your mobility disappeared.

Dr. Q: I remember—I feel embarrassed arguing with you.

E: You see, I watched your eyelids, and if Dr. Rossi wasn't taken by surprise, he could have noted the glazing of your eyes when I said "10." I actually began at five.

R: Your counting was so "out of context" that it resulted in Dr. Q's attention being momentarily fixated; his consciousness did not know what it was, but it had to have a meaning, so his unconscious supplied a meaning by having him enter trance.

E: Without his consciousness knowing! After he goes into trance and comes out, he is saying, "Yes, it was out of context, what you said, but it just had to have a different meaning."

R: The conscious awareness of the significance of your words as cues for trance comes after he has entered and come out of trance. So the subject enters trance without conscious awareness of what is happening.

Another Subtle and Indirect Trance Induction

E: Now, if you've read that report on Susie (in Erickson, Haley, & Weakland, 1959), I told her she could go into a trance when I counted to 20 in various ways. I swatted a fly and talked about other things, how children came *cheaper by the dozen and so on till "20"* which was the cue for Susie to enter trance. [Pause as Dr. Q apparently enters trance again.] Now, why weren't you [Dr. R] watching his eyelids?

R: I guess I'm the poorest student you ever had.

R: Why does he enter trance again here?

E: You missed the fact that I counted from one to 20 again with that "cheaper by the dozen" story about how Susie entered trance.

R: Oh! I missed that completely! I thought you were just telling one of your stories again! You used the same cue of counting from one to 20 in a different context to put him into trance again without either of us realizing how you did it! You mentioned a "dozen and so on till 20" as a subtle way of counting from one to 20.

Studying the Patient's Frame of Reference

E: He [Dr. Q] obviously wants to learn. [Pause for about two to three minutes as Dr. Q apparently goes progressively deeper into trance.] And you can take your own time in awakening.

R: Here you are reinforcing the trance by giving approval for his wanting to learn.

E: But he did not hear it as an obvious approval. It was an objective observation to you which he heard. And there is no higher approval than that. You see, that was so casual. His unconscious knew how to respond, but you could read over the transcript and still not know what was happening. Why don't you use your unconscious mind?

R: I'm trying to!

E: You were placing *your* meanings on my words. But what was *my* meaning?

R: I've got to start practicing that: looking at other people's frames of reference; the meaning that their words have for them, not for me. The therapist has to avoid placing his own meanings on the patient's words. This is so important because therapists often distort patients' words by reinterpreting them from the therapist's own theoretical frames of reference (Freudian, Jungian, etc.), rather than the patient's.

Unconscious Communication Rather than Prestige

E: When you [Dr. R] see that happening, it takes away all the magic and all the prestige. He knew unconsciously how to respond.

R: The unconscious can respond out of the logical context of conscious understanding.

E: Yes, and that is how you should look upon human behavior. [To Dr. Q] You didn't go into trance because you were bored with me. You did not go into that trance to get away from the environment. You went into the trance because you had been programmed with a certain awareness. Now, you can awaken now. [Dr. Q awakens.]

R: In other words, it is not prestige and magic that counts; understanding and communicating with the unconscious is what counts!

E: Yes, the unconscious can respond out of the logical context of unconscious understanding.

Indirect and Unrecognized Posthypnotic Suggestion in Trance Induction

R: Although we have dealt with the subject before (Erickson & Rossi, 1979), I'd like to learn more about your indirect approaches to posthypnotic suggestion. In your major paper on posthypnotic behavior (Erickson & Erickson, 1941) you say the following:

> Once the initial trance has been induced and limited to strictly passive sleeping behavior, with only the additional item of an acceptable posthypnotic suggestion given in such fashion that its execution can fit into the natural course of ordinary waking events, there is then an opportunity to elicit the posthypnotic performance with its concomitant spontaneous trance. Proper interference (with the posthypnotic performance) can then serve to arrest the subject in the trance state. (p. 12.)

Can you give me further illustrations of "an acceptable post-hypnotic suggestion . . . that can fit into the natural course of ordinary waking events?"

E: When I used to smoke, I'd *first* put a cigarette out and *then* induce a trance.
R: So putting a cigarette out became a conditioned cue for entering trance.
E: Later on in the interview, after they had been awakened and engaged in discussion, I'd light up a cigarette and then *very slowly* reach over to put it out, talking *slowly.*

R: Is that a way of fixing their attention when you do it very slowly? The very slow gesture arrests attention, initiates an inner search for its meaning, and allows the unconscious to express itself.
E: But it fits in with ordinary behavior and is *not recognized* as a posthypnotic suggestion to reenter trance.
R: Yes, it's only a slight modification of ordinary behavior. As they see that hand moving slowly, before they can figure out why it is moving slowly—
E: They are in a trance!
R: So when they come out of trance, they have no real understanding of why they went into a trance.
E: They say, "I don't know what happened. I awakened from a trance and we were talking, and you lit a cigarette or I was about to reach for one. But I guess I never did."
R: When their eyes close, do you let them rest in trance for a while, or do you start working with the trance immediately? Do you wait for signs that they have reached a proper depth or whatever?
E: I say, "All right, I think you're really deep enough now. That tells them, *"Be deep enough!"* That does the rest of it.

Nonverbal Trance Induction as a Conditioned Response

R: Tell me another approach you've used.

E: [Erickson illustrates silently by adjusting his telephone.] In other words, any little acceptable thing can become a subtle cue.

R: You can set up a conditioned response by doing something, any inconsequential thing just before you induce trance. Their consciousness does not associate it with the trance induction that follows since it is such a casual thing, but it nonetheless serves as a conditioned cue for their unconscious.

E: [Erickson illustrates another pretrance cue by moving his chair up half an inch closer.]

R: I thought I could provide such a cue by lowering the light in the room must before trance induction, but that is too obvious a thing.

E: That *is* too obvious!

R: Since it is so obvious, the conscious mind can immediately set up barriers to trance work. These barriers are not so much a resistance against hypnosis per se. I suspect the so-called resistance is a naturally built-in mechanism by which the conscious mind is always protecting itself against being overwhelmed by the unconscious. It is this natural barrier that your indirect approaches are designed to cope with. So far, you've illustrated nonverbal cues. Is there something particularly valuable about nonverbal movement cues?

E: That way you don't have to interrupt what you are saying. You can say something just before the movement cue and during the cue—that is what they remember in the waking state as the last thing you said. There are so many little things that you can do. [Erickson demonstrates by turning a cube with pictures of his family.] I'm apparently thinking.

R: You appear to be quietly, meditatively thinking as you turn the cube in the clockwise direction.

E: Then, when the patient is in trance with eyes open, I turn the cube in a counterclockwise direction, and they awaken. So you don't have to depend upon verbal constructions because you want your patient to do a lot of things. You don't want to have to tell the patients everything they are to do.

R: Otherwise the therapist would have to do all the work rather than helping the patients utilize their own creativity.

E: Therefore you build up a situation so they are free to respond on their own initiative. [Erickson illustrates by making a fist over the cube and then turning it.]

R: You attract the patient's attention by putting one fist over the cube, and then you turn it to induce trance or awaken the patient from trance.

E: Use a 180-degree clockwise turn to enter trance and then a 180-degree counterclockwise turn to awaken.

R: Is that an easy thing to do? I'm worried it won't work.

E: You are worried about it working, and I assume it *will* work!

R: That assumption is a very potent thing.

E: It is a *very* potent thing!

R: They feel it and are caught in the strength of your assumption.

E: You've had the experience innumerable times of knowing that somebody was expecting something of you.

R: That's it! That's what you create—that *expectancy!*

E: But I don't define it verbally!

R: A person's life history of experience with expectation is a very powerful built-in mechanism that you utilize in your induction.

E: It is very powerful.

R: As children we have a lot of daily experience in struggling to live up to expectations, and it is this life long experience that you are utilizing.

E: That's right. It belongs to them, why not use it?

Serial Posthypnotic Suggestion: Utilizing a Negative Mood

R: Another approach you describe in the same paper (Erickson & Erickson, 1941) and our previous work (Erickson & Rossi, 1979) is sequential phenomenon leading to trance induction. Can you elaborate on the value and purpose of serial posthypnotic suggestions? You mention the example of a five-year-old girl who was induced to enter trance by suggestions for sleep. You then proceed as follows (Erickson & Erickson, 1941):

> Then she was told, as a posthypnotic suggestion, that some other day the hypnotist would ask her about her doll, whereupon she was to (a) place it in a chair, (b) sit down near it, and (c) wait for it to go to sleep. . . . This three-fold form (sequential) of a posthypnotic suggestion was employed since obedience to it would lead progressively to an essentially static situation for the subject, (p. 118)

E: [Erickson now gives another illustration of this use of sequential structuring of behavior. In order to conduct an oral examination on one of his daughters at the age of three—while she was in a recalcitrant mood— he proceeded as follows, while she was sitting on the bed holding her favorite toy rabbit.]

E: Rabbit *can't* lie down with its head on the pillow!

Daughter: Tan too! [She lays the rabbit down to prove it.]

E: Rabbit can't lay down with its eyes shut *the way you can.*

D: Tan too! [She now lays down with the rabbit.]

E: Can't go to sleep like you can.

D: Tan too!

E: And then they both went to sleep!

R: A series of suggestions phrased in a negative way neatly utilizes her recalcitrant mood. You progressively channel her behavior until it became trance behavior.

E: Can't lay still when touched.

D: Tan too [said noticeably softer].

E: Can't have mouth open and throat looked at [spoken very softly].

D: Tan too [whispered].

E: At this point she opened her mouth and I looked. After the examination a physician who was in attendance said, "Now that didn't hurt, did it little girl?"

D: You're poopid [stupid]! It did too hurt, but I didn't mind it.

R: So the importance of sequential or serial behavior is to gradually built up a momentum, shaping behavior in the desired direction.

An Indirect Approach to Automatic Writing: Utilization Rather than Programming

E: [Erickson illustrates further with an example of shaping automatic writing through a series of verbal suggestions as follows.] Ordinarily, when there is paper and pencil available, something can be written. Often one doesn't know what is going to be written. Of course, the pencil that I've picked up before has written. Now, a left-handed person will pick it up with the left hand.

E: The patient is right-handed. I've made an observation, but I haven't said, "Pick it up in your right hand." The patient thinks, "I'm not left-handed, I'm right-handed. *I pick up the pencil with my right hand."* That's the patient's thinking.

R: This approach is the ingenious aspect of your approach: You get patients to think certain things in a very indirect way by *implication.* You don't make direct suggestions to put something in the patient's mind. You arrange circumstances so the patients make the suggestions to themselves.

E: Yes. If they hesitate to pick up the pencil, I say, "Now ..."

R: You say, "Now . . ." and pause as if reflecting in order to say something unrelated to the subject at hand. But the unconscious hears that "now," and that facilitates picking up of the pencil *now.* The conscious mind heard the "now" as belonging to another context, but their unconscious channeled it into the previous series of suggestions to facilitate the picking up of the pencil.

E: Yes! They've got that word *now* hanging there, to which they have to attach a meaning. I've done this with people awake as well as in trance. You don't have to know hypnosis. All you have to know is how people think this way and that way. You say this, and they are absolutely conditioned to think in a certain way.

R: You utilize those conditionings that are built in us as often as possible in waking as well as hypnotic work.

E: This is a *naturalistic* technique, a *utilization* technique.

R: This is your unique contribution, isn't it? Previous to your work, hypnotherapists thought they were programming their patients. You have shown that actually we are utilizing what is already there in the patient.

E: *Programming is a very confusing way to tell a patient to use his own abilities*.

SESSION TWO:
The Experiential Learning of Hypnotic Phenomena

Trance Induction via Body Immobility: Intercontextual Cues and Suggestions

[This session begins the next day with Dr. Q questioning Erickson about his selection of good hypnotic subjects from an audience. Erickson explains that he looks for "frozen people," who show little body mobility. He then tells Dr. Q he can experience it by remaining as immobile as *he can.]*

E: To remain frozen fixates attention. You can enter hypnosis through this door or that, whichever you wish. "As he can" covers all the possibilities: He can do it a little, he can do it 90 percent; I've covered all the possibilities from 0 to 100 percent.

R: The last two words, "he can," are also a strong indirect suggestion that he can remain immobile.

E: Yes, it is a strong suggestion.

R: The unconscious can pick up suggestions out of context and utilize them in ways unrecognized by consciousness.

E: In my paper, "The method employed to formulate a complex story for the induction of the experimental neurosis" (Erickson, 1944), I emphasize and contrast the meaning of this word with the following word. For example, the phrase "Now as you continue": *Now* is the present: *as you continue* brings in the future; *continue* is a command.

R: The same word can have many meanings: only some of them are evident from the total context perceived by consciousness; most of them are buried within the context. We could call the buried ones *Intercontextual Cues and Suggestions.*

"Try" for Fail-Safe Suggestions

E: *Try to remain frozen.* [Long pause as Dr. Q fixates his eyes and remains immobile. He soon closes his eyes, and a quieting of his respiration is noted after he takes a deeper breath or two. After about 10 minutes of silence, wherein Dr. Q makes only minor facial movements and an occasional finger movement, Erickson continues.]

E: All suggestions are used to reinforce, substantiate, and validate others. Right there, for example: *"Try* to remain frozen." If he has any doubt, all he has to do is make a good *try.*

R: So even if he fails, it is okay, since he tried.

E: Yes, he made a try.

Implication to Ratify Trance

E: And you can begin counting backward from 20 to one, now!

E: For what reason do you count backward from one to 20? From a trance!

R: Dr. Q thought he was just demonstrating his ability to remain frozen, but because counting from one to 20 was used to induce trance in the previous session, counting backward now turns his current experience into a ratified trance as you awaken him.

E: Yes, I say it is a trance without making my statement disputable. It is an implication, and you can't test implications.

R: How about if someone says, "Gee, I don't like the implications of your remarks."

E: Then I would say, "I don't know what they are for you."

R: Whatever implications they get are their associations and not necessarily yours. You may have an idea of what you are implying, but the implication is actually a construction that they build within themselves.

Ratifying Trance by Implication and Reorienting to Normal Body Tonus

[After a one-minute pause Dr. Q reorients to his body by stretching, opening his eyes, clenching and unclenching his hands, adjusting his feet and seat posture, etc.]

E: *What happened to you?*

Dr. Q: Well, I enjoyed the first trance so much I *thought I'd do another one.*

E: You thought you'd do another. Why?

Dr. Q: I watched you and I got the signal from you that it was okay.

E: The signal?

Dr. Q: *You told me not to move.*

E: [To Dr. R] Seems the unconscious really understood. But his conscious mind didn't—it found that out afterward.

E: How often do you go around clenching and unclenching your hands? It is his behavior, and it is ratifying the trance.

The implication of my question, "What happened to you?" is that something did happen! In his answer he is validating verbally that his first experience was a trance.

R: So he is now putting all his previous doubts to rest.

E: "I thought I'd do another one." He now taking all the credit. That is what we want him to do.

Anything he wants to consider a signal to achieve his wishes is okay, especially if it is going in my direction. "You told me not to move"—that is his interpretation. I only told him to try and you can. He is the one who carried it out.

Experiential Learning of Hypnotic Phenomena

Dr. Q: I think it was the second time you told me to try again. I'm thinking backward. That gave me the idea of—letting it go.

E: Here he is defining the times at which he learned. He is validating the previous trances and trying to determine at which point he learned this and that hypnotic phenomenon. I'm not telling him to learn this at this moment and that at that moment.

R: This is characteristic of your approach to the *experiential learning of hypnotic phenomena.* You do not attempt to directly program hypnotic phenomena; you simply arrange circumstances so the patients will learn through their own experiences.

Ratifying Trance with Questions

E: How long do you think you would have remained in the trance? Dr. Q: Fifteen or 20 minutes.

E: I ask him this question to give him another opportunity to validate his trance, and he does so when he answers, "fifteen or 20 minutes."

Truisms and Distraction to Discharge Resistance

E: *You could have remained in it for hours, so long as you didn't hear me leave*.

E: I'm telling him it can be hours long and then make the unnecessary stipulation, ". . . so long as you didn't hear me leave."

R: Why that unnecessary stipulation? E: That takes up his attention!

R: You've made a daring direct suggestion that he could remain in trance for hours. Then to obviate resistance, you immediately distract his attention with the unnecessary stipulation. You have simultaneously displaced his attention and discharged his resistance.

E: Yes, in a very safe way. I don't know how much resistance anybody has, but I can talk as if he had a great deal of resistance. It does not alter the meaning of what I say to mention a few unnecessary words. They are too few to bother about.

R: Is this another technique of displacing and discharging resistance: simply adding on unnecessary words? You tack an unnecessary truism onto a strong direct suggestion, and that distracts attention and tends to discharge resistance.

E: Yes, and it makes the subject agree with you. You ought to have your techniques so worded that there are escape routes for all resistances—intellectual, emotional, situational.

A Surprise: Unconscious Communication not Understood Consciously

Dr. Q: I agree with that. *I don't know why.*

E: There is nothing mystical or magical about that.

Dr. Q: It is *surprising.*

E: Surprising to you, yes, because you didn't realize the whole series of indirect suggestions leading up to it.

Dr. Q: *I didn't realize?*

E: An emphatic agreement here, but "I don't know why." That is a beautiful communication at the unconscious level that is consciously heard but not understood.

R: He agrees but does not know why. He is not aware of your approach of using a truism to gain acceptance of an associated suggestion. It is the conscious mind that finds the situation "surprising."

E: When he questions, "I didn't realize?" it implies that he didn't recognize all my indirect suggestions. That is beautifully said.

Posthypnotic Suggestions: Conscious and Unconscious Communication

E: *That would send you in a trance.* But I knew it would, and I let Dr. Rossi watch it. *What is the meaning of posthypnotic suggestion?!* Posthypnotic suggestion isn't, "Now you must at such and such a time, under such and such circumstances, do such and such."

R: It is not that direct.

Dr. Q. *It's not?!*

E: "That would send you in a trance," seems ungrammatical, but I'm actually speaking of the series of indirect suggestions.

"What's the meaning of posthypnotic suggestions?!" has both a question mark and an exclamation point because it is communication on the conscious (requiring a question mark) and unconscious (requiring an exclamation point) levels.

R: It's interesting that he responds with the same mixture of question and exclamation when he says, "It's not?!" That suggests he did receive your communication on both levels.

"Now": Conditioned Trance Induction and Arousal Through Voice Dynamics

E: It isn't. You know that *now!* You say something that seemingly has some simple meaning, and then you find out what it means after you start doing it.

E: I have been conditioning Dr. Q to this word *now.*

R: When you say the word *now* very softly and a bit drawn out, it has acquired conditioning properties for entering trance because you always say it that way when giving people instructions to enter trance. I had to close my eyes for a moment just then as you said it, so strong was the hypnotic conditioning I have acquired simply by being an observer. When you say "now!" sharply and abruptly, as in "You can awaken from trance by counting backwards from 20 to one, *now!"* it becomes a conditioned cue for awakening. When you use emphasis and particular intonation with certain words, you are actually conditioning patients through voice dynamics.

E: That isn't verbal communication, even though it is verbal. How can you really describe that to our readers?

The Illusion of Free Choice: A Lacuna of Consciousness

Dr. Q: *I have a feeling of choice in that.* That I realized what was happening and I chose to have it happen.

E: That makes you feel very comfortable, doesn't it? Kubie speaks about "illusory choice."

Dr. Q: Illusory choice?

E: *The Godfather choice:* your signature or your brains on this contract. Which is no choice at all.

Dr. Q: It is not a choice if you want to do something?

E: But I set it up that way. Only you didn't hear or see or know that I set it up that way.

Dr. Q: *I had a need to cooperate.* So I can't say how much I was setting up with you and how much you were setting up. I had the feeling of choice.

E: Now he is stepping over to my side.

R: He believes he had free choice in what he did, but actually you were conditioning him.

E: I gave him no choice. While he is puzzling about the "Godfather choice," his unconscious is understanding that I did tell him to do certain things. I merely reinforced previous suggestions.

He then makes an effort to defend his conscious mind with, "It is not a choice if you want to do something?" And again with "I had a need to cooperate." His consciousness is defending its rights.

R: That is a significant lacuna of consciousness: He has a conscious feeling of choice even though his behavior is determined by your relation to his unconscious processes.

E: I give him a feeling of choice even though I'm determining it.

The Fundamental Problem of Modern Consciousness: The Experiential Release of Involuntary Behavior

E: [Erickson reaches over and with very light touches indicates direction, so that Dr. Q moves his arm to a position about a foot above his thigh. The arm remains cataleptic, and he gradually closes his eyes and remains quiet and immobile for about five minutes. He then wiggles his fingers, very slightly at first, then more so. His hand moves about in space and finally touches his knee, seemingly by accident. He makes an almost imperceptible startle, probably nothing more than a tensing about the eyelids, and then opens his eyes and reorients to his body with the typical movements of awakening.]

Dr. Q: ***I wanted to test it. I wanted to test the suggestion. I wanted to see how much choice I had. I was afraid to test it too much.*** **Then at a point I just decided, well, let it go. At one point I wanted it [his arm] to go this way, but it wanted to go that way, and I could feel that.**

R: He now illustrates and describes his own efforts to test his free choice in trance by altering his arm position. He makes the fascinating phenomenological discovery that although he did have voluntary control ("I was afraid to test it too much"), there was also an involuntary component that wanted the arm to go another way. He is thus involved in the experiential learning of the involuntary or autonomous processes that are released during trance. He is learning that he can "let it go"—he can give up conscious control and let other response systems take over within him. This is the most basic and fundamental experience, that the modern, rationalistic mind needs to break out of the illusion that consciousness creates and controls everything. It's an experiential prolegomenon to deeper trance.

Fascination with Autonomous Behavior: A Numinous State of Being

R: Your free choice was to extend it, and yet—

Dr. Q: ***I felt it resting. It wasn't like it took over, it's like I felt it was there. I kind of felt like I still had the feeling of choice. But it seemed to have its—it's a hand*****!**

E: And you know what it is. It's an undefinable thing. It's neither father nor mother nor child nor parent. ***It is it: a state of being.***

Dr. Q: One that is very hard to accept as existing even in spite of seeing it. E: You had it.

R: Referring to his own hand as "it" suggests he is dissociating it. Does that mean his hand is outside the usual range of ego control?

E: It is completely out of it.

R: From a Freudian framework one would say that some of the usual ego cathexis has been withdrawn so the hand is closer to autonomous unconscious functioning?

E: Yes.

R: You actually use more of an existential framework when you say, "It is it: a state of being." But Dr. Q is so fascinated with it that I'm more reminded of Jung's conception of the numinous as an experience of "the other" or otherness within ourselves. This experience of the autonomous quality of his hand is necessary to help him break out of the limiting conceptions of his rational mind. As is characteristic of so many professionals, it is obvious that he very much wants this experience. It is very clear that we are here touching upon the fundamental problem of modern consciousness: How can consciousness observe and maintain some control while yet giving more room for autonomous processes of creativity—the unconscious—to take over when consciousness recognizes that it has reached its limitations? How can consciousness participate in and to some degree direct those creative processes that are usually autonomous and unconscious? After centuries of struggle to develop the rational functions of the left hemisphere and rejecting the nonrational processes of the right hemisphere, man finds himself impoverished. In our current quest for release from the rational (via psychedelic drugs, Eastern religions, yoga, the mystical, etc.), we are desperately searching for means of reaching the inner potentials that are sometimes released through ritual, cult, and the practices of faith and miracle healing. The holographic approach of Pribram (1971, 1978) and Bohm (1977, in Weber, 1978) is a currently interesting effort to understand and integrate the rational and nonrational functions. (See also Jung, *Collected Works,* Vols. 6 and 8 [especially "The Transcendent Function"].) From this new point of view modern hypnosis can provide an experiential access to the unconscious and the nonrational, and the possibility of integrating it with consciousness.

Faking It? Resistance to Dissociating Conscious and Unconscious

Dr. Q: *I feel resistance to that being legitimate and having—I can't tell how much I'm faking it and how much it is happening*.

E: AH right, what was the deciding factor in your awakening? Dr. Q: In my awakening? I don't know, I just felt like I wanted to.

R: This statement about not knowing how much is fake and how much is happening by itself is highly characteristic of most people when they first learn to experience involuntary movements.

E: Yes, and he is trying to convince himself there isn't that dissociation by asking if he is faking it.

R: The modern scientific mind really does not believe in the unconscious and the possibility of dissociation, because it is so caught up in its belief in its own unity and the dominance of its ego and consciousness. The modern mind has a dangerous hubris; it does not believe it can be split, dissociated. Yet that is what happens in modern consciousness when individuals are caught up in mass movements and belief systems that alienate them from their own basic nature and personal background. Jung *(Collected Works,* Vols. 8, 9,18) felt this was the basis of psychopathology in the individual as well as in mass movements and in all the *isms* that eventually lead to conflict and war.

Awakening with the Alien Intrusions Ending Dissociation: Time Distortion: Different Names in Trance

E: I know what the deciding factor was. When you touched your hand to your knee, that was the crucial moment, that tipped the balance in favor of awakening. *Something alien was introduced. The alienness was a realization that belonged to your conscious mind.*

Dr. Q: Yeah.

E: Tell me, what time do you think it is?

Dr. Q: It is about—12:20.

E: Want to look? How long were you struggling with your hand?

Dr. Q: Three or four minutes.

R: I did not time it, but my impression is that it was a little bit longer.

E: Over 10 minutes.

Dr. Q: That amazes me. I did not think I did that many things that took 10 minutes to do.

R: Can you say more about how the alien realization from the conscious mind intruding on the unconscious led to awakening?

E: His hand is dissociated from his body, and therefore his body is dissociated from his hand. When his hand touches his knee, they are brought together again.

R: Contact of the dissociated parts naturally unites them and ends their dissociation. That is probably why you don't like people to have their hands in contact when you induce a trance in a formal way; it facilitates dissociation to keep hands apart. That is why in inducing trance you often try to separate things: You want to separate me from Dr. Q; the conscious from the unconscious; the person from his surroundings, his time sense, his memories (as in amnesia), his sensations, anesthesia, etc. You use division to divide consciousness; it breaks up the unity of consciousness.

E: Yes, it breaks up the unity.

R: That is why you will sometimes give the person in trance a different name, a different personality. So division is very important; divide and conquer. [See Chapter 10 on creating identity in Erickson & Rossi, 1979.]

E: Note his complete readiness to accept my statement about 10 minutes here.

Prestige and Magic: Their Function and Basis

E: That is why I keep that clock there [on a bookcase in back of the patient], nobody knows when I look at it. Is there anything prestigious about what I'm doing? You mentioned that yesterday.

Dr. Q: Well, I don't know of anything. *I just have a feeling of magic about someone who understands how a mind works.*

E: Do you think it is magic to be able to speak Chinese?

Dr. Q: I think it is magical to be able to understand, let's say, how atoms combine to form water and oxygen.

E: Do you really understand that? Does anybody? Dr. Q: I don't know.

E: Any Chinese baby knows how to speak Chinese. It would be magic if you started talking Chinese, even baby Chinese.

Dr. Q: Yes, that would be magic.

R: Do you really believe therapist prestige is not important in doing hypnotherapy?

E: Prestige is important, but you don't brag about it. A patient comes to you because he can't do the things he thinks he should be able to do. Therefore he comes giving you the prestige.

R: The patient gives the therapist prestige, a form of potency, to do the things the patient cannot do for himself. The giving of prestige is a desperate hope that something can be done.

E: Yes. You accept that prestige and enhance it indirectly because he needs it. You keep it by being very modest about it.

R: That's an interesting idea: It is the patient who needs to give the therapist prestige. The therapist accepts the prestige because the patient needs it. It is not the therapist who needs prestige. The phenomenology of prestige, from this point of view, becomes very interesting. We naturally confer prestige on those who help us transcend our own limitations. Hopefully, the hypnotherapist is helping the patients transcend their learned limitations in order to realize their own potentials. That is the only legitimate basis of prestige. Something similar can be said for the sense of the magical: Magic is essentially understanding how the mind works, and facilitating its potentials is "white magic"; using that understanding for harmful intent, of course, is "black magic."

Appropriate Moment for Induction: indirect Suggestion for a Kiss and the Basic Paradigm of Hypnosis

E: I did not do anything you [R] could not do. Only difference was I knew when to reach my hand out.

R: And how did you [E] know when to reach your hand out?

E: When I thought Dr. Q could do it, I knew if I reached my hand out, what he would do. And I let him find out and I let you [R] find out. And you found out how Dr. Q struggles.

Dr. Q: How I could struggle against control?

E: When you tried to extend your arm, it pulled back.

R: There is an appropriate moment to initiate ah induction or hypnotic phenomenon?

E: Yes.

R: How do you know when? Do you notice spontaneous shifts toward a trance condition that you then merely facilitate? Do you see the eyes glazing, the face freezing, body motion being retarded? Do you notice partial aspects of trance and then realize that is the appropriate moment for induction?

E: Take an example from ordinary life. When do you kiss a pretty girl?

R: When she seems to be ready for it.

E: That's it! When she is ready, not when you are ready. You wait for that undefinable behavior that she manifests. You don't ask a girl for a kiss, but in her presence you just gaze thoughtfully at the mistletoe. You are just being thoughtful. She gets the idea, and she starts thinking about the kiss.

R: You've indirectly planted an idea in her head. E: Yes, she doesn't know you did.

R: Therefore it is all the more potent because she is going to soon wonder, "Gee, I want a kiss," not, "He wants a kiss."

E: That's right, and there is the excuse, mistletoe. R: That is a paradigm of all hypnotic work, isn't it?

E: Yes, you know what the frames of reference can be and you utilize them.

R: That is the basic knowledge of the hypnotherapist: knowing what the frames of reference can be and how to facilitate them.

The Experiential Learning of Trance: Ratifying the Phenomenology of Dissociation

Dr. Q: I had the feeling, though, of initiating the struggle. I feel that is part of my curiosity. I was able to question it and felt a need to test it. I needed not to be completely passive in the situation. ***I needed to make the situation valid by testing it. Not understanding, not believing what was happening until it did. Up until that time I could not be sure whether I was faking it or what was happening.***

E: How did you know what to fake?

Dr. Q: You told me to reach my arm out. You were saying by that, "You're supposed to now act hypnotized."

E: What was your arm supposed to do after I touched it?

Dr. Q: ***It wasn't supposed to stay there.***

E: He really verbalizes beautifully, doesn't he?

R: Yes. What is the struggle he is engaged in here?

E: He knows what his usual behavior is, but what is this behavior? Now he begins conceptualizing two separate types of behavior.

R: Normal ego control versus dissociated behavior. Here is a modern rationalistic mind learning that its own conscious ego does not always control everything. That is the basic experience for the modern mind to have if it is going to learn trance. His experiential learning takes place through the typical processes of hypothesis testing: Can I initiate control over my own hand movements in trance? He does not believe in the situation until he can make it valid by testing it.

E: Yes, this is also indicated when he says, "It wasn't supposed to stay there," yet it did! So it wasn't faking! It wasn't supposed to stay there!

The Typical Process of Testing the Reality of Trance and Dissociation

E: Now, I wanted Dr. Rossi to see how your eyes didn't close completely and how you struggled with your arm.

Dr. Q: I can't imagine how you wanted me to struggle with my arm.

E: I knew that you would because everybody else does it!

Dr. Q: I thought I was being a bad kid!

E: So does everybody else!

R: [To Dr. Q] You thought you were being a properly skeptical psychiatrist—scientific.

Dr. Q: I didn't want to accept something when you were suggesting.

E: But I had to offer some suggestion, so I just touched your hand.

Dr. Q: I know what that meant.

E: What did it mean?

Dr. Q: It meant I had to hold my arm out.

E: Did it?

R: Dr. Q believed he was unique in his scientific doubts about the reality of his trance experience. Yet his experience is so typical that it makes an excellent case for illustrating your approach to coping with this critical and debunking attitude of the current climate of scientific opinion. His need to reality test the inner phenomenology of his experience is entirely appropriate because there is in fact so much bunk that goes on about psychology and especially hypnosis these days. That's why the older authoritarian approaches are no longer appropriate today. In an open and democratic society a high value is placed on everyone being free to question and test the reality of their life experience. Because of this, your Experiential Approach to learning trance is most appropriate.

Delicate Tactile Guidance for Dissociation and Catalepsy: Bypassing Habitual Frameworks; Initiating Unconscious Responses

Dr. Q: You grabbed it and you held it.

E: Did I?

Dr. Q: It seemed that way.

E: I didn't grab it and I didn't hold it. You had your hand up in the air, and I touched it. [Erickson again reaches out and touches Dr. Q's right hand, which was poised in a natural gesture about halfway between his lap and chest as he spoke. His eyes close after a few minutes of carefully watching his hand remain fixed in one position. His breathing changes, and he is obviously going into trance. His right arm remains cataleptic in the position it was in when Erickson touched it. After a while Dr. Q begins to make small, tentative movements of his hand, obviously testing it. He moves a finger or two slightly, and then his elbow. The fingers and arm always return to the cataleptic position. He then tries to push his right arm with his left and obviously encounters resistance.]

R: [Erickson now demonstrates on R's arm.] You didn't grab it. Your hand is so soft in touching my arm, but it does indicate direction, and I actually move it without seeming to.

E: You are moving it! You maintain the same contact with my hand. I'm moving my hand, but you're keeping that contact.

R: My hand is following yours, but you are not pulling my hand. There is a subtle difference. With the slightest of pressures you are indicating where my hand should go.

E: Yes.

R: This is training the patient to follow you and be very sensitive to you. The patient has to reach out and ask: What is he doing? What does he want? Where does he want it to go? Where? Where? Where? His whole consciousness is directed to following you.

E: And I haven't grabbed a thing!

R: I'd resent it if you grabbed my hand or pulled it. But since your touch is so light, I have to cooperate with you and follow you.

E: The patient doesn't know what he did.

R: He doesn't know the degree to which he cooperated.

E: That's it! The delicacy of your touch is important.

R: That is a tactile way of doing what you always do verbally: You guide the subject, but so lightly he has to listen very carefully and then naturally seems to do something in the range of possibilities you have initiated. But he can't resent it because he is supplying so much of the momentum and choice himself. That is a fundamental aspect of your work in whatever modality of communication you use: You provide only the lightest and most indirect suggestion to initiate a process, so the patient has the experience of behavior taking place autonomously.

[Erickson demonstrates again on R's arm.] You're touching my hand so lightly with cues for downward movement that I have to sense very carefully and then let it go. And as I follow your touch, I start to get a strange dissociated feeling.

E: Yes.

R: It is dissociated because I'm not used to sensing another's touch so carefully. I'm thrown out of my usual frames of reference.

E: The slight touch, the silence, and the look of expectancy.

R: That is your form of mumbo-jumbo that bypasses the habitual frames of reference.

E: Um-hum.

R: It bypasses the usual frames of reference, and the subject is thrown back on the questions: What is expected of me? What am I to do? He is desperately trying to do something.

E: And he has to follow his own patterns of behavior!

R: Now that is it! The subject has to follow his own patterns of behavior. He is really not following you except for the most general context. You are initiating something, but you do it so delicately that his own patterns of behavior come forth from his unconscious, his behavioral matrix, to fill the gap.

E: That's right. Then I can select any one of those patterns— R: —for a therapeutic goal.

E: Um-hum.

R: And it is not the subject's conscious mind that is directing, because his conscious mind does not know what to do in this unusual frame of reference, so he is thrown back on habitual patterns from the unconscious.

E: It is all his own exploration. R: You've initiated this in him.

E: I've set up a situation in which his patterns can come forth. He doesn't know they were called forth, but there they are, so he starts examining them. We all can dissociate naturally.

R: Dissociation is a natural ability we all have. Every time we daydream, we are dissociating.

E: But we don't know how well we can do it.

R: The modern mind has forgotten all about dissociation and no longer believes it can do it. The modern mind likes to believe in its fundamental oneness, its fundamental unity.

A Self-Induced Analgesia

[Dr. Q then pinches his right hand, evidently testing it for analgesia.]

Dr. Q: It lost a lot of its sensitivity.

E: Why?

Dr. Q: I don't know.

E: I didn't suggest, did I?

Dr. Q: No. I just thought of testing if it was analgesic.

R: You never did anything to initiate an analgesia—not even directly, except insofar as analgesia and many other sensory-perceptual distortions take place spontaneously during catalepsy. The analgesia Dr. Q is experiencing could be either the spontaneous sort or the result of an inner suggestion he is giving himself without realizing it under the guise of reality-testing his dissociation. His own unconscious expectations and processes are becoming activated in ways he does not himself understand.

Indirect Reinforcement of Hypnotic Learning

E: *Yesterday* I tried to impress upon you how ignorant you were. I knew you'd be a good subject.

Dr. Q: How did you know?

[We all nod in acknowledgment that such recognition of good subjects has become rather automatic to Erickson.]

E: I can make this attack on him here because I say, "yesterday."

R: You are implying he was ignorant yesterday but smart today. That indirectly reinforces all the new learning he is going through today and bypasses his skepticism of yesterday even more.

E: That's right. A very careful use of "yesterday." Then his questioning about how I knew he'd be a good subject implies a complete acceptance!

Trance as a State of Inner Exploration

Dr. Q: That time I was much more interested in pushing the limits of the test a lot further than before.

E: I'll tell you something you didn't know, though. You also developed some analgesia in your left arm and hand.

Dr. Q: *In my arm, too?*

E: In your hand, I'm certain.

Dr. Q: *How?*

E: You didn't know it?

Dr. Q: *No.*

E: Dr. Rossi could see there was something wrong with your hand movements.

Dr. Q: *Of my left hand?*

E: Yes, through analgesia you lost the proper mobility.

R: This testing is the essence of the modern experiential approach to trance experience. The testing is actually a form of internal self-exploration. It fixates and

focuses attention inward, and this, of course, is a basic aspect of trance. It has that peculiarly detached, impersonal, and objective quality of ego observation in trance.

E: Notice the ease with which he now accepts my observations about his left arm and hand anesthesia. His questions all imply an acceptance.

Dissociation as a Creative Act: New States of Awareness in Modern Hypnosis

Dr. Q: Of my left hand? I noticed something else when I was pushing my arm. *When I let it go, I seemed to be losing, I seem to be threatening this state by letting go rapidly.* Now, I didn't want to threaten this state, so I started letting go gently. *Another threat to this state when I felt my muscles tensing.*

E: Let's go back to that word *threat.* What was the threat?

R: What does he mean by "threatening this state"?

E: Any break is a threat. You break a state of awareness; the break carries with it a destructive significance. I can break a pencil, I can break a state of dissociation.

R: Breaking a state of dissociation brings you back to ordinary consciousness. It is like when people say, "I was flying high, and then they brought me down." They mean their inflated mood was broken. So to maintain the dissociated state is a creative act.

E: That's right.

R: It's not just a passive splitting of consciousness.

E: You call it "creative," I call it "discovering." He doesn't want to do anything that will threaten that discovery.

Normalizing Forces Interfering with Creative Dissociation: Self-Discovery as the Appropriate Frame of Reference for the Experiential Approach to Trance

Dr. Q: I was aware that there were forces at work that would wake me up, that would cause me to be what I'm used to being,

E: But why is that a threat?

Dr. Q: Well, it was against what I wanted. It was a threat, too.

E: That's the word you are using. Why do you say threat? There was an awareness.

Dr. Q: I see.

E: But the word you used was threat. It's just an awareness, not a threat.

E: He is verbalizing the forces that interfere with his discovering more about trance.

R: He knows he is outside his usual frame of reference (". . . what I'm used to being"). Now, what were those "forces at work that would make me wake up?"

E: There are so many forces: foci of attention.

R: The tendency to go into the multiplicity of foci of attention characteristic of normal consciousness is always tending to intrude on the creative dissociation where there are relatively fewer foci. Then, with the distinction you make between *threat* and *awareness,* you are just trying to educate him about that awareness?

E: Yes.

R: Would you say that modern hypnosis is the discovery of other states of awareness that are there but not always explained in a conscious way? The old-time hypnotherapy was a process of being directly programmed by someone who did mumbo-jumbo on the patient, shook up his frames of reference, and then tried to stick in new stuff. But in modern work we don't dare use mumbu-jumbo because that is against the modern scientific world view. But discovery and self-discovery are acceptable with Dr. Q's frames of reference; therefore, we can use them to give him new states of awareness.

E: I agree.

Recognizing the Developing Presence of the Unconscious and Trance

Dr. Q: There was one other piece of information you gave me that was very helpful when I recall it. When you said that "your conscious mind was an intrusion" that changed the state, *I could see my unconscious mind intruding again.*

E: Did I say a single word to you the second time?

Dr. Q: No, it was a way of thinking about the situation which I was able to use.

E: I didn't ask you to change your way of thinking, did I? Dr. Q: No.

E: He could see his unconscious mind intruding on his conscious mind—taking over, in other words.

R: He is developing a sensitivity to that. A similar sensation develops in me while lying in my hammock on a Sunday afternoon—getting drowsy and sensing the unconscious come in as daydreamy thoughts, images, and that comfortable, easy feeling of deepening relaxation. You realize you must be going to sleep since your body feels so light.

E: Yes. [Erickson now gives an example from his youth of lying in the hay on a sunny day and thinking how nice it would be to go to sleep. He heard a chicken cackling and wondered how soon the cackling would fade away, indicating that he was asleep. The cackling seemed to get further and further away as he went into sleep.]

The Subjective Exploration of Catalepsy: Distortions of Suggestions as Indicators of Trance

E: I suppose you [Dr. R] ought to dictate into the record what you have observed. Go ahead.

R: [Dictating a summary of observations] The procedure was initiated when Dr. Erickson touched Dr. Q's hand. Dr. Q watched his hand while Dr. Erickson carefully watched Dr. Q's eyes and face. Dr. Q seemed to become really involved in watching his hand. Dr. Erickson sat back, relaxed, and after a moment or two Dr. Q closed his eyes. Then there was a five-minute period where Dr. Q seemed to be just simply drifting into trance, letting his right hand hover in a cataleptic manner. One would assume by Dr. Q's bobbing head movements and altered breathing that he was apparently dozing.

E: Head movements, but he wanted to move his hand. He had the concept of lifting and lowering. But he lifted his head and lowered his head because he couldn't get the concept of lifting from his head to his hand. He was trying to move his hand! It is like a child learning to write. He tries to move his hand with his head. Here is Dr. Q, an adult, trying to move his hand with his head!

E: He had the concept of lowering his hand, but moved his head instead.

R: Recently I had a patient whose hand did not lift very much with suggestions for hand levitation, but her whole body began to tilt toward the hand. I then utilized that body-tilting to continue the induction. It's in just such distortions of your suggestions that the patient's altered state become more obviously manifest. That peculiarly lethargic and seemingly obstinate contrariness of some people in the early stages of learning to experience trance is, in fact, a marvelous indicator of autonomous processes beginning to take over.

Idiosyncratic Ideomotor Signaling

Dr. Q: I had the pendulum going with a friend of mine, and I wanted it to answer Yes or No, but I found myself moving my head. I was aware that I was moving my head [in today's trance], but I did not know why.

E: He is discovering why he did not move his head.

R: It's fascinating to note how a modern scientific consciousness discovers the idiosyncratic and autonomous within itself. We simply do not know at this point why his psychological system is more prone to expressing itself in ideomotor signals with his head than his fingers with the chevreul pendulum.

Catalepsy as an Early Level of Psychomotor Functioning: Unfamiliar Frames of Reference as Altered States of Consciousness

R: [Continuing the dictation] After about five minutes Dr. Q's left hand reached over toward his cataleptic right hand, and I wondered if he was coming out of trance. But all he did was to touch the lower edge of his right hand, as if to gingerly test it. As he proceeded in testing, his touches got firmer and firmer, as if he was trying to knock his right hand out of its poised alignment. I was really amazed, because I now realized his cataleptic right arm was really fixed.

E: He discovered he could not move his right hand. To move his right cataleptic hand, he had to use his left hand. He found out he had to use his left hand to lift that right arm at the elbow. He tried to bend it and move it up and down. He moved his right fingers back and forth with his left hand. But he could not move them with his right.

E: Ordinarily when you want to move your right hand, you use your right hand to do it, but here he was using his left hand to move his right.

R: Was he thereby protecting the dissociation in his right hand?

E: He did not know how to move his right hand. His right hand was an object he had to move with his left. Just as you can see a baby reach for its right hand (seen as an object) with its left hand. It takes quite some time for the baby to see the hand as part of itself.

R: So dissociation is a return to those early levels of functioning? E: That's right.

R: Does the dissociation phenomenon support the atavistic theory of hypnosis?

E: Would you call a baby's cooing atavistic?

R: No. It is a matter of terms. You don't like the term *atavistic* even though we are going back to modes of functioning that were more prominent earlier in our lives?

E: Yes, we are going back to an early learning period, but not atavistic. When your hand becomes an object, how are you going to handle an object? You use the natural way you use as an adult to handle an alien thing. The dissociation of your right hand makes it alien, and you naturally pick up that alien thing with your other hand, which is

not alien. That isn't really primitive because that is what you do all the time. You pick up a pencil because it is alien to you.

This is the Experiential Mode of Hypnotic Induction. You let the subject experience his own behavior and toy with it. It is an experiential phenomenon by which the self teaches the self by studying dissociated frames of reference, frames of reference that are unfamiliar.

R: These unfamiliar frames of reference are what many people now call altered states of consciousness.

Analgesia: Testing Sensations and Movements as an Experiential Ratification of Trance

Dr. Q: *I* used about 25 pounds of force to move my right arm.

R: After about seven or eight minutes of that you began pinching your right hand, testing for analgesia.

Dr. Q: I felt what it was doing, but it was not painful. It was a diminished sensitivity.

R: You were aware of touch but not pain.

Dr. Q: I still have a little of it [analgesia] left.

R: I was very interested in your question about free choice. You felt you had free choice in the trance.

E: He was disputing with me about that.

R: Yes, you feel it is an illusory free choice.

Dr. Q: I feel I haven't tested definitely. It was a test within certain limits.

E: All right, now, how many times did I have to test to see if my glasses are there?

Dr. Q: Well, you have had a lifetime of leaving an object there and knowing it will stay there.

E: And you have had a lifetime of feeling at one touch. But you kept on repeating your test.

E: It is ridiculous when he talks of using 25 pounds of force because you don't bend one arm with the other. He didn't realize the absurdity of it. And you don't have to "test" your sensations in the normal state of consciousness.

R: If you have to test your sensations, you are already in an altered state.

E: Yes.

R: So all these tests and explorations are actually experiential ratifications of trance.

E: He likes this altered state, he doesn't want to do anything to destroy it. Therefore he is going to put limits on his tests. You see a beautiful, fragile thing, and you want to feel it, you lift it, you touch it, you want to be very careful because you don't want to break it.

R: This is the experience of someone who is beginning to learn how to experience trance. It is a fragile state initially, and he is going to be very careful he doesn't break it. Other well-experienced subjects don't have this concern.

E: Dr. Q has his need to support his skepticism.

R: He is still supporting his skepticism with all this testing even though it is also a way of very gingerly learning how to experience trance in a safe way. But why does the hand tend to become analgesic when dissociated?

E: When the hand becomes alien—

R: —All the sensations of the hand become alien because they are in a new frame of reference, and we don't know how to experience that frame of reference yet. Is that right?

E: That's right. With a good subject any frame of reference is okay because he or she trusts us.

R: So when we bypass our shift frames of reference, we must support the patient in a safe way, and that is usually the transference.

E: Or trust.

Shift in Frame of Reference for the Experiential Induction of Trance

Dr. Q: *It is a new situation to me. I did not quite have the same awareness*.

E: OK, let's take up the next thing. Have you ever heard someone say, "I'm just frozen here. I was so astonished I didn't know what to say and I couldn't speak"?

Dr. Q: Yeah, I haven't experienced that myself a lot. I can't think of any. E: But that is a learning you've had since childhood. Dr. Q: Yeah.

E: That's what you're inquiring into right now: past moods, past learnings.

R: His initial statement about not having quite the same awareness in a new situation implies that a *shift in frame of reference is part of hypnotic induction,* doesn't it? A new situation, a new frame of reference, results in an altered state of awareness.

E: Yes.

R: Theoretically you could induce a trance simply by asking a patient to sensitively explore one hand with the other. That would introduce a fairly unusual frame of reference; it would focus and fixate attention, and then you are on your way.

E: I have induced trance in that way. It works. It is slow, but it is

very impressive later to the subject.

Resistance to Accepting the Altered State of Trance

Dr. Q: *Still I feel a foreignness about the whole thing. It still has an unnaturalness. I kind of feel a part of me is unwilling to accept what I've experienced, somehow*.

E: Those are your words. The correct statement is, "Part of you does not know how to accept the other part." The new learning doesn't fit with your previous learnings. How do you accept it?

Dr. Q: I'm willing to accept that experience as a valid one that does not— so unfamiliar.

E: It has to be valid because you are having trouble with it. You wouldn't be having trouble with it if it wasn't valid. [Erickson elaborates several personal experiences of being dumfounded.]

R: So it is misunderstandings that give rise to the experience of being dumbfounded.

E: An inability to understand.

R: Why are you emphasizing this inability to understand now?

E: He [Dr. Q] cannot understand how analgesia develops out of catalepsy. He couldn't understand the passage of time. And he kept on testing and testing. He always found

the same response. All the results were contradictory to past experiences and learnings.

E: He's still feeling "unnaturalness."

R: That means he is still experiencing an altered state.

E: Yes.

R: I used the word "misunderstanding," while you spoke of "an inability to understand." Is there any substantial difference in meaning here?

E: Yes. It is not a "misunderstanding" but an *absence of understanding* that leaves you dumbfounded and open.

R: Your usual frames of reference are bypassed, leaving you open and ready for structuring suggestions.

E: Yes.

R: It is very important for the hypnotherapist to tune into the hypnotic process along a dimension of structure or lack of structure in a patient's comprehension. Dr. Q's very *absence of understanding* indicates that his usual conscious sets and habitual frames of reference have been bypassed to the point where he experiences himself in an alien territory of consciousness; he senses a "foreignness about the whole thing." This foreignness is in fact the altered state of trance that his usual everyday states of consciousness find so difficult to accept.

"Fake" and the Skeptical View of Hypnosis as a Rationalization: Creative Moments in Everyday Life as an Altered State

Dr. Q: *Yes, and a part of me wanted to make the conclusion that it was a fake, because that would explain it. I was faking it*.

E: But how could you fake it when you did not know what was going to happen?

Dr. Q: *I had to have a way of understanding it*.

E: The easiest way is to *not* understand and call it a fake. That's an avoidance of understanding.

Dr. Q: Yeah, but it satisfies my need for the meantime. If I understand it as a fake, I can drop it.

E: You can drop it and then not have to learn. Just as Dr. Harvey was called a faker when he said the blood circulated. No doctors wanted to understand. It was so much more comfortable thinking the blood did not circulate.

Dr. Q: Yes, there is an unwillingness to change a system of knowledge.

E: And a willingness to accept magic if you don't have to think about it. Hypnosis was a forbidden subject because it required understanding.

E: "Part of me wanted to make the conclusion that it was fake."

R: Yes, that is his old skeptical frame of reference. Labeling the experience as "fake" would be a safe way of rationalizing it back into his old familiar skeptical point of view.

E: But he couldn't, and he kept testing and testing.

R: So this is the problem of those who have the skeptical view about hypnotic phenomenon. They are trying to fit their new hypnotic experience into their old rationalistic frame of reference. They are denying the reality of their living experience in order to support their old views.

E: "I had to have a way of understanding it." The only view that was open to him was "fake," and so he had to test it until the fake explanation didn't fit.

R: Would you say this was the problem of many researchers of the past generation in hypnosis who were on the skeptical end of the continuum? They were trying to fit phenomena they did not understand into the typical rationalistic frames of reference of the 19th century that in essence believed hypnotic phenomena were fake: Nothing but "motivated instruction," role-playing, or what not.

They failed to understand the very real struggle we are all constantly engaged in to stabilize our world view with the familiar, which in turn must give way to the new that is constantly created within us. When the new comes forth into our consciousness (Rossi, 1972), it is frequently experienced as a threat. It is in fact a threat to our older frames of reference, which must now give way to the new. This is the essence of the constant struggle of consciousness to renew itself. The actual transformation between the old and the new usually takes in an altered state: a dream, a trance, a meditative reverie, a moment of inspiration, the creative moment in everyday life when our usual point of view is momentarily suspended so that the new can become manifest within our consciousness.

E: It ruins a magician's act if he explains to you how he did it. You've taken it out of the alien frame of reference and put it into the ordinary frame of reference.

R: It is the very fact that hypnotic phenomena are in an alien frame of reference that allows us to bypass the limitations of our ordinary frames of reference during trance so that we can do things we could not ordinarily do with our everyday ego consciousness. If you rationalize away the "alien" quality, you lose the potency of the altered state of trance. Is that right?

E: Yes. The best way to "not understand" is to call it a "fake." It is an easy way out and an avoidance of understanding.

R: So you'd say a lot of research purporting to support the skeptical view of hypnosis as an altered state is an avoidance of understanding.

E: Um-hum. It is a "fake," so I can drop it. I won't have to exercise any more intelligence.

R: This reminds me of that difficult situation in science, particularly psychology, where a fundamentally new insight can crystallize only when we are able to redefine or expand our view of what something is. Freud gave us profound insights into the dynamics of sexuality, but he could only do it by changing, broadening, our definition of what was sexual. In a similar way you can maintain the view of trance as an altered state only by expanding our definition of an altered state to include those familiar acts of daydreaming, reverie, meditation, moments of inspiration, etc., as being varieties of altered states. Even the moment of radically shifting one's point of view or frames of reference is now defined as an altered state. There is actually much justification for this, since people are momentarily frozen in cataleptic poses during such creative moments, just as they are immobilized while dreaming and hallucinating. There seems to be an inverse relationship between body activity and moments of intense inner work. That's why people are typically quiet and immobile during the deeper states of trance.

Difficulties in Learning Hypnosis

E: You know what human behavior is. The unfamiliar is unacceptable unless you can make it very mystical.

Dr. Q: That explains a lot of things.

E: I knew you could do analgesia from past experience. I don't think Dr. Rossi knew it, but he could see you doing it.

Dr. Q: I don't know what made me test for analgesia, maybe things I read. E: Because you had lost sensation and you had to find out something.

R: You were not consciously aware that you lost sensation, but something in you knew and prompted you to test.

E: Acupuncture was so easily accepted in this country because it is so easy to do. Anybody can put a needle in a certain spot.

R: But that is not the case with hypnosis. It is difficult to do.

E: Yes, it is difficult. You have to learn to recognize different frames of reference.

R: In the workshops of the American Society of Clinical Hypnosis they are always telling the beginning students that hypnosis is very easy. It is very simple to learn by rote some mechanical approaches to hypnotic inductions, but to learn to recognize and understand the unique manifestations of trance in each individual requires much patience and effort.

E: That's right.

R: There is a lot of subtle thinking about frames of reference that is required.

E: I say you have to understand this, and every time I demonstrate something before a professional audience, I tell them, "Now you didn't see, you didn't hear, you didn't think. These are the steps." It is so much easier to think there is something special about me then learn to really observe and think. "Erickson is mystical," they say.

R: Rather than really trying to understand what Erickson is doing.

The Experiential Ratification of Trance: Assessing Sensory-Perceptual Differences

Dr. Q: *There were a lot of differences*.

E: And if you wanted to identify some of those differences, you weren't faking. I did not suggest catalepsy, I just touched your hand in midair.

E: If he wanted to identify some of those differences, he wasn't faking.

R: The very fact that he is trying to identify them means there is something there.

E: And it was his endeavor, not my instructions.

Conscious Conviction and the Ratification with Altered Sensations and Movement

Dr. Q: It's much easier for me to accept the analgesia. Having tested it that way seems very satisfying. I believe only 20 percent in the catalepsy and 95 percent on the analgesia.

E: You don't dispute with patients when you see them responding.

R: You don't argue with the skepticism of their conscious mind regarding the genuineness of the hypnotic phenomenon they have just experienced.

E: Too many people who use hypnosis try to argue with that skepticism. I don't bother. That is part of my prestige—I just don't argue.

R: Conscious conviction is something that is going to have to come out of their own experience gradually.

E: That's right. I can't put it there.

Dr. Q: I'm much more convinced this second time. The first time I was only 35 percent sure.

R: I noticed that you experienced three catalepsies in all, and the third was the most striking to see. The first required some support, with your hand touching your leg; the second was not as solid as the third, when your arm remained rigid in midair even when you tried to move it with your other hand.

E: You build your confidence.

R: [To E] The catalepsy seemed to become more genuine as he began to test it. It became more solidly established as catalepsy as he tried to move that right hand with his left. Is that true of others?

E: That was his experience. Others simply accept it with no question.

R: Their conscious minds have a good receptivity to their inner experiences.

> E: Only 20 percent belief in catalepsy, yet he has muscles. He has had long experience in growing and using his muscles, but how much fuss do we make about developing our ability to test sensations? We accept sensations, but we learn to develop our control over our muscles.
>
> R: That accounts for the 20-95 percent discrepancy. Sensation seems to come by itself, and when it disappears, it is more startling to us; therefore he has 95 percent belief in hypnosis with analgesia. But muscle control is voluntary, and thus he has only 20 percent belief in catalepsy. Sensations are closer to autonomous levels of functioning, so when we see a change there, it is more convincing.
>
> E: That's right. I don't argue, I take their frame of reference—in the direction I want it to go. You let your subjects see everything.
>
> R: And the more they see, the more they can become convinced.

1. Dissociation and the Modern Experiential Approach to Altered States

R: Can you say anything about the how or why of dissociation and how it works in your experiential approach to altered states?

E: The unconscious has many foci of attention, and when you withdraw that from any part of your body, you don't destroy your intellectual, conscious comprehension of that part, but it becomes an object because the unconscious foci of attention are withdrawn.

R: The psychoanalyst would say that **the usual unconscious** body **cathexis** is withdrawn (Federn, 1952).

Observing your work, I've been struck by the extremely attentive and expectant attitude you shower on patients. Some of them have later commented to me about how moved they felt with your deeply searching eyes and manner. I wonder if this expectant attitude contributes to the ease with which you elicit dissociation in your hypnotic work. Your expectant attitude immediately changes the atmosphere so that it is strikingly different from ordinary everyday life experience; it places the patient in a new frame of reference charged with an expectancy that he is familiar with.

His ego becomes uncertain and now has to reexamine even the most familiar acts from this new point of view. This new point of view is, of course, strange and alien at first, and it is

precisely this strange and alien feeling combined with his uncertainty and the apparent autonomy of his ordinary acts that makes them seem different or "hypnotic." The ego loses its usual sense of control when placed in the unusual frame of reference of "hypnotherapy," and that permits the patient's unconscious or the therapist to fill in that gap.

This could also account for the potency of "strange" gestures and atmospheres in religious and magical ceremonies as well as the potency of any charlatan who succeeds in mystifying an audience with a bit of mumbo-jumbo. For example, I once watched a stage hypnotist who divided his act into two parts. During the first half he simply performed a number of magical tricks: He began with the rabbit-out-of-hat type trick, and then progressed to "amazing" feats of memory and mind reading. He was really good, and I'd be at a loss trying to figure out how he performed them. Then the orchestra played a few tunes while his assistant removed the magical props, and finally, with a crescendo of music and an atmosphere of high expectation, it was announced that now he would do the hypnosis. Of course the audience was by now ready to believe anything; all their usual frames of reference were temporarily suspended, and he was highly successful in eliciting many hypnotic phenomena from volunteers he first carefully selected from the audience with a few suggestibility tests like the hand-lock and involuntary hand movements.

His mumbo-jumbo, his bag of magical stunts, actually fixated and in part suspended the usual conscious sets of the audience. The amazing and unusual suspends and bypasses the frame of reference which gives us our usual reality sense. When this generalized reality orientation goes, normal ego control goes. When normal ego control goes, the unconscious comes in autonomously to fill the gap. The therapist can also step in at this point and evoke processes that would not be possible for the patient in his usual frames of reference. A flow diagram adapted from our previous formulation (Erickson & Rossi, 1979) would go somewhat as follows:

1.	Fixation of Attention 	via	Utilizing the patient's beliefs and behavior for focusing attention on inner realities. Presentation of the strange, unusual and "amazing."
2.	Depotentiating Habitual Frameworks and Belief Systems	via	Distraction, shock, surprise, "magic," doubt, confusion, dissociation, or any other process that interrupts the patient's habitual frameworks. Ordinary "Normal" awareness is disrupted.
3.	Unconscious search	via	Implications, questions, puns, and other indirect forms of hypnotic suggestion. Direct suggestions are more likely to be accepted because of the disruption and gap in ordinary awareness.
4.	Unconscious process	via	
5.	Hypnotic Repsonse	via	An expression of behavioral potentials that are experienced as taking place autonomously.

Usually it is no longer appropriate for the modern hypnotherapist to use tricks or the various forms of mumbo-jumbo to fixate attention and suspend a patient's usual frames of reference. For a well-educated subject like Dr. Q, therefore, you use your attitude of intense interest and expectancy about his inner exploration to fixate his attention and suspend his usual frames of reference. From that point on the process is as diagrammed above. Exploring self-experience in a new way, in an unusual context, replaces the older forms of mumbo-jumbo to initiate hypnotic phenomenon. Does that make sense to you?

E: Yes. [Erickson demonstrates a sleight-of-hand trick where he apparently loses his thumb and then finds it in a drawer and attaches it again to his hand.] The child watches you do that, and then he tries to do it by pulling at his thumb. He has seen you do it. That is a world of magic for a child. When you have an intellectual subject, you stick to the intellectual. That is what he will understand and will accept. You have to fit your technique to the patient's frame of reference.

2. Learning Indirect Communication: Frames of Reference, Metalevels, and Psychotherapy

E: When I first began the study of hypnosis, I wondered greatly about verbal technique. You take a subject in the present time, and you're offering him ideas that are to affect his future. You're also to distract his mind from the present. And you're to take his mind away from surrounding reality and direct it to his inner world of experience.

One of my first questions was, How do you move the patient's attention away from the immediate present and the immediate reality to the future and to future activities not yet known or not yet even thought about? And so I began trying to write out a verbal technique in which I could mention the present and define very exactly what I mean by the immediate reality situation. Then I make a reference to the future as if the future were in the remote future. And then I worked out phrases by which that remote future became closer and closer and closer to the immediate moment. By doing that, the subject had no opportunity to resist the fact that there is a next week and next Friday, next Thursday, next Wednesday, next Tuesday, next Monday, the next afternoon, the next forenoon. And I build up an acceptance of all those statements of the future because I deprive him of the privilege, of the right, of the possibility of disputing that future. I bring the remote future closer and closer to the present. (See "The Method Employed to Formulate a Complex Story for the Induction of an Experimental Neurosis in a Hypnotic Subject," Erickson, 1944.)

I worked out a total of 30 pages single-spaced, typewritten verbalization for the induction of hand levitation, or the induction of regression, or the induction of hallucinations. Then I began refining that 30 pages down to 25 pages, 20 pages, 15 pages, 10 pages, five pages, selecting the phrasing that seemed to be the actually effective phrasing that enabled me to build up an automatic response of patient behavior. I tried that on a lot of fellow students, all 30 pages, 25 pages, and so on. It is a marvelous experience.

Anybody who does that learns a great deal about the way they are thinking. As they understand the way they are thinking, they have to entertain the idea of how the other fellow thinks in relation to these words. In that way you learn to respect *the frame of reference* of the other person.

When you are doing psychotherapy, you listen to what the patients say, you use their words, and you can understand those words. You can place your own meaning on those words, but the real question is what is the meaning that a patient places on those words. You cannot know because you do not know the patient's frame of reference.

A young man says, "It's a nice day today." His frame of reference is a picnic with his sweetheart. A farmer says, "It is a nice day today." His frame of reference is that it is a good day to mow hay. The young man's frame of reference was his own subjective pleasure, the farmer's was the work he did in relation to hard reality.

R: They used identical words with entirely different meanings, entirely different frames of reference.

E: Totally different meanings, yet you could understand them when you knew their frame of reference.

R: So the therapist is always working with a frame of reference rather than the actual words. In hypnotherapy, when you are talking to a patient, you are actually addressing his frame of reference.

E: You are dealing with his frame of reference.

R: Your words are changing his frame of reference?

E: You are using his own words to alter the patient's access to his various frames of reference

R: That's the therapeutic response: gaining access to a new frame of reference.

E: Yes, getting a new frame of reference.

R: A patient is a patient because he does not know how to use his different frames of reference in a skillful manner; I believe these frames of reference are actually metalevals of communication. Bateson (1972) has described metacommunication as communication (on a higher or secondary level) about communication (on a lower or primary level). Similarly, we may view a frame of reference as a metastructure that gives meaning to words on the primary level. The metalevels are usually unconscious. You are always dealing with these unconscious metalevels of communication, since they are the determiners of meaning on the primary level in consciousness. These metalevels of communication were found necessary by Whitehead and Russell in their monumental work, *Mathematica Principea* (1910), to resolve many of the paradoxes that arose in the foundations of logic and mathematics when we were limited to only one primary level of discourse. Carnap developed a calculus of these multiple levels of communication within logic in his *Logical Syntax of Language* (1959). I have previously illustrated in some detail how dreams utilize multiple levels of communication to cope with psychological problems (Rossi, 1972, 1973c). Psychological problems have their genesis in the limitations of a consciousness that is restricted to one primary level of functioning.

I now suspect that you are doing the same thing with hypnosis. Consciousness on a primary level is stuck within the limitations of whatever belief system (frame of reference, metalevel of communication) is giving meaning to its contents. Consciousness at any given moment is limited to whatever is within its focus of awareness, and it can manipulate only these contents within its focus on its own level. Consciousness cannot reach up and change the metastructures, giving meaning to its contents; contents on the primary level cannot alter contents on a secondary level above it; it is the secondary or metalevel that structures and gives meaning to the primary.

Thus we may say that a patient is one who experiences the locus of his problem on the conscious or primary level, since he cannot make the contents of his conscious everyday experience what he wants them to be. He comes to the therapist and is really saying, "Help, help me with my metalevels, my frames of reference, so that I will experience more comfort (adaptation, happiness, creativity, or whatever) on my primary level of conscious experience. I cannot change my own conscious experience because it is being determined by metastructures outside the range of my own conscious control. So, Doctor, will you please work with my metastructures up there so I can experience some relief down here?"

With your indirect approaches you are attempting to deal with structure on these metalevels rather than the primary level of conscious experience. The patients usually do not know what you are doing because they are limited by the focal nature of consciousness to the contents on their primary levels of awareness. At present you are doing this somewhat as an art form. To make left-hemispheric science of this in the future, I believe we would need psychologists trained in symbolic logic to analyze the paradigms whereby you deal directly with a patient's metastructures. Then we will be able to analyze and outline those syntactical, semantic, and pragmatic paradigms of semiotic that are fundamental in coping with

metalevels. These paradigms could then be tested empirically in a cont rolled and systematic fashion. (See "The Indirect Forms of Suggestion" in Vol. I of *The Collected Papers of Milton H. Erickson on Hypnosis,* 1980, for our initial effort to utilize symbolic logic in the formulation of suggestions; see also White, 1979.)

Alternatively, we may find that these metalevels are actually right-hemispheric styles of coping that have a peculiar logic of their own in the form of symbols, imagery, and all the nonrational forms of life experience that have been intuitively recognized as healing. In this case we need to develop a right-hemispheric science of what in the past has been the domain of mysticism, art, and the spiritual modes of healing.

PSYCHOLOGICAL SIGNIFICANCE OF PHYSICAL RESTRAINT TO MENTAL PATIENTS

Milton H. Erickson, M. D.

Reprinted from *The American Journal of Psychiatry*, VOL 105, No. 8, February, 1949

Ever since chains and manacles were removed from the mentally ill, the general tendency of both the lay and the professional public is to regard any form of restraint employed upon the mentally ill patient as an undesirable, abhorrent, deplorable, punitive practice. Unwilling, grudging recognition is given to the fact that restraint is necessarily an integral part of the care of the institutionalized mental patient, since even the fact of hospitalization itself is a form of physical restraint. All too often there is a mistaken, unintentional disregard of the patient's own needs for protection from the self and from others, and a maintenance of false standards in the hospital by which the patient's welfare is really disregarded in favor of uncritical, uninformed public approval.

Rationalizations and justifications of restraint are offered in apologetic declarations, often true, that restraint is frequently necessary for the protection of both patients and others. Every effort is made to reduce the amount of restraint necessary and to seek for types of restraint that are less obvious, more concealed, and not so striking and so offensive to the eye of the observer, and the general policy of most mental hospitals is to decry the use of restraint as a shameful punitive practice.

Little is to be found in the literature concerning the meaningfulness and the significance of restraint to the individual patient. That which can be found is usually expressive of the generally accepted attitude of the wrongfulness of restraint. The problem of how the patient in restraint feels about it, what purposes restraint serves the individual patient, and the personality needs affected by the restraint are all disregarded in the general condemnation of restraint.

However, before reporting upon observations of the meaningfulness of restraint to mentally ill patients, certain items of common knowledge and experience will be cited as a measure of orientation. These will be mentioned briefly, and without much elaboration since they are self-explanatory.

First of all, there is the example of the frightened, hurt, sick, anxious, insecure baby or small child who desperately wants and needs to be held tightly in the confining safety of his mother's arms, and the more tightly he is held, the safer he feels.

Then there is the nervous passenger on the airplane whose sole comfort and security on a long trip is the carefully tightened safety belt.

Consider the soldier assigned to overseas duty bidding his wife farewell, both of them wanting and needing to embrace with a painfully tight embrace, to quote, "Hold me so tight I can't even move."

There is also the soldier under fire who wants the shelter of a foxhole, not a big, roomy, comfortable foxhole, but one that is just barely large enough to crowd into so that he can feel the comforting restraint of the solid, unyielding earth.

In bomb shelters a frequent request was, "Hang on to me, don't let me make a move." Frightened, terrified, distressed people need to huddle and crowd together in order to get the comfort of a form of physical restraint that paradoxically gives them a feeling of security.

Then there is another type of analogous behavior expressive of deep underlying fundamental needs in regard to spatial relationships. It is the need of little children to get into and to crawl through small apertures. They squeeze between chairs rather than walk around them. The closer the bed is to the floor, the more important it becomes to crawl under it. The drainage pipe, the keg or barrel on the way to school are the delight of the child and the bane of parents and police.

Mention is made of these items since they illustrate so clearly that any comprehensive view of physical restraint must encompass normal needs and desires as well as normal abhorrence of restraint. Ordinarily restraint is looked upon as an administrative problem that reflects to the discredit of the authorities, as something to be avoided and minimized, with no real consideration given to the actual significance of restraint for the individual patient. During 20 years of experience, there has been ample opportunity to discover that physical restraint should properly be viewed as a specific experience of great meaningfulness to the individual patient.

No attempt will be made to offer a statistical study for the reason that physical restraint is often a matter of good administration and housekeeping, as well as a matter of psychological experience of great importance to the individual patient.

In following the clinical course of patients from the time of admission to the time of discharge there has been an opportunity to discover how patients not only reacted to restraint but what it meant to them as persons. In order to clarify this problem, various individual case histories will be cited and those given will be selected on the basis of their representativeness of how patients actually do respond to restraint.

> There was Pauline, whose clinical course was marked by recurrent disturbed episodes of 2 to 3 weeks duration, during which she was combative and complete physical restraint seemed to be the only measure possible to control her. Observation disclosed that each such episode was prefaced by act hour or two of anxious fearful behavior during which she would huddle in corners, crowd between a bed and the wall, or hide between the mattress and the bed springs until she lost control of herself. Experimentation disclosed that whenever Pauline

manifested this type of behavior, her disturbed episode could be aborted by forcibly placing her in a tight wet pack against which she would struggle violently for a few minutes and then lapse into a restful sleep and an hour later she could be released without fear of disturbed behavior.

Sarah and Harold were two disturbed manic patients; their proud boast was that it required at least six attendants to put them in restraint, and they would rage furiously throughout the time they were in restraint. Both explained inadequately their need to fight something and an agreement was reached with them that they could have any form of restraint any time they wanted it and for as long a time as they felt they needed it, this agreement being reached before their disturbed behavior began. Both patients tested the physician's sincerity and when they discovered that they could rely implicitly upon him the restraint problem was greatly minimized. Thus Sarah, quiet, orderly, well behaved, at 9 o'clock would state, "At 11 o'clock, put me in full restraint, let me fight it out until 2 o'clock, then you can release me. Never mind what I say before 2 o'clock."

Harold would declare, "You better keep me in restraint today until the medical students arrive, and when they get here, let me out for about 2 hours. I can take that much time but don't try to stretch the time."

It became possible with these 2 patients as well as others to arrange to put them in restraint for an agreed-upon period of time, sometimes as little as 5 minutes and render unnecessary further restraint for even several days.

Jimmy and Frank were both graduates in psychology and both had clinical histories of catatonic stupors of months in duration. Both explained that something would happen within them that they could not control except "by freezing up and then it takes so long to unfreeze. Can't you do something to freeze me and then you can unfreeze me and I won't be in a stupor so long." Their wishes were met by the expedient of full rigid restraint, and instead of a stupor of many weeks' or months' duration, restraint of a few days against which they fought and struggled incessantly met their needs.

Albert, Jack, and Johnny had ground privileges but periodically became disturbed and violent and had to be returned to the closed ward for weeks or months at a time. Experimentation disclosed that they all became aware of impending disturbed states and that these could be abbreviated by placing them in seclusion rooms and letting them give vent in an uncontrolled fashion to their inner distresses for an hour or even a day and then they could be returned to ground privileges.

Teresa was a quiet, orderly patient who periodically developed prolonged periods of violently aggressive behavior. Systematic inquiry disclosed that "external unknown mystical forces" seized upon her and forced her to do things against her will. Experimentation disclosed that a belt and wristlets constituted a perfect

defense against those unknown forces and by keeping the wristlets loose she was at liberty to free her hands at any time or to place them back in the wristlets in full accord with her personality needs. She wore the belt and wristlets for many months as a form of magical armament against uncontrollable hostile forces.

Eddie and Gerald were 2 chronic patients who periodically enjoyed ground privileges or were on the closed ward because of disturbed behavior, sometimes lasting 3 or 4 months at a time. Experimentation disclosed that heavy sedation from 24 to 72 hours followed by 1 or 2 days' seclusion with or without physical restraint would actually abort their disturbed periods.

Marie, who suffered from an agitated depression, would plead piteously not to be placed in restraints. This type of pleading always occurred when she became tremendously distressed by suicidal compulsions, and it was her way of so informing the ward physician. Only one type of restraint was suitable, namely, belt and wristlets, and once placed in restraint she would struggle and quarrel with the restraints as a measure of keeping compulsive suicidal ideas out of her mind. When well along in her convalescence she would now and then beg frantically for restraints, and, upon the granting of her request, would scold and struggle furiously against the restraints. Subsequently, she would explain how necessary it had been to her, as a person, to be in restraint and thus to free herself of compulsive self-destructive ideation.

Gertrude was a violently disturbed paranoid schizophrenic, who required full restraint because of her combativeness. However, it was discovered that she looked upon restraint as proof of her divinity, and that she utilized violence as a means of insuring the presence of such proof. Accordingly, arrangements were made with her to have whatever restraint was necessary to satisfy her personal beliefs, with the result that her violence disappeared.

These are but a few of the many cases that could be cited. They all serve to illustrate the importance of looking upon restraint from the patient's point of view and not from the normal person's point of view of abhorrence. It is true that patients do not like physical restraint, but it is also true that human nature tends to regard a repugnant remedy as effective. The disturbed patient needs something more concrete to fight than unknown unrealized personality conflicts. The symptomatic needs of the patient are tremendously important and adequate respect should be paid them. Physical restraint should not be purely an administrative problem, nor just a matter of good housekeeping, nor ever an item of punishment as it so often is. Instead, it should be viewed as a symptomatic measure intended to meet a patient's needs. Everyone recognizes that a patient's aggressive tendencies can often be met by letting them drive nails or tear rags in the O. T. shop. The same holds true with restraint. Experimentation has disclosed that patients ordinarily kept in restraint can have their distorted psychotic needs met with a reality that they can actually fight, resent, and discard with an actual sense of personal achievement. Often full restraint for as brief a period as 10 minutes will serve to enable a patient, who otherwise would require 24-hour restraint, to make a good ward adjustment throughout

the day. The employment of restraint as an immediate therapeutic procedure instead of as a punitive last-resort measure would serve greatly to better both the patient's and the general public's attitude toward restraint.

This is not a plea for more restraint. Rather, it is a plea that, when used, restraint should be employed with the full realization that it can be made a therapeutic experience for the patient.

Book Review

Milton H. Erickson

Hypnotherapy: A Survey of the Literature

By Margaret Brenman and Merton M. Gill. New York: International University Press, 1947.

A monograph, entitled "Hypnotherapy," published in 1944, four case studies published from the Menninger Clinic during the years Of 1943-46, and a University of Kansas doctoral thesis submitted in 1942 by the senior author constitute the contents of this book.

The monograph section accounts for 117 pages of the 253 pages of text, and, except for a new format and one new footnote on page 87, there have been no revisions of the 1944 issue.

It has a bibliography of 295 titles, chosen from over 1200 references. The selection, the authors state, was made on the basis of availability as well as pertinence. Hence, not too critical a selection was made. For example, there are three listings of the discredited works of a well-known charlatan. The initial work of the clinically untrained and inexperienced amateur is given the same importance as that of well-trained, well-experienced clinicians. Some references are no more than arm chair productions, based not on actual knowledge of or experience with hypnotherapy, sometimes not even with hypnosis in general, but on theoretical assumptions and even misconceptions. Other references, in themselves good publications, make only casual mention of hypnosis. Additionally, the references are divided into chapter bibliographies with many duplications, reducing the actual total given. The placing of an asterisk before those titles considered by the authors to be the more outstanding representative contributions, and the addition of a supplementary list of the many studies in hypnotherapy published since 1944 would have been an excellent service.

The first chapter (12 pages), "The Historical Development of Hypnotherapy," considering its brevity, is fair, although somewhat marred by interwoven accounts of incidental controversies and a seeming over-defensiveness of psychoanalysis. Also, even though the authors later emphasize that hypnoanalysis holds the greater promise for a shortened method of psychotherapy, no mention is made in this chapter of the experimental and clinical hypnotic work constituting the direct foundations of hypnoanalysis.

Chapter II, "Methods of Inducing and Terminating Hypnosis," is mistitled since it is only concerned with the methods of induction. Even then, they "restrict this discussion ... to a

presentation of classic, standard techniques in current use." These "classic standard techniques," as opposed to "unorthodox techniques," are discussed under the headings of "sleeping methods," "drug hypnosis," "hypnoidization" and "waking hypnosis." In essence these techniques are but a formalization of age-old ritualistic and mystical prestige-evoking procedures that date back to times previous to the recognition of the psychodynamics of human behavior.

Furthermore, there is no real recognition that, in hypnotherapy, a trance induction is one order of experience and that the trance state itself is another; that the latter is an end result of special processes of learning and experiencing on the part of the subject; that whether traditional rituals or methods leading to a dynamic participation by the subject in inducing a trance are used, is relatively insignificant since the goal is the development of a dynamic hypnotherapeutic situation. Emphasis is placed upon what the hypnotist does with no real consideration of what the subject does, which, after all, is the really important thing. Neither is there recognition of the need to discuss, in a book on hypnotherapy, instead of induction techniques for hypnosis in general, the actual problems encountered in attempting the therapeutic use of hypnosis.

Chapter III, "Susceptibility to Hypnosis," belongs preferably in a general text on hypnosis. Instead of discussing the methods, conditions and situations favorable to hypnotherapy, general questions about the hypnotizability of people are discussed. Even then, too much emphasis is placed upon certain aspects of the personality, special responses, and specific traits, and no direct discussion is offered of the much more important problems of interpersonal and intrapersonal relationships, and personality needs and purposes with which the patient confronts the therapist.

In the chapter, "Therapeutic Implications," pages 51-90, a summary is offered of six methods with a statement of advantages, limitations, and the types of cases treated by each. These are listed as:

1. Prolonged hypnosis without direct suggestion or exploration.
2. Direct suggestion of symptom-disappearance.
3. Direct suggestion of disappearance of attitudes underlying symptoms.
4. Abreaction of traumatic experience.
5. The use of specialized hypnotic techniques.
6. Hypoanalysis.

Actually the first three methods are identical if consideration is given to the patient and his behavior instead of limiting consideration to what the hypnotist does and says. In psychotherapy of any kind, the therapy derives from the work the patient does. This, the authors emphasize. Yet, in their evaluation of the "methods," they overlook this most significant fact. For example, in the typical cases cited in pages 37 to 48, the coming of the patient for treatment dynamically implied that he came to have his illness cured, even if nothing were mentioned about the dynamics involved. To be cured meant the correction of the symptom, underlying attitudes, misunderstandings and all things pertaining to that illness. To hypnotize the patient, with the direct understanding that the

hypnosis is therapeutic, is direct suggestion even if not verbalized. To suggest directly by word, deed, or attitude that a pain will be removed constitutes a direct suggestion that the sufferer, relieved, will, as he must, take a new attitude toward himself and evolve a significant alteration of his behavior. It is from these dynamics of the patient's understandings that the therapy derives. Yet, the authors describe these three methods in terms of what the therapist says. The intensely dynamic total situation is disregarded. By way of an analogy, silently to hand a sobbing child a piece of candy and to elicit pleased and happy behavior constitutes direct and indirect suggestion, leads the child to intrapsychic exploration, an alteration of behavior, symptom disappearance, change of intrapersonal and interpersonal relationships, reorganization of attitudes underlying symptoms and the development of new patterns of behavior.

The next two methods are similarly inadequately reviewed, although there is better appreciation by the authors that the patient does work. Their chief error is the assumption that abreaction, projection, repression, or dissociation can be used separately and in pure form or out of relation to all the other forms of dynamic behavior constituting the total psychotherapeutic situation. The patient abreacting is also necessarily doing many other things, even if they are not named or even not known. Greater attention to this would have enabled the authors to offer a more instructive appraisal of these "two" methods.

Hypnoanalysis is appraised as the potentially most promising method for shorter psychotherapy. As described by the authors, it is essentially a combination of the fourth and fifth methods to which have been added psychoanalytic techniques with the therapy conducted preferably by psychoanalysts. Actually, of course, there is no reason why procedures four and five cannot be utilized in combination with psychoanalytic techniques and insights by anyone competent and qualified to do psychotherapy. Nor should hypnotherapeutic techniques be termed "unorthodox" because they are psychodynamically oriented and not restricted by tradition or such ritualistic procedures as eye fixation and hand clasping described earlier in the book.

To summarize, approximately 30 of the 40 pages of this chapter are devoted to a running commentary upon 135 references. Quotations, approximating 8 pages, are cited from 16 references. To appraise these, consideration is given to the actual date of the work or the original publication and not to the date of translation or republication. In all, 4 of the quotations date from 1895, 1 from 1909, 6 from between I920 and 1927, and the remaining 5 are respectively 1935, 1938, 1941, 1943, and 1944. Of these last 5, they are in order an autobiography, 2 textbooks on psychotherapy, the authors' paper included in full later in this book, and the other is a text on hypnotherapy. In content, the quotations are largely generalities, speculations, or symptom description. At best they constitute a general background for a preliminary discussion of hypnotherapy.

In brief, had the authors made this chapter an account of the progressive recognition and utilization, from Mesmer's time to the present, of the psychodynamics of human behavior in the therapeutic situation, they could readily have achieved a most instructive exposition of the development of hypnotherapy.

The chapter closes with two pages of discussion on *supposed dangers of hypnotherapy*. This reviewer agrees with the authors completely that the dangers are suppositional only, and that, when deleterious conditions arise, they spring from incidental things and not from the hypnosis. However, a curious question arises in this connection. In a previous publication the senior author emphasized the realness of the dangers of hypnosis, but makes no mention of that publication in this connection where it would be most pertinent, since hypnotherapy is hypnosis. Or has additional experience effected a revision of understandings?

Chapter V, "Theory of Hypnosis," is primarily a review of various theories concerning hypnosis in general, with no significant discussion in relationship to hypnotherapy. The review of the second part of the book will be brief.

The first three papers, each a single case report, do demonstrate well that hypnosis and psychoanalysis can be combined effectively in securing therapeutic results in difficult psychiatric problems. However, in all the papers, the authors appear over defensive about psychoanalysis. They stress the importance of psychoanalytic techniques if hypnosis is to be used effectively; they readily ascribe specialized psychoanalytic significances to hypnotic procedures and states; and they unhesitatingly make rather sweeping statements.

For example, the first paper is described in *The Bulletin of the Menninger Clinic*, 7:162, Sept.-Nov., 1943, as a report of preliminary work for a projected program. Yet, the authors, on the basis of a study of a single patient in whom the end results were not too gratifying, speak generally of a special transference deriving from trance induction which differs from the transference that arises out of the hypnotic interview. In a similar manner, they declare unequivocally (page 133) that "We believe that analysis of the transference in hypnotic psychotherapy plays a particularly important role in establishing . . . ego participation." Whether right or wrong, the data to support this assertion are lacking and no references are given in the paper to substantiate it.

The fourth paper describes a patient who resisted attempted analysis for five months. Then, in return for a special indulgence, the patient agreed to cooperate for hypnosis and (page 17g) "went into light hypnosis for an hour on each of two successive days while in the pack." Thereafter, the patient refused to cooperate for hypnosis. However, many, many months of other types of psychotherapy by the authors and others led to significant improvement. Unless the authors wish to attribute the eventual good results to the (page 179) "attempted hypnosis," this paper has no place in this book.

The bibliography for the four case studies lists 17 titles, one of which is the first paper itself, another relates to experimental hypnosis, eleven pertain to anorexia nervosa, and the others are general references.

The final 58 pages of text are devoted to a condensed version of the senior author's doctoral thesis. Since the purpose of the thesis, as stated on page 250, was primarily to illustrate a method of research using hypnosis as a tool, it has no place in a book dealing presumably with hypnotherapy.

Concerning Present Inadequacies in the Legal Recognition and Handling of the Mentally Ill

Milton Erickson, M.D.

Published in *Diseases of the Nervous System*, Vol VII, No. 4, April 1946.

The purpose of this paper is to present a brief discussion of an existing state of affairs which constitutes both an obstacle to the development and practice of institutional psychiatry and a barrier to the full recognition by the lay and professional public of psychiatry as a medical specialty requiring extensive training and experience. No effort will be made to propose remedies or to offer suggestions to correct the existing procedure. Instead, an endeavor will be made to outline two particular aspects of a significant problem which needs to be recognized and understood generally, namely, that psychiatry should be given equal rating as a medical specialty along with internal medicine, cardiology, dermatology, and other branches of medicine, and should not remain an undefined field in which legal technicalities, lay judgment, and inexperienced medical opinion is allowed to determine the welfare and the future of mentally ill persons.

For the most part this discussion is based upon the general situation existing in the state of Michigan, but it is, nevertheless, either in full or in part, directly pertinent to legal procedures in other states.

The first aspect to be discussed concerns the established legal procedure for the commitment of mentally ill patients. Without being pedantically exhaustive, the usual course of events in Michigan, as in various other states, is for some responsible person to file a petition with the Probate Court, stating their beliefs regarding the sanity of the individual, whereupon the court may issue a temporary order for the detention of the patient in some suitable institution. Before the expiration of that temporary order, two physicians are appointed to examine the patient and upon their findings the court may discharge the patient as not mentally ill or a permanent detention order may be issued. It is not the prerogative of the court to take cognizance of the findings made in the public institution where the patient may be placed for observation. Rather, those findings, however definitive and informative they may be, are legally to be disregarded. Thus, the order for temporary detention and study often constitutes nothing more than a legal but totally meaningless gesture.

The qualifications of the examining physicians appointed by the court to determine the future of a possibly mentally ill patient are essentially that these examining physicians shall be properly licensed, not connected with the institution to which the patient may be committed, and that they shall have had 3 to 5 years experience in the practice of medicine. As a result of these legally established qualifications, the author has seen commitment papers signed by pediatricians, dermatologists, pathologists, obstetricians,

cardiologists, general practitioners and even some psychiatrists. One can readily recognize the folly of a common practice of asking a psychiatrist to be the deciding consultant in an obscure cardiac case, but unfortunately, as yet the reverse is not readily appreciated.

The law properly provides that a person may be committed as mentally ill only on the basis of certain established facts. Lack of training and inexperience in psychiatry has resulted in innumerable instances of persons, actually psychotic and in need of institutional care, being committed illegally because the committing physicians' reports were not properly written, the necessary facts were not correctly established, and the court, in the rush of work and in the simple acceptance of mere opinion ordered such commitment. For example, the committing physicians' statements on one patient read, "This patient is insane, with catatonic dementia praecox, and should be sent to a mental hospital and treated for this condition."

Such a statement is merely a personal opinion, is not substantiated by factual statements as required by law and hence the commitment based upon it was illegal. Furthermore, in this particular instance, although the patient was acutely psychotic and in need of immediate psychiatric care, the correct diagnosis was general paresis. Hence that patient could not possibly be legally committed as suffering from catatonic dementia praecox, and the commitment was an absolute denial of his legal rights and privileges.

Nor is this an isolated instance. From time to time, patients actually psychotic at the time of commitment and still psychotic are discharged from the mental hospital because of illegal commitment, to their own detriment and to that of society as a whole, to say nothing of the debasement of psychiatry as a medical specialty in the eyes of the public and the discredit of the particular institution detaining the patient. The medical and psychiatric rights, privileges, and needs of the mentally ill patient should not be subordinated and sacrificed to questions of legal technicalities. In the case cited of the patient illegally committed as suffering from catatonic dementia praecox when the actual condition was one of general paresis, the court could properly have discharged the patient from the hospital to await commitment on legitimate grounds, all of which would have forced an unnecessary and even destructive delay in the proper treatment of that patient. And such discharges do occur, to the disadvantage of the patient and all concerned.

While it is true that the superintendent of a mental hospital has the right to accept or to refuse admission to a mentally ill patient and can rightly and arbitrarily refuse to accept patients improperly committed, the needs of the individual and of society as a whole cannot be satisfied by arbitrary legal considerations. Nor can the mental hospital serve the community conscientiously and adequately by disregarding the needs of an individual because of an error by someone not directly interested in proper psychiatric treatment of an individual.

The socially conscious superintendent must necessarily place the welfare of the individual and of society above debatable legal questions. He cannot arbitrarily discharge a patient committed to the hospital and accepted in good faith because of a subsequent

discovery that legal technicalities actually render the commitment illegal or questionable. The patient's rights and needs as a sick person, and the importance of early and adequate psychiatric treatment cannot and should not be made to wait upon a final judicial determination of what constitutes proper legal procedure. Nevertheless, as has been mentioned, the court is at full liberty, in case of an error in commitment, to discharge a patient seriously in need of psychiatric treatment, and frequently does so to the disadvantage of the patient, the discredit of the institution, the detriment of psychiatry, and without profit in the correction of the defects of the legal procedure.

The second aspect of the problem concerns the failure of the untrained, the inexperienced physician to recognize psychiatric problems and his consequent inability to appreciate their significance. Too frequently patients who are definitely and unmistakably psychotic but whose symptomatology is of such character as to require specialized training and experience to be recognized are denied the benefits of hospitalization and treatment in the early stages of their mental illness.

As mentioned before, it is of little real medical significance who recommends commitment for the mentally ill patients, but it is of serious and destructive significance to the mentally ill patient and to his relatives and to society as a whole to have an early, obscure, or difficult to recognize mental illness completely unrecognized and disregarded. In psychiatry and especially in relation to psychoses, the entire future and welfare of the patient and often that of his family is at stake, and merely an arbitrary number of years in an unrelated field of medicine does not qualify any physician to sit in judgment upon the proper psychiatric care of that patient. Nevertheless, under existing legalities, the untrained, the unqualified, and the inexperienced sit in judgment to determine a psychiatric patient's entire future. And the court, in accord with established legal custom, is, in essence, forced to disregard entirely the findings and the advice of those physicians qualified by training and experience, to whose care the patient was temporarily committed for observation and study, presumably for the guidance of the court but actually merely to fulfill the letter of the law and not really to serve adequately human needs.

In those cases where the patient expresses a wealth of hallucinatory and delusional ideation and shows bizarre behavior easily recognizable as psychotic, no specialized training is necessary to permit the ready recognition of an obvious psychosis. However, all psychotic patients are not easily recognized as mentally ill, even when they have a wealth of delusional and hallucinatory ideas. They may be so secretive that they may be unwilling to disclose to a stranger their distorted ideas, or they may have sufficient insight to recognize the possible inferences that might be drawn by the court physician if they became communicative. Such patients can easily and often do give sufficiently normal replies to the customary questions asked of them to convince the court examiner of their mental soundness. This is not an infrequent occurrence.

Furthermore, a psychiatric problem is not always to be recognized in a few minutes or even a few days, and no court physician has the time to make a long continued observation and study of a patient. Indeed, patients are often placed by the court in the

mental hospital on a thirty-day observation order. While this is a legal recognition of the need and importance of time in studying a psychiatric patient by competent psychiatrists, the discharge of that patient may depend wholly upon a few minutes observation by psychiatrically untrained physicians, who may be totally at variance with experienced psychiatrists in their findings.

Then too, the same sort of diagnostic problems that exist in other fields of medicine obtain in the field of psychiatry. The correct differentiation between a simple maladjustment, a behavior problem, a neurotic manifestation, and an early sign of a psychosis requires diagnostic skill based upon highly specialized training and experience. The more difficult the task, the earlier the signs of mental illness, the greater is the need of the patient and all those concerned for competent psychiatric help. Failure of the recognition of mental cases and refusal and consequent postponement of treatment serve only to increase the severity of mental illness, to render treatment less hopeful, and to militate against the patient's future welfare.

To illustrate some of the problems that arise from the present procedure of relying upon psychiatrically untrained physicians for presumably expert opinion to determine the future of mentally ill patients, the following case histories will be cited briefly. They have been selected from a large number of comparable instances because they disclose the difficulties forced upon the untrained physician or because they exemplify the tragic possibilities of an error in judgment. The case histories have been disguised to conceal identities, but there has been no significant alteration in the psychiatric symptomatology, and while most of them represent Michigan cases, some are from other states.

Patient No. 1 demonstrates the tragedy that may result from lack of psychiatric training. This twelve-year-old child was first seen in psychiatric consultation in a general hospital because of continuous sobbing, fear reactions, and almost delusional statements about being "bad". The psychiatrist recommended immediate commitment and prompt treatment for early schizophrenia.

The court-appointed physicians found only evidence of simple maladjustment in an unhappy home situation and commitment was not recommended. Approximately 18 months later the patient was admitted to a mental hospital for temporary observation, this time with a history of progressively worse adjustment, culminating in homicidal attacks upon members of the family.

Adjustment to the psychiatric ward was excellent and when seen by the court physicians, both concluded the patient to be mentally well and both physicians criticized the hospital for detaining so young a patient. Before one of the physicians had filed his report, however, he visited the hospital to interview another temporary observation patient. He again checked on Patient No. 1 and discovered a state of catatonic stupor which led him to revise his report. As a result of the disagreement of the court physicians at the court hearing, the case was postponed and another temporary observation period ordered. The third physician appointed discovered the patient in a state of catatonic excitement, and commitment was ordered. Thus approximately two years after the patient had been

recognized by a trained psychiatrist as suffering from early schizophrenia and in need of prompt treatment, therapy first became available. One can only speculate as to the traumatic effect upon the patient of the long series of maladjustments finally leading to commitment and upon the role those experiences played in the patient's slow and unsatisfactory convalescence. It is reasonable to believe that had treatment been instituted when first recommended, the further progress of the patient's mental disorder to a homicidal state could have been prevented. Certainly, this patient's rights as a mentally ill patient were violated, even if legally so.

Patient No. 2. This patient illustrates clearly the need for psychiatric training to permit recognition of mental disorders. A young man was brought to the hospital on an emergency order by the police who declared he had delusions about electricity. Four trained psychiatrists interviewed him extensively, found no delusions about electricity or other psychopathological ideational trends. However, each psychiatrist independently reached the clinical conclusion that the patient was suffering from early schizophrenia because of general inadequacies of affective responses. Finally two of the psychiatrists, determined to verify their clinical impression, reinterviewed him exhaustively without critical results until resort was deliberately made to a schizophrenic mispronouncement of the word "electricity" as "electric city."

The patient's reply was most illuminating. "I've been wondering when you fellows would get around to asking me about electric city instead of electricity. I thought you weren't interested, so I just told you what I knew about electricity until you showed some interest." There followed a wealth of delusions centering about "Electric City," which enabled the patient to set the stage for the court physicians by demanding to know if they were just interested in electricity, or if they really wanted to know about "electric city." In the ordinary course of events this patient would have been discharged until such time as he would have volunteered his secret ideational content. However, specialized psychiatric training permitted an appreciation of those intangible affective reactions and a recognition of the frequent need to meet a schizophrenic patient on his own terms and to use, if necessary, his own peculiar schizoid language.

Patient No. 3 represents a serious social tragedy. A 45-year-old man became assaultive when ordered to "move on" by a policeman. He was arrested, suffered an epileptic convulsion, and was judged by two competent psychiatrists to be suffering from a psychosis with epilepsy and to have serious homicidal trends. He was transferred to a mental hospital for observation because of the recommendations of the psychiatrists. When seen by the court physicians, he made a good impression on them, and they observed no evidence of a psychosis nor of homicidal trends. Six days after his discharge as not psychotic by the court he suffered another convulsion, seemed to make good recovery from that seizure, but a few hours later killed a family of five with an axe.

To ask the psychiatrically untrained physician to offer an expert opinion on such a problem Is criminally wrong. Only extensive experience and specialized training can qualify the medical man to deal adequately with such a problem, and even the well-experienced psychiatrist can easily reach the wrong conclusion in such a case as this.

However, in this instance, two psychiatrists did reach the right conclusion but their opinion was over-ruled by inexperience at a tremendous social cost.

Patient No. 4 represents an instance where the patient's own needs were recognized only after a roundabout procedure. After having been in four different mental hospitals, the patient was finally ordered released by the Probate Court, a sanity hearing was ordered, and restoration of sanity was the result. Shortly thereafter the patient's unusual and bizarre behavior resulted in arrest and a temporary order for mental observation. The first three court physicians found the patient mentally well but at the insistence of the patient's family physician and the family attorney, the temporary order for observation was continued until the court had appointed two psychiatrists who promptly made a diagnosis of schizophrenia, paranoid type, and commitment was then finally ordered.

This patient has been used repeatedly for teaching purposes because of the perfection with which the role of a mentally normal person is played. Invariably the medical students are convinced that there has been a miscarriage of justice until the patient selects from the group some one who appears sufficiently trustworthy for the patient to relate confidentially a wealth of bizarre delusions and hallucinations otherwise inaccessible.

While the patient's general behavior as a free member of society would have forced eventually a recognition of the mental disorder, 4 different hospitalizations, a restoration of sanity, and further temporary observation were futile, ineffectual procedures that actually delayed any effective care of the patient until the intervention of the family physician and the family attorney secured competent psychiatric opinion.

Patient No. 5 is an instance of individual tragedy. She was admitted on a temporary order as suffering from a possible alcoholic psychosis. The hospital psychiatrists made a diagnosis of chronic alcoholism with psychosis. Within ten days the patient had made an excellent superficial recovery, and upon the recommendations of the court physicians she was ordered discharged, despite the insistence of the ward physician that commitment and treatment were warranted. Two months later, all her resources exhausted, she was picked up by the police while intoxicated and was returned to the hospital acutely psychotic and seriously damaged organically by her prolonged debauch.
While the future of any alcoholic is uncertain, this patient's life history indicated a reasonably good prognosis up to the moment of her discharge from the hospital by the Probate Court. Now, more than a year later, she is progressively deteriorating.

Patients Nos. 6, 7, 8 and 9 are all instances of tragedy to the family as a result of existing legal procedures. All were women, admitted for temporary observation upon the petition of the husbands and all were found by the hospital psychiatrists to be acutely psychotic with alternating periods of excited behavior and seemingly normal lucid intervals. In each instance, the court physicians found the patients not psychotic, their discharge from the hospital automatically followed and the subsequent development in each case was a disruption of the home and the scattering of the children in three of the cases among relatives, since the husband could not take care of his wife and the children also. In the

fourth instance there were no children, and the patient left her husband to live with other relatives, thereby disrupting another home because of her vagaries.

In each of these cases, while the psychoses were unmistakable to the trained psychiatrist, there was adequate opportunity for an error in judgment by someone lacking specialized training. The future for each of these patients is, in all probability, an aggravation of their symptomatology and eventual commitment to a mental hospital at a later date with treatment much less hopeful.

Patient No. 10 represents another type requiring special training to recognize. Over a period of a year she had been admitted to various private hospitals but each time she had herself removed by relatives before a diagnostic study could be made. She finally sought an order from the Probate Court for temporary observation in a mental hospital. After an extensive study, the hospital psychiatrists made a diagnosis of schizophrenia, catatonic type.

This patient had a college background, had studied psychology and psychiatric textbooks, and was able to discuss her hallucinations, her feelings of depersonalization and unreality and her periods of muteness and physical rigidity in a competent, objective fashion with a remarkable degree of purely intellectual insight.

When she was examined by the court physicians, the patient, as she carefully explained later, "took a perverse delight in giving them all the normal answers and convincing them that I am not in the least psychotic." As a result, both physicians believed her to be mentally well.

When she was questioned about her need for treatment and the adverse effect of the court physician's opinion upon this, the patient readily agreed that she needed treatment, but declared cryptically that the opinion of the court physicians was of no concern to her because she could not be removed from the hospital against her will.

What she meant by this became apparent the day before her hearing in court, at which time she developed a severe stupor and remained in that stupor for a week. Thereby she forced a postponement of the hearing, re-examination by duly appointed physicians, and subsequent commitment.

After adequate treatment she was paroled from the hospital and continued in good remission, earning her own living, until contact with her was lost.

In this case, only the patient can be given the credit for effecting a recognition of her needs and rights as a mentally ill patient. Her educational background, her understanding of existing legal procedures, her awareness of the tendency of the committing court to disregard the findings of the institution in which a patient is placed for mental observation and study, and her own pathological need to dominate the total situation, served fortunately to rectify a serious unintentional error of judgment by well-intentioned but not adequately qualified medical men.

Case 11 is an instance in which psychiatry, medicine, and the court all came to serious grief because of the existing legal procedures. It is merely an example of numerous other similar cases and reflects the tremendous need for adequate legal provision for the recognition of mental disease by properly trained and experienced psychiatrists.

This patient, confined to a mental hospital because of mental illness characterized by paranoid trends, was given a hearing in court to determine if hospitalization should be continued. Despite the availability of the hospital records, the presence of the ward psychiatrist at the court hearing, and the actual verbalized protests of the ward psychiatrist, the court took cognizance, in perfectly legal fashion, only of the opinions of two physicians appointed by the court. In accord with their recommendations, the court released the patient, who within a month's time killed two members of his family and committed suicide, all in full accord with the actual predictions made by the ward psychiatrist, and in accord with the information available in the hospital records.

Nor is this the only instance in which untrained, inexperienced, and unqualified medical men are called upon, under existing legal procedures, to assume responsibilities not rightly theirs. Not always are the results so tragic and so apparent, but in many instances the fate of an individual and even of his family has been tragically resolved on the basis of untrained medical advice when there was available better qualified advice and understanding. In the practice of medicine it is the obligation of every practitioner, if he cannot do good, at least to avoid doing harm. Especially does that obligation rest upon those whom an outmoded legal procedure calls upon to furnish skills not possessed and which are available and acceptable and which lack only the general recognition that must come first from the medical man himself before it can become an established legal custom.

While only 11 cases have been cited, they are but a selected few from a long list of those available to the author. Furthermore, those presented or available for presentation are not unique, since mental hospitals throughout the country could cite extensively similar material. One needs only to read social service histories on out-of-state patients to realize how frequently psychiatry as a medical specialty requiring definite training, skill and experience has been unrecognized, overlooked, and even disregarded by the courts and by the lay and professional public.

In brief, there is need for the lay and professional public to acknowledge that the welfare and the future of mentally ill patients need more legal recognition and protection than is possible under existing legal procedures.

A Teaching Program for Commissioned Reserve Medical Officers

Milton H. Erickson, M.D.

Reprinted from *Diseases of the Nervous System*, Vol. V, No. 4, April 1944.

The experience of the first world war clearly demonstrated the tremendous importance of psychiatry in military medicine. That lesson has now resulted in an ever-increasing utilization of psychiatry in the present conflict, an item of fact which is well known and requires no further discussion. However, despite the significant growth in the recognition of the importance of psychiatry as a medical specialty, there has not yet been sufficient time since the first world war to place psychiatry on the same basis of adequate teaching in medical schools that has been accorded to other medical subjects.

As all of us know from personal experience and as Ebaugh and Rymer have shown in their extensive study of "Psychiatry in Medical Education," the average medical student is much too frequently graduated with an inadequate and often sketchy knowledge of psychiatry. Teaching too often is limited to a restricted number of didactic lectures and an insufficient amount of clinical work, usually with frankly psychotic patients who represent primarily only a limited section of the field of psychiatry. A knowledge of those problems that constitute the greater part of psychiatric practice such as. personality problems and maladjustments, behavior disturbances, emotional instability and immaturity, psychoneuroses, psychosomatic disorder, defects of intelligence, the incipient states of the psychoses and all those psychopathological conditions that require the service of a psychiatrist for recognition and treatment, is left primarily to the experience to be gained after formal educational requirements are fulfilled.

The crowded medical curriculum actually precludes the average medical student from becoming adequately acquainted with all the variety of psychiatric problems that constitute so significant a part of medical practice and which needs to be recognized and understood sympathetically if proper treatment is to be given the patient. We are all aware of the tragic results of neglect, misunderstanding and failure of treatment that may attend upon the simple statement, "There is nothing physically wrong with you," when such a statement disregards the significant fact that psychologically the patient is as much disabled as if he were bed-ridden by chronic somatic disease.

Nor in the present organization of medical teaching is there any clinical setting to permit the student to acquire an adequate knowledge of what is psychologically normal or abnormal since such concepts are son intangible as compared with physical evidences of disease. Hence, it is almost essential that prolonged experience be relied upon as a measure of teaching what may be considered normal and what may be regarded as falling into the field of psychiatry.

That this is an unfortunate state of affairs in medical education is readily appreciated even in peacetime. It is even more quickly recognized and regretted now when the newly trained physician, before he has had the time or opportunity to glean that special experience with and understanding of psychological illness, is being taken into the army where psychiatric knowledge and techniques are so essential in every phase of military medicine. Hence, there is now a special, actually imperative, need to provide much more adequate and effective psychiatric training for the medical student than ever before because of the imminence of military service, during which the medical man, regardless of training and specialty, will face along with infection and injury the problems of shell shock, hysteria, conversion neuroses, panic reactions, personality disturbances and a wealth of other psychiatric problems.

As yet, the reorganization of the medical school curriculum to meet wartime needs and the enrollment of eligible students in the medical reserve corps has done little to provide the opportunity for that additional psychiatric training actually required by the present military needs. Accordingly, this need for better psychiatric training constitutes a problem directly incumbent upon those interested in psychiatric teaching to meet as rapidly and as completely as possible and with least interference with established teaching conditions.

Study of this important teaching need and discussion of it with Dr. Henry Reye, head of the department of neuropsychiatry at the Wayne University College of Medicine, with Lieutenant-Colonel Roscoe W. Cavell, Senior Medical Officer at the Detroit Induction Station, and with Colonel Roy Halloran, Chief of the Division of Neuropsychiatry for the United States Army, coupled with personal experience at the United States Army Recruiting and Induction Station at Detroit as an examining psychiatrist suggested the possibility of a new teaching venture in psychiatry.

As it was envisaged, this plan would provide medical students with a new and exceedingly rich variety of clinical experience. Furthermore, it would serve materially to give those students holding reserve commissions a valid understanding and significant appreciation of the psychiatric problems they would be likely to meet in the armed forces. The program as it has been worked out has proved pleasingly simple and it has been satisfyingly effective and instructive. Informal permission and approval were secured from the authorities to permit those senior students at Wayne University College of Medicine holding reserve commissions to attend regularly at the induction station in groups of two or three at least one entire day per week. There, under the tutelage of qualified psychiatrists interested in teaching, the students sit in on the regular psychiatric examination of selectees and recruits. In this situation they are given ample opportunity to observe intensively and repetitiously, under actual clinical conditions, literally every variety of psychiatric problem, and to make direct and immediate contrasts between the normal and the abnormal and to note the range and the variety of both the normal and the abnormal, an item of paramount importance in teaching psychiatry.

In actual procedure the students are given an initial or preliminary discussion of the nature and character of the psychiatric examinations to be made. The purpose and the

significance of the routine questions asked and especially the index character of the questions is explained in detail, and, of course, all of this is subsequently illustrated over and over throughout the day. Thus, they understand that the question, "How far through school did you go and how old were you when you left school?" if it elicits a reply of "Fourth grade at 17 years," constitutes a possible index of intellectual defect. Similarly the question "Have you ever been arrested and for what?", often constitutes a good index of the selectee's capacity for adjustment to authority and order.

Instruction is given on the need to inspect the selectee carefully as he enters the booth, to observe any physical defects, signs of neurological disease, psychomotor incoordination, unusual or overcompensatory behavior patterns, evidences of emotional disturbance or instability, and to note the character of his response to the examination situation, whether friendly, cooperative, antagonistic, belligerent, indifferent, detached, or fearful and worried. Emphasis is also placed upon the need to observe any inconsistencies, incongruities or any unusual manifestations of behavior not readily understandable and each of these possible observations is stressed as a point of special inquiry, and their possible significance is indicated with the full knowledge that sooner or later during the day they will all be adequately demonstrated and illustrated.

After this preliminary discussion the routine procedure of examining selectees is begun with the student sitting at the table beside the psychiatrist and attending to the examination procedure.

At this point it may be well to anticipate any special inquiry and objection regarding the undesirability of the presence of a third party during a psychiatric interview. Originally it was feared that such lack of privacy would constitute a serious barrier to a satisfactory questioning of selectees, especially in relation to intimate questions. Actual experience, however, has disclosed this fear to be unfounded. Among the thousands of selectees that have been examined since this plan was inaugurated less than ten have objected to the presence of the students and all of these were found to be obviously unsuited for military service. The procedure of the induction station examinations serves to prepare the selectees to accept the presence of another person at the psychiatric examination as a matter of simple routine.

During the actual examination as each selectee is questioned a running commentary is offered to the student on any significant positive or negative information obtained and this is related in each detail to the general introductory comments made in discussing the proposed examination with the student. Sometimes this running commentary is in the form of further questions that elicit additional detailed information to permit the student to grasp more fully the significance of the information obtained. Frequently, it is possible to offer a direct critical commentary upon the information given in such fashion that it not only enables the student to understand but it serves also to make the selectee feel that his complaints and symptoms are fully understood and appreciated sympathetically and thus it proves an actual aid in the examination. As each examination is concluded a concise statement of the outstanding observations, whether normal or abnormal, is given,

and in case of a rejection the reasons for the rejection recorded on the examination blank are concisely reviewed and their importance indicated.

This constant repetition, while at first a bit confusing to the student, soon serves to teach him to observe and to expect a definite pattern of behavior which, though it may change somewhat in content, invariably leads to either a positive or a negative conclusion for understandable reasons. Above all it teaches the student as no other procedure could that fingernail biting, hyperhidrosis, gastric complaints and phobic reactions can constitute an integrated pattern of response that may be found over and over, and, further, that not one of these symptomatic items should ever be considered as an isolated symptom. Of primary importance in the teaching of psychiatry is this need to convey to the student an adequate appreciation of the interrelationship and pattern-like character of psychological complaints.

Usually at the beginning of each day an effort is made to select for the first half dozen selectees those who are obviously suitable for military service and attention is systematically called to every evidence of normality that they show and also to the range of normal behavior manifested. Following this, there is an effort made to select from the waiting line possible rejectees to establish a sharp contrast between suitable and unsuitable military material. Particularly illustrative cases are dealt with in the same detail and, through the helpful cooperation of the other examining psychiatrists, many instructive cases are sent to the psychiatrist with the student.

No effort is made to sell psychiatry to the students. A straightforward matter-of-fact attitude is taken toward the whole situation. They are cautioned, however, to be highly critical of every psychiatric judgment made and to keep well in mind for later discussion any exceptions and disagreements that they may have. As the day continues and more and more selectees are seen, the students develop an ability to appreciate sharply the contrasts between the acceptable and the unacceptable selectees and to recognize the reality and the validity of a never-ending variety of neurotic complaints reflected against the background of personality maladjustments and social, intellectual and economic inadequacy and incompetency. Their first reaction is to discount and discredit neurotic complaints, to pay little attention to over-compensatory behavior, vasomotor instability and to overlook completely evidences of emotional immaturity and inadequacy. But as the contrast between the normal selectees and those unfitted for military service continue repetitiously throughout the day, they become increasingly enthusiastic in their attention to the significance of psychiatric signs and symptoms.

One other item of importance concerns the development of the student's attitude toward psychological illness. This may be illustrated best by an account given by one of the students. His statement was, "I have assisted one of the local physicians who does physical examinations for the local draft board. On all of the neurotics my attitude has been, 'Put him in the army and make a man of him.' My experience here today has made me realize that a neurotic is sick, that he cannot measure up to the normal man and that just putting him into the army will not make a man out of him but will serve only to make him a hospitalized psychiatric patient and thus a liability to the entire country." This same

significant realization has been offered spontaneously by a large proportion of the group, and in itself demonstrates the effectiveness of this teaching venture.

The reaction of the students to this program has been most gratifying. At first, because it was established as an additional and actually extra curricular course, the students were resentful over this new demand upon their time. Many declared that they were not fundamentally interested in psychiatry, that there could be little sense spending an entire day listening to so-called psychiatric examinations of healthy normal young men and that the entire program seemed to be nothing more than a wishful effort to exaggerate the importance of psychiatry.

However, after the first few students had spent a day at the induction station and had reported upon their experience to their classmates there was a complete reversal of attitude. The majority of the class requested the opportunity for additional days at the induction center. Every member of the group insisted that the course should be continued indefinitely for each succeeding class with the provision that it be opened also to those not holding commissions as a measure of better preparing them for the practice of medicine. Finally, the original antagonistic attitude has been altered to a general criticism of the teaching of medicine without sufficient emphasis upon the importance of psychiatry.

In brief, this psychiatric teaching program has served satisfactorily to give medical students a genuine appreciation of clinical psychiatry and of the existence of psychological illness unrelated to the question of physical soundness. It has made them realize that psychological illness is exceedingly common, that it does constitute a serious medical problem, and that it is something requiring intelligent recognition and disposition rather than dismissal as inconsequential. Finally, it has made the students realize, as never before, the importance of psychiatry in military medicine as well as in general medicine.

Hypnotism

Encyclopedia Britannia, 14th Edition, 1961.

Hypnotism is the term applied to a unique, complex form of unusual but normal behavior which can probably be induced in all normal persons under suitable conditions and also in many persons suffering from various types of abnormality. It is primarily a special psychological state with certain physiological attributes, resembling sleep only superficially and marked by a functioning of the individual at a level of awareness other than the ordinary conscious state; for convenience in conceptualization, this is called unconscious or subconscious awareness. Functioning at this special level of awareness is characterized by a state of receptiveness and responsiveness in which inner experiential learnings and understandings can be accorded values comparable with or even the same as those ordinarily given only to external reality stimuli.

When hypnotized, or in the hypnotic trance, the subject can think, act and behave in relationship to either ideas or reality objects as adequately as, and usually better than, he can in the ordinary state of awareness. In all probability this ability derives from intensity and restriction of attention to the task in hand, and the consequent freedom from the ordinary conscious tendency to orient constantly to distracting, even irrelevant, reality considerations.

The subject is not, as is commonly and wrongly believed, without will power, or under the power of the hypnotist. Instead, the relationship between the subject and tie hypnotist is one of inter-personal co-operation based upon mutually acceptable and reasonable considerations. Hence, the subject cannot be forced, as a function of hypnosis itself, to do things against his will, as is sometimes claimed. He can be aided in achieving possible defined goals, but frequent failures in hypnotherapy attest the limitation of hypnosis in accomplishing even wanted purposes and extensive and reliably controlled studies discredit the possibilities of and social use of hypnosis.

The history of hypnosis is as ancient as that of sorcery, magic and medicine, to the armamentaria of which it belonged. Its scientific history began in the latter part of the 18th century with Franz Mesmer (q.v.), a Viennese physician who used it in the treatment of patients. Because of his mistaken belief that it was an occult force, which he termed “animal magnetism,” that flowed through the hypnotist into the subject, he was soon discredited; but mesmerism as it was named after him, continued to interest medical men. Extensive use was made of it by a number of clinicians, without adequate recognition of its nature until the middle of the 19th century when the English physician James Braid studied its phenomena and coined the terms hypnotism and hypnosis.

Thereafter many scientifically trained men studied hypnosis, but not until after World War I was much progress made. This progress derived from the recognition of the re-educative possibilities afforded by hypnosis. World War II gave further impetus to its study, greatly extended its recognition and utilization and freed it from many of the superstitions, fears, and misconceptions that had hampered its scientific acceptance and investigation. The next significant developments in the history of hypnosis occurred in the Mid-1950s when both the British and American Medical associations formally approved its medical use and discountenanced its use by the laity, At that period also was organized the American Society of Clinical Hypnosis, with international scientific societies.

Hypnotic Technique

Popular belief still ascribes significance to illogical devices and rituals such as "making passes" or stroking the body, the use of "hypnotic crystals," the "eagle eye" and the "hypnotic command," all of which belong to the charlatan's stock in trade. Actually, the important consideration in inducing hypnosis is that the subject be willing, co-operative and interested in learning a new experience. To such a subject a trusted operator can, progressively, persuasively, and repetitiously, suggest tiredness, relaxation, eye closure, loss of interest in externalities, and an increasingly absorbing interest in inner experiential processes, until the subject can function with increasing adequacy at the level of unconscious awareness. The length of time required to induce a trance differs greatly with subjects and with trance situations, and the time spent should be in reasonable accord with both the importance and the specific character of the hypnotic work to be done. The charlatan boasts of his speed; the scientist considers time an important variable. "Thus, the dentist might need only a few minutes to induce the trance state requisite to permit a tooth extraction; the psychologist might need an hour to effect those psycho-neuro-physiological responses needed for a long involved laboratory experiment; and the hypnotherapist, because of his patient's needs, might distribute over a period of months the development of a trance state otherwise possible in a short period of time.

Another essential element in technique—for either investigative or therapeutic work—is the utilization of the subject's own patterns of learning and response, rather than an attempt to force upon him by suggestion the hypnotist's limited comprehension of what constitutes experiential validity for the subject. Failures in hypnotic experimentation and therapy often derive from treating the subject is all automaton, expected to execute commands in accord with the hypnotist's understanding, rather than as a personality with individual patterns of response and behavior.

Hypnotic Phenomena

Hypnotic phenomena differ from one subject to another and from one trance to another, depending upon the purposes to be served and the depth of the trance. Hypnosis is a phenomenon of degrees, ranging from light to profound trance states but with no fixed constancy. There are, however, certain basic manifestations, the extent and clarity of which vary. Foremost among these is rapport, which signifies the limitation of the

subject's awareness to that which is included in the hypnotic situation. Usually the subject responds only to stimuli from the hypnotist, who may limit or direct the subject's awareness or responsiveness as is desired or needful. However, in accord with personality needs or the demands of the situation, the subject may remain in or actively establish contact with part or all of the circumstances surrounding the trance.

Catalepsy, another hypnotic manifestation, is properly tested only indirectly, since direct tests may elicit at as a responsive rather than as a spontaneous phenomenon. Catalepsy is a state of balanced muscle tonicity which permits great economy of effort, allowing the subject to maintain postures and positions for unusually long periods of time.

Suggestibility a state of greatly enhanced receptiveness and responsiveness to suggestions and stimuli, constitutes the central phenomenon of hypnosis. It is characterized by the remarkable facility with which the subject can respond to either external stimuli or those deriving from inner experiential acquisitions. However, suggestions must be acceptable to the subject, and rejection of them can be based upon whim as easily as upon sound reasons. By acceptance of and response to suggestions, the subject can become psychologically deaf, blind, hallucinated, amnesic, anesthetic or dissociated, or he can develop various special types of behavior regarded by him as reasonable, or desirable in the given situation.

The psychological processes involved are essentially those of vivification of memories, ideas, understandings, emotions—indeed, any type of experiential acquisition—so that they are experienced subjectively as deriving from external events rather than from internal processes. This is the feature of hypnosis most often abused by the charlatan, and it is also the feature that permits the greatest accomplishments in psychology, dentistry and medicine.

A most fascinating manifestation, also of great scientific importance, is that of posthypnotic suggestion and behavior. By this is meant the execution, at some later time, of instructions and suggestions given in a trance and intended to become a part, either interpolated or integrated; of a later activity. For example, a pregnant patient may be instructed posthypnotically to develop, at some future time when labor begins, an obstetrical anesthesia to meet the needs of childbirth. Such use of posthypnotic phenomena offers extensive opportunities for direction and guidance of behavior in terms of the individual's needs and patterns of response without dependency upon immediate guidance and relationships.

Amnesia of any degree of selectiveness or comprehensiveness may be developed in hypnosis, either, spontaneously or by instruction. It may include all the events of the trance state or only selected items, or it may he manifested in connection with matters unrelated to the trance. Hypnotic amnesia is reversible; it may be induced, abolished, reinduced, or altered by the operator or by the subject if adequate personal motivation develops. It is very useful in both experimentation and therapy and can be used in a variety of ways. For example, otherwise uncontrollable pain in malignant disease has been partially controlled by use of amnesia.

Conversely, hypermnesia, an ability to remember that transcends the everyday ability is another aspect of hypnotic behavior that is valuable experimentally and therapeutically. For or example, in the trance state, the subject, by virtue of an uncritical willingness to make the effort and a freedom from inhibitions deriving from preformed judgments, can remember vividly long-forgotten, even deeply repressed experiences, recount them in extensive detail and still maintain all amnesia for them at the ordinary level of consciousness. This remarkable ability permits the recovery of memories otherwise unavailable, makes possible extensive exploration of the experiential past, and offers opportunities for studies of basic processes underlying learning and memory.

A striking phenomenon of the profound trance is somnambulism. This is a state of deep hypnosis in which the subject can present the outward appearance and behavior of ordinary awareness but is able to manifest readily and often spontaneously any type of hypnotic behavior within his personal capabilities. Some subjects never achieve this state, some reach it with a minimum of effort. It is of great value in certain specialized procedures and studies. Experience and training are often required even to recognize the somnambulistic state, and even more experience is necessary to induce it readily and to utilize it adequately.

Ordinarily all trance behavior is characterized by a simplicity, a directness, and a literalness of understanding, action, and emotional response suggestive of childhood. This is the phenomenon of regression, which can be enhanced so that the subject experiences a retrogressive loss of memories, learning, and responses, and those belonging to an earlier age are re-established. When developed carefully, this regression is not a re-enactment or a revivification of the past in terms of current understanding, but a restoration of previous response patterns through a process of amnesic loss of subsequent learning. This manifestation permits extensive exploration of the developmental aspects of the subject's experiential loss.

Dissociation, a detachment or separation of subjective from objective values, another highly complicated phenomenon, is of particular significance in effecting specialized leanings (for example, anesthesia or emotional objectivity) without arousing impeding or obstructing subjective reactions—the hypnotized subject, that is, can be made insensitive to a needle prick because the dissociation phenomenon prevents a subjective reaction (pain) from occurring.

Time distortion, first elaborated as a specific scientific concept in the mid-1940's, has proved to be useful in both hypnotic therapy and experimentation. It is essentially a function of speed of cerebration, a s a result of which the passage of time is perceived subjectively in terms of inner experiential processes and events. As a consequence, time as a personal experience may be "expanded? Or "condensed" with resulting alterations in subjective values and psychological and physiological functioning.

Among other interesting hypnotic manifestations are enhanced visual and auditory imagery, automatic writing, depersonalization, various types of disorientation, and acceleration or inhibition of physiological functions.

Autohypnosis

Autohypnosis, or self-hypnosis, is both possible and feasible, but it is often a sterile procedure because of misconceptions of its nature and use. Usually the autohypnotist tries too hard to direct *consciously* the activities he wishes to take place a t the hypnotic level of awareness, this nullifying the effort.

Acceptance of autohypnotic processes, rather than attempted direction of them, leads to productive results. Usually autohypnosis is best learned through supervised instruction.

Related Questions

Certain questions are repeatedly asked about hypnosis. Among these is the possibility of employing hypnosis to commit crimes. The better scientific studies deny this possibility and therapeutic experience discredits it, but a few experimental studies, either inadequately controlled, or in protective situations, have resulted in pretended crimes. However, pretense is not reality, nor is hypnosis as essential in pretense.

Concerning harmful effects, none have been reported by earnest students of long experience, but the inexperienced and the arm-chair theorist are often emphatic in affirming such possibilities. Occasionally an amateur will hypnotize a person suffering from a personality disorder and mistake the evidence of that disorder from hypnotic effects. In this connection may be mentioned the harmfulness of lay hypnosis. This derives not form the hypnosis itself but from the misconceptions promulgated and from the discredit and disrepute that always attend dabbling by the uninformed in, and exploitation by the charlatan of, any field of beneficial learning.

Can hypnosis be induced without the subject's willingness or awareness? Hypnosis is based upon willingness and co-operation, but this may be concealed behind a superficial attitude of unwillingness; similarly, superficial willingness may conceal deep-seated unwillingness, with a consequent failure of trance induction. A trance state cannot be maintained without the subject's consent—actual or implied.

Then there is the question of what would happen if the subject could not be awakened, or if in some way the hypnotist were to be removed, leaving the subject in a trance state. The reply is simply that the trance state, being dependent upon an interpersonal relationship of mutual co-operation, would terminate upon the cessation of that relationship. It is possible to arrange with a subject to remain in a trance in the absence of the hypnotist, but this is merely a form of continued co-operation. Occasionally a subject may refuse through a shim to arouse immediately from a trance, but this is a problem only for the inexperienced and is not significant.

Early Recognition of Mental Disease

Milton H. Erickson, M.D.

Delivered April 24, 1940 at the *Post-Graduate Clinic for General Practitioners*, Eloise Hospital, Eloise, Michigan. Published in *Diseases of the Nervous System*, Vol. II, No. 3, March 1941.

In the practice of medicine, whatever the branch may be, there is no better teacher than that form of experience usually called *Hind Sight*. No other teacher can possibly offer the instruction and the information to be gained by looking backward and realizing, in terms of the final outcome, what things might better have been done for the patient. By so looking backward adequately, one gains a full understanding of the entire course of an illness from the time of its earliest manifestations and symptoms to the time of its final result. It is only by means of a comprehensive longitudinal view of the patient and his illness that one can learn to recognize and to appreciate the significance and meaningfulness of the earliest symptoms.

This mention of hind sight is made because of its importance in mental hospital psychiatry, perhaps more so there than anywhere else. It is only with the patient in the mental hospital that one comes to realize so fully the importance and the revealing character of the individual's remote past history when seen from the perspective of a psychotic development as the final result. The absolute need, if the mental hospital patient is to be treated adequately, of knowing fully the innumerable items of the patient's personal growth, development and experience; or, in other words, of having adequate hind sight bearing upon the patient's entire past life, is readily recognized. To gain the knowledge requisite to any satisfactory psychiatric therapy, there need to be secured extensive social service histories, and all the detailed intimate facts about the patient that can be obtained from the family, relatives, friends, acquaintances, employers and, most particularly, if possible, from the family physician, who properly should constitute the most desirable source of special information of a helpful constructive type.

It is from the vantage point of these extensive histories, so carefully and deliberately compiled by the social service department and so necessary to the laying of any foundation for adequate psychiatric therapy, that the mental hospital psychiatrist has the opportunity to recognize not only what the early symptomatology was, but to recognize and to appreciate oversights, misunderstandings, failures, misjudgments, errors of omission and commission and all the other things that served to permit the patient's earliest symptoms of maladjustment to remain unrecognized and to grow progressively more serious and finally to become evidence of serious mental disease.

In other words, the adequate social service history constitutes primarily a systematic account of the earliest symptoms and manifestations of the course of the development over a long period of time to the final signs of full-blown mental disease. Hence, the

opportunity afforded by the social service history to view the mental patient with hind sight is unparalleled and it is against this background that we propose to offer our discussion of the early recognition of mental disease, and to present a consideration of the symptomatology of mental disease as it confronts the general practitioner, who properly comes into contact with mental disorders long before commitment is necessary.

However, before proceeding to a consideration of the actual early symptoms of mental disorder as they are seen by the general practitioner, discussion should properly be offered of the criteria or the yardstick by which recognition can be made early of the normality or abnormality in the individual case. In this connection, the concession is to be made at once that there can be no infallible rule by which to judge the individual patient, even as is the situation in general medicine. However, in ordinary practice, the physician is not likely to be mistaken who employs the simple yardstick of a marked rise in temperature as a definite indication of somatic illness. Likewise, in the matter of the early recognition of mental disease, we propose to offer a similar simple, though not infallible, yardstick or criterion of mental soundness, namely, one based upon simple common sense and the long and intensive experience every general practitioner has had with human beings of all types and varieties.

To explain: As you all realize, the patient comes to the general practitioner not to disclose his strengths and special aptitudes and abilities, but rather to reveal his weaknesses and inadequacies. Hence, the physician comes to know thoroughly and comprehensively the nature, character, variety, extent and number of human weaknesses and frailties without being misled by false fronts and pretenses. Perhaps no other class of people has a better opportunity of knowing what human beings really are than has the general practitioner, who sees his patients in all varieties of situations and circumstances. And it is this background of general, but intimate, knowledge of human nature that qualifies the general practitioner, interested in so doing, to recognize and to deal with the early symptoms of mental disease.

Thus, without even trying, the general practitioner comes to learn what sort of behavior may reasonably be expected of this person or that, and he is not surprised when one of his patients gets into trouble and when another achieves success. He has an adequate knowledge of how many bad things and how many good things to expect from his average patient. Thus, he knows that he is going to return in about a year to deliver another baby to Mrs. Jones; that Mr. Jones is not going to hold his job more than three months; that Mary Smith is certainly going to get in trouble before another six months; and that Bill Brown just hasn't a chance of making good in his present position. All of these items and innumerable other intimate facts are known by the general practitioner about the people in his community. They place him in an enviable position to recognize when something unusual or strange or inexplicable is happening to any one of his patients. Furthermore, his knowledge tells him roughly just how much that is unusual or bad can be expected in each individual case so that when the general balance in the individual's behavior becomes disturbed, he can readily appreciate that some sort of a serious change is occurring in that patient. In other words, the general practitioner may expect in each of his patients some quirks and oddities and eccentricities, but only so

many oddities for each particular patient, and when those peculiarities suddenly change and increase, he can appreciate easily and readily that something really is wrong.

And so, when recognition is given to the fact that everyone is queer in some respects, the question arises, "By what means, criterion or yardstick may judgment of abnormality be passed effectively and correctly?" Or in other words, how may the general practitioner, with a reasonable degree of certainty, decide that various manifestations in the behavior of his patient actually constitute early symptoms of mental disease and are not an evidence merely of individuality?

The suggestion we wish to offer in this regard as a generally satisfactory yardstick of normality concerns the purposefulness and usefulness of behavior. While we agree that all human behavior is necessarily purposeful, the usefulness of normal behavior is clearly recognizable, understandable, and effective so far as a reasonable achievement of personal goals and aims is concerned. Abnormal behavior, on the other hand, is not purposeful in a clearly understandable, recognizable, and effective fashion, and it is primarily directed to goals that are not in keeping or harmony with what one properly expects of that individual. Thus, behavior that does not serve a readily understandable and useful goal for the individual, that is not in keeping with what may reasonably be expected of that person, that is persisted in to such an extent that it interferes with the person's other and understandably useful behavior, is definitely abnormal and should be looked upon as necessitating medical attention by someone qualified by general experience in dealing with human nature. For example, the child who develops one temper tantrum after another until it gains its way and then capitalizes upon the gains so achieved, and thus carries out its own wishes, constitutes only a problem in management and education. But the child who develops innumerable temper tantrums for no readily understandable reason and does not make use of those tantrums to gain its own ends, but seems only to express thereby its disapproval of the world in general, constitutes another problem of a definitely abnormal type. Likewise, the woman who nags her husband for adequate reason is purposeful in her behavior so long as she does not let that nagging, however justified, interfere too greatly with the discharge of her own duties and obligations. But when that nagging becomes so extensive that it takes all her time and energy, it falls into the same category as that of the woman who nags her husband constantly without reason. Hence, it becomes abnormal because of its definite lack of a useful purposeful character. Or again, the young man who works hard and saves his money to attend college and then suddenly dissipates all of his savings and then returns to work and again saves his money, only to repeat his previous conduct, is showing behavior primarily lacking in understandable purposes and hence it is abnormal.

However, this does not necessarily mean that the purpose and goal of human behavior must necessarily be legitimate and desirable, since human nature is not perfect. Normal human behavior can be subject to prejudices, misunderstandings, ignorance, and to all the weaknesses of mankind, and yet have purposes and goals readily understood and appreciated as being harmonious to an individual possessed of normal desires and strivings, regardless of any errors of judgment and the lack of common sense in his behavior. In other words, to be abnormal, behavior must necessarily be lacking in

purposeful useful qualities so far as the reasonable average goals of the specific individual person are concerned. Such behavior is inconsistent and at variance with the other forms of behavior properly expected or common to the person, and it constitutes a handicap in his functioning as a capable citizen, since it results in a loss and waste of energy, and a defeating of his personal goals and aims.

In brief, to judge whether or not any particular item of behavior is normal or abnormal, one needs only to view that item in direct relationship to the general average pattern of behavior that is known and may reasonably be expected in that person. By such comparison and contrast, effective and reasonably correct judgment can be passed. Simply to view the item of behavior as an isolated phenomenon and as without relationship to the individual's background, leads to error and misunderstanding.

One other consideration relates to the variety of changes in the purposeful character of behavior. The changes, alterations and variations in the purposefulness of behavior vary from over-emphasis to complete loss, to a distortion in an explicable fashion. For example, the woman who scrubs her floors endlessly to the neglect of other duties shows an over-emphasis of purpose upon an ordinarily useful task. Or the young man with a good industrial history who loses his job and then sits quietly about home, always planning month after month to look for work on the 'morrow, shows a complete loss of purpose. And as for distortion in a nonunderstandable fashion, one may take the example of the obese girl who, resenting the ridicule of her associates, diets to the point of the extreme emaciation of anorexia nervosa. To these examples, out of your own experience, you can add innumerable instances, with ready appreciation of the need to judge behavior according to the purposes it serves for the specific person.

We may proceed now with a consideration of what those forms of behavior are, which, judged against the background of their purposefulness to the individual, constitute early symptoms of mental disorder and disease. Perhaps the best approach is by a discussion of various separate categories determined in relation to the particular types of mental disorder to which they may lead. Accordingly, we shall take up first the various items that indicate behavior problems and behavior disorders in children, and, as an essential caution in this connection, we wish to emphasize that each and every one of the evidences of behavior disorder that may be found in children, normally and naturally occurs in practically all children as a part of the proper and necessary growth and development of the child. It is only when these various disorders occupy too much of the child's time and effort, when they bring about a general disturbance in the child's total adjustments, that they are to be considered abnormal. It is not necessary for any one of these evidences of maladjustment to be abnormal in itself, but if it interferes with the ordinary life of the child, or if it causes those concerned with the child's welfare to place too much emphasis and stress upon it to the detriment of the child's welfare, then it is to be regarded as a definitely destructive influence upon the child.

The decision as to the normality or abnormality of any one or more items of behavior should properly rest with the family physician who has the opportunity of appreciating adequately what type of behavior may reasonably be expected within a family group,

what purposes that behavior may serve and what effect that behavior may have upon the individual and those associated with him. With this caution, we shall proceed to the individual items signifying behavior disorders and the instances we mention refer only to those occurrences in which the particular manifestation is excessive and destructive to the child's welfare.

Ordinarily, the evidences of behavior disorders in children are the most easily recognizable, but all too frequently they are dismissed as unimportant on the assumption that the child will necessarily outgrow them. A review of the case histories of our patients here, however, will disclose too often that childhood maladjustments never were outgrown. Rather, those early maladjustments serve to establish and to fix within the individual unhealthy and abnormal ways of behaving so that the individual becomes progressively more handicapped in his general life situation.

Childhood behavior disorders are easily recognized since we all have an excellent idea of what kind of behavior to expect from any child of a given age, regardless of physical and mental endowments. Hence, any departure by the child from that general average of behavior is most noticeable. Thus, we expect a baby to wet the bed, but not a six-year-old. We expect the little girl to have a dirty face, but not the 14-year-old lady. And we expect the 10-year-old boy to be constantly scuffling and on the alert with healthy disregard of everybody else and not mooning ambitious adolescent dreams like his teen-age brother. But let the child step out of his class and show behavior that is consistently too old or too young for him and you know at once that there exists some manner of behavior disorder, the seriousness of which depends upon the actual number, forms, patterns and persistence of the wrong behavior. The general manifestations of childhood disorders we may list briefly and concisely in special categories with emphasis placed primarily upon those symptoms most likely to lead to serious results.

First of all are those symptoms that relate to *unhealthy attitudes toward the body*—such as finger sucking, nail biting, pulling one's hair, incontinence and faulty elimination habits, over-eating, body fingering and hypochondriacal reactions—all to such a degree as to hamper and handicap the child's general patterns of adjustment. Often these items, however extensive in degree, are looked upon as mere nuisances rather than as indications of serious behavior problems. The child whose finger nails are always bitten to the quick is one who, in achieving this result, has spent a tremendous amount of time, energy and effort that no child can afford to spare from play activities so much more pleasant and educative, and so necessary for normal development. One might summarize by the paraphrase, "All finger nail biting and no play makes Jack not only a dull boy but deprives him of the opportunity to learn many necessary things from normal play."

Likewise, the case of the child who stands about sucking his thumb instead of joining his fellows in games, thereby loses time and opportunities in the matter of development. Similarly, the child who soils and wets his clothes long after the age of infancy, is building up a pattern of behavior that makes him, even from his own point of view, a social outcast and which bars him from ever establishing an adequate control over or developing adequate healthy respect for his own body. In the same way, the bed wetter,

faced each morning with the humiliating, disheartening experience of a wet bed, builds up within himself a distrust and a mistrust of his own physical competence and ability. One need only call to mind a small boy proudly displaying his muscles to realize how important a sense of pride, trust and confidence in one's own body is for a normal healthy outlook upon life.

Another example is the child who runs constantly to the toilet; who seems to spend all of his time and energy in attention upon elimination and who thereby manifests too much concern and interest in bodily processes, properly of only momentary interest to the child. Such narrowing of attention precludes the child from developing more adequate and healthier interests elsewhere. Or again, the child who has recovered from an illness but persists in whimpering and whining and who demands constant babying thereafter is disclosing a serious weakness in his ability to be a normal healthy child, and he needs helpful medical advice and not just an opportunity to outgrow this behavior. The process of outgrowing requires too much time and effort and prevents the acquisition of other lessons in life that must be learned if there is to be mental health. As we look back over the histories of our mentally ill patients, these are the sorts of body attitudes we find in the accounts of their childhood. It is true that all children show these reactions at one time or another, but the normal healthy child is too busy to persist for long in these types of body attitudes. It is only when these habits become persistent and dominant that the child misses many of his opportunities for normal development.

Another type of behavior disorder relates to *general habits*—specifically eating, sleeping and playing. We all know the normal range of behavior for each of these and we recognize their extreme importance in each individual's life. Likewise, we need to recognize and emphasize that any extensive disturbance in any of these habits is also of marked importance in the individual's physical health and life. The child with a healthy body who sleeps too much or too little is building up a most destructive habit that takes away the time or strength necessary for healthy mental growth. The child who persistently overeats, vomits and overeats again, or who under eats is training his body and altering his physiological responses in a most undesirable fashion. The child who plays by himself by choice, or who only looks on without participation, or sits about idly, perhaps futilely wishing there were something he could play, is neglecting his opportunities for the development of initiative and resourcefulness and thereby failing to learn lessons vital to mental health and personality growth.

Another type of early symptomatology centers around social reactions and trends such as withdrawal from the group, lying, disobedience, cruelty, selfishness, stealing and truancy. Particularly do we find significant information bearing upon these items in the histories of our mentally ill patients. A reasonable occurrence of various of these items is essentially normal in each individual's life. In fact, a certain incidence of these forms of misbehavior is almost requisite, if one is to be graduated successfully from the school of experience. But the child who persists in these undesirable or asocial or actually antisocial practices and makes a constant habit of them prolonged over a period of time needs the kindly understanding advice and guidance of the family physician so that he may not grow up to need the services of the psychiatrist.

In these evidences of social maladjustment, not only the type but the number and the variety as well as the degree and extent are of great importance in passing judgment. In brief, they should be regarded with as much concern as is an undiagnosed skin rash, since the social health of the individual is fully as important as the physical health. Particularly does one feel concerned about these types of social failure and maladjustment when it is realized that society reacts in a punitive fashion, with the result that too often the unfortunate child is denied adequate opportunity for normal social development, and thereby is forced to continue in these undesirable patterns of social behavior.

Another and not well realized aspect of this general problem of social maladjustment concerns the failure of the child to be sufficiently aggressive to get into mischief. The child who has not sufficient initiative to get into mischief, who is always a model child, fails to learn from the "school of hard knocks," and hence does not get exposed to the lessons of life necessary for mental well-being. Among our patients here we can demonstrate many who were such model children that they never learned the realities of life. In other words, the diet for social development and health must include a reasonable amount of "roughage".

Now it may seem that we are giving too much attention to childhood behavior problems and it may be well, before proceeding, to emphasize that all the behavior disorders of childhood can be found, perhaps slightly altered in form, perhaps unchanged, in the early youth, in the adolescent and in the adult. In our patients on the ward, from the youngest child to the oldest senile, we can find the same general symptoms at every age level. And so, when the adult comes to your office with an infantile behavior reaction, or a child comes with hypochondriacal complaints more often seen at the involutional period, the physician's problem is essentially the same; that of recognizing and understanding the change in the purposefulness and usefulness of the patient's behavior.

The symptoms of mental disease, particularly in the early forms, concern body attitudes, social reactions and trends, general habits, emotional manifestations and such special spheres of human experience as the sexual, and so the problem of the general practitioner is to recognize these general symptoms early in their course before the development of an actual psychosis has transformed them into delusions and hallucinations and other forms of disorganized and distorted behavior. By learning to recognize and to appreciate childhood behavior disorders, one establishes a foundation upon which to recognize and to appreciate the same symptomatology in older patients in whom the behavior disorder has progressed to the state of an early mental disease. Only the outward form of the manifestation or the words used to describe the complaint may be different. The underlying significances to the individual personality are the same, whether he is a child or an adult, and so, just as men are but children grown taller, so should the general practitioner look upon his adult patients as suffering from all the ills of childhood, including, as symptoms of early mental disease, the childhood behavior disorders. With this special emphasis upon the essential identity of behavior problems and early mental disease, we may continue with the manifestations of unhealthy emotional reactions, such as hates, fears, spite reactions, jealousies, rivalries and temper tantrums.

As in the case of social maladjustments, little needs to be said about the undesirable character of *unhealthy emotional reactions*, particularly if they are so persistent as to make the child forget his play and devote his energies to their manifestation. The child with undue fears, anxieties, phobias and intense rejections of an emotional character is laying an adequate foundation for a future anxiety neurosis, just as the child who indulges in jealous, spiteful, hate reactions to the exclusion of other and normal activities is laying the foundation for a future pathological depression. Similarly, the child who labors daily under a burden of hate, resentment and rivalry is showing early manifestations that need correction before a paranoid reaction develops. One expects of every child adequate manifestations of each of these unpleasant emotional reactions, but also, one does not expect any child to hold too long these intense unpleasant emotional reactions. The rapidity with which children can quarrel and make up is most amazing to adults and the strongest of their intense emotional reactions cannot normally survive the enchantment of a new toy. But the child who constantly sulks or pouts or broods or reacts with innumerable temper tantrums, fails to experience the normal flux of emotions and develops a rigid unyielding emotional pattern that leads progressively to greater troubles.

Now by that statement we do not mean that greater troubles must necessarily and invariably develop, even though the emotionally disturbed child is neglected and mismanaged, but we do mean that those deviations from the normal in children do lead to a greater susceptibility to mental illness. This is emphasized by the case histories of our patients here, which disclose long continued records of early emotional maladjustment. As a crude parallel, we might cite the patient with coronary disease who may live five minutes or 10 years more—one cannot know. But one does know that sudden acute strains upon such a heart may be fatal, though not necessarily so, and such is the case of the child whose emotional development is handicapped and distorted. Sudden acute strains or an intense burden may warp and distort still further to a pathological degree.

Concerning the treatment of these various disorders, we have little to say at this moment, since the primary need, we believe, is to enable the physician to recognize and to understand these problems, so that he can then rely upon his own common sense and wealth of experience in handling human nature.

To proceed now with the problems of the early symptomatology of mental disease after the period of childhood, we need to deal with specific types of mental disorder. The most common of these to be seen by the general practitioner are the neuroses, particularly the anxiety states. The clinical picture of this condition varies with the individual experiential background and the number, variety, character and severity of both the subjective and objective symptoms. In general, however, this neurotic type of patient shows such symptoms as excessive, prolonged and all-absorbing interest and concern over essentially normal body processes and functions, or he may show feelings of fear, uncertainty, worry and anxiety about the functioning of his body and of the possible effects of such simple physical difficulties as headaches, mild infections, perspiration and similar items ordinarily given a minimum of attention. Or the patient may complain of obsessive thoughts, of compulsions, of feelings of unreality and of despair, without being able to

give any understandable justification of his complaint. Or. more frequently, the complaint concerns the loss of energy and interest, and feelings of incapacity and the tendency to restrict in a progressively inclusive fashion all of his activities.

Ordinarily, these patients are essentially healthy, physically speaking, although the existence of any small physical disability is seized upon and exaggerated and used to further their general complaints. The practitioner's task in listening to such complaints is not primarily reassurance of the patient that all is well and that these matters may be forgotten. Rather, his task is to listen to each of these apparently unreasonable complaints and to appreciate the extent to which they interfere with the patient's normal functioning as a useful citizen. He can best evaluate the meaning and significance of all of these complaints by determining the extent to which they disrupt the patient's daily life. When he finds that the patient's symptoms have brought about a marked variation and change in the daily behavior, and that much of the patient's general activity has lost its purposefulness and usefulness, he can then appreciate that a condition exists, which is as worthy of medical attention as any infection that disrupted the patient's daily life to the same degree.

The mere fact that a patient complains bitterly month after month about a weakness in an arm and devotes all waking moments to that complaint, when adequate medical examination discloses no physical basis for the complaint, signifies an illness as real and as destructive to the personality as would be a paralysis of that arm. In brief, the paralysis of hysteria is fully as incapacitating as that deriving from a cerebral hemorrhage and the physician's task is not that of dismissing the patient, but rather of correcting the patient's condition. In other words, regardless of any organic background for a disability, the patient must be judged in terms of his actual ability to function as a useful citizen.

As general experience will teach, we all have a rough idea of how the average adult person should behave and we base our expectations upon our knowledge of that person's past history. When a patient suddenly begins to show behavior that is lacking in purpose and usefulness, that is not in harmony and keeping with what can normally be expected of a person of that age and experience, then there is evidence that the person requires intelligent and capable medical aid.

Concerning the early symptoms of the anxiety states, there probably is little point in mentioning them since the general practitioner has heard innumerable stories about weakness, tiredness, excessive perspiration, headaches, loss of appetite, easy fatigue, pressure on the head, constant worrying, recurrence of obsessive thoughts, tremors, aches and pains, feelings of unreality, expectation of sudden catastrophes and calamities and all of the other symptoms that cannot be found to have any organic background upon careful medical examination. Nevertheless, despite this lack of organic background, these symptoms are real to the patient, and when they interfere seriously with that person's social, economic and personal adjustments, when they cause his behavior to become purposeless and useless, adequate recognition and attention should be given to these complaints, as signifying an illness requiring medical attention, and such attention should be given before the patient's symptoms become so fixed and rigid and uncontrollable that

it requires a specialist to give therapeutic aid, if indeed the specialist is able to do s0 Indeed, the general practitioner who is consulted at the early development of these symptoms is in an advantageous position to correct them before they grow to too unwieldy proportions.

However, I would like to mention, as of particular interest, that the general practitioner, in viewing these patients, will recognize in them the child's infantile patterns of behavior and attitudes, so out of keeping and harmony with their years and stature. Their complaints constitute essentially the childhood behavior disorders grown older and larger. When so viewed and understood, there can then be ready realization that any adult whose ordinary daily life is so dominated by infantilisms must necessarily be as much in need of medical attention as is the adult suffering from childhood infections. The neurotic's complaints, however unreal physically, do dominate, limit and restrict normal functioning as much as does actual physical disease. Enabling his patients to meet routine daily obligations is a physician's primary duty, no matter what the nature of the personal disability.

Another general category of mental disease with which the general practitioner comes into contact are the early stages of *manic-depressive psychosis*, particularly the depressive reactions. In regard to these patients, there is little difficulty in realizing that something is definitely wrong with the personality. Rather, the primary problem is the task of appreciating the extent and seriousness of the illness. Thus, in the early manic phase, there is a rush and pressure of activity, usually within the normal range of what may be expected of the person, but there is too much activity, too much enterprise, too little restraint and there is constant extravagance and clash with the environment, with errors of judgment and common sense at every turn. Likewise, there is loss of sleep, neglect of ordinary minor daily duties, and marked increase in emotional responses, either of pleasure or displeasure. The physician who sees the patient who previously has had a long history of a stable, well-ordered daily existence, who suddenly becomes over-active in a progressively disordered fashion, needs to realize at once that such behavior signifies an over - emphasis upon purpose and usefulness that defeats its own ends. His task is to realize the probable outcome of such energetic, misguided, overactive behavior and thus be prepared to protect his patient's interests by seeing to it that the patient's relatives are apprised of the situation and that the patient himself is induced to seek proper medical aid.

The problem in relation to the depressive reactions is not quite so urgent though fully as serious, since there is a tendency for the patient to become depressed over a longer period of time and at a slower rate. A depressive patient shows, particularly, a loss of initiative, of interest and hope; daily duties are neglected, time is idled away, vague feeble complaints are made and the patient is unable to sleep and usually develops physical disorders such as loss of appetite and weight, constipation and menstrual and sexual disorders. These symptoms, however early, seen in a patient who has a long history of industry and well-ordered activity, are suggestive of serious personality disorders. With this recognition, the general practitioner can give heed to the patient's vague and apparently unfounded complaints and, by lending a sympathetic ear, he will be in a

position to uncover in their early form development of delusional and suicidal tendencies. Thus he will be in a position to apprise the relatives of the situation and to provide adequate psychiatric care and protection for the patient.

In both the manic and the depressive reactions, the treatment is essentially that provided by the mental hospital, but the duration of the illness for the patient depends, in many instances, upon the promptness with which the family physician recognizes the warnings and arranges for adequate psychiatric care. And the general recognition of either condition is essentially a matter of viewing the patient's immediate behavior and conduct and judging its purposeful and useful character in terms of what can reasonably be expected of that individual. Behavior markedly out of harmony with a past history of stable industrious activity signifies a change in the personality that requires the critical gaze of someone experienced in human nature.

The last type of mental disorder I wish to discuss is the schizophrenic reaction type, or *dementia praecox*. These 'are the patients so often seen early by the general practitioner and whose difficulty is so easily overlooked because the patients seem to show so little upon which to base any opinion. Yet they are patients who have a decidedly consistent past history of behavior disorders and social and personality maladjustments of a progressively increasing character. These patients are of two general types-the one characterized by more or less passive indifferent behavior and the other characterized by an increasing display of unusual, odd, unexpected, impulsive and finally socially unacceptable behavior.

The patients of the first type tend to be shy, quiet, retiring and unobtrusive in behavior. They hold themselves aloof from realities, they become increasingly withdrawn and disinterested without ever doing anything of a positive character to attract either favorable or unfavorable attention, except in a negative way. These patients are the model children who never do anything wrong and who have never learned the necessary lessons to be derived from the experience of mischievous mistakes and bad judgment. As the years pass, however well these patients may perform their daily routine duties in life, there is a progressive withdrawing from reality, a substitution of daydreaming for activities and the tendency to accept a place in life and in the family more suitable for one much younger. There is a loss of ambition, of interest, a failure in capacity for attention, a dulling or a loss of proper wholehearted emotional responses and there is a progressive need for them to limit and to restrict all of their activities and finally there is a development of frankly psychotic symptoms such as delusions and hallucinations.

The second type comprises those patients who react in a much more positive way; who tend to be anti-social, destructive and impulsive, and highly emotional in an extreme and often offensive way. There is a lack of consideration for others, an incapacity to learn from sad experience, a tendency to repeat an error in adjustment over and over again and there is a development of and a persistence in unreasonably ambitious ideas and hopes and plans. Their emotional attitude is one of disinterest in others, of callous disregard and extreme selfishness. As these tendencies increase and develop there comes about a slow alteration into progressively more psychotic manifestations such as preoccupation,

excitements, confusions, feelings of unreality, depersonalization, and the development of various types of hallucinations and delusions.

As one views the schizophrenic patient and looks over his life history, one is impressed repeatedly by the lack of understandable purposefulness in his behavior, the uselessness of many things that he does and the general tendency toward infantile and childish behavior, which would be suggestive in a small child of a behavior disorder. Hence the practitioner whose patient tends to show markedly childish and infantile behavior, who shows no consistency of readily appreciated purposes in any of his activities, or who shows a purpose that is extremely consistent but not in accord with practical realities, there should be a question in mind as to the existence of early schizophrenia.

Perhaps the best example to give, illustrative of this type of disorder, relates to a young man of good intelligence who, as a child, progressively lost interest in his school work, in his friends, in all of the recreational activities of his neighborhood; who worked well at first under the supervision of his father and other employers but who could not hold a position for long; who showed a progressive loss in his emotional responses care and protection for the patient.

In both the manic and the depressive reactions, the treatment is essentially that provided by the mental hospital, but the duration of the illness for the patient depends, in many instances, upon the promptness with which the family physician recognizes the warnings and arranges for adequate psychiatric care. And the general recognition of either condition is essentially a matter of viewing the patient's immediate behavior and conduct and judging its purposeful and useful character in terms of what can reasonably be expected of that individual. Behavior markedly out of harmony with a past history of stable industrious activity signifies a change in the personality that requires the critical gaze of someone experienced in human nature.

The last type of mental disorder I wish to discuss is the schizophrenic reaction type, or *dementia praecox*. Perhaps the best example to give, illustrative of this type of disorder, relates to a young man of good intelligence who, as a child, progressively lost interest in his school work, in his friends, in all of the recreational activities of his neighborhood; who worked well at first under the supervision of his father and other employers but who could not hold a position for long; who showed a progressive loss in his emotional responses to the rest of the family and often developed unreasonable prolonged temper tantrums until finally he had antagonized every member of the family. From that point he became increasingly self-absorbed, uninterested in everything, now and then talked about writing a novel, although he had not finished the sixth grade, and about becoming a millionaire. When finally discharged from his position as a janitor for a garage, a job given him by charity, he came home and complained of a pain in his chest. The family physician saw him repeatedly, but the patient discounted the seriousness of his complaints, showed no particular interest in the doctor's visit and no concern about his own general welfare. Periodically over the course of five years, the patient's mother had him examined by the family physician, since the patient constantly planned to go to work as soon as he was rested and the pains in his chest ceased. After five years of idling about the house, daydreaming, never even finishing the reading of a book that was once begun, the family found themselves unable to support him any longer. When admitted to the hospital, more than an hour's time was required to elicit frankly psychotic delusions and hallucinations,

but so far as the general practitioner is concerned, a young man who spends five years idling about the house in such a futile fashion is showing the best of evidence of mental disorder.

To summarize very briefly, then, the problem of recognizing the early symptoms of mental disorder and disease. The general practitioner needs primarily to judge his patient's behavior in terms of what may reasonably be expected of the particular individual, in terms of what is purposeful and useful to the individual and in terms of what behavior is in keeping and harmony with the general established patterns of behavior of the specific person.

In presenting this discussion, I realize that I have emphasized and stressed repeatedly the significance and importance of a great variety of early manifestations of personality disorder and disease. I have not hesitated in placing so much emphasis upon them since the wealth of experience every general practitioner has with human nature will prevent him from developing any alarmist attitudes toward every little thing that may occur. My purpose has been only to point out that apparently simple insignificant changes in the patient's ordinary purposeful behavior can portend as tragic an outcome as can a little insignificant painless lump in the breast. Not every tumor of the breast is cancerous in potentialities, but it is the physician's duty to have that possibility clearly in mind without becoming excited and alarmed. And so it is with the early symptomatology of mental disease. The physician who first sees the patient in the earliest stages should have clearly in mind the possibilities of eventual development, and then, against the background of his own wealth of common sense and experience, he should weigh those symptoms and decide what measures, if any, are necessary for that particular patient.

Criminality in a Group of Male Psychiatric Patients

Milton H. Erickson, M.D.

Published in Mental Hygiene, Vol. XXII, No. 3, July, 1938, pp. 459-476.

Within the last few years the attention of the public has been directed repeatedly to the commission of crimes by persons who show various recognizable forms of psychopathology, who suffer from definite mental disease, or who have a history of commitment to a mental hospital. The questionable responsibility of such offenders, coupled with the frequently grave character of their offenses, renders the entire social problem represented one of immediate and serious consideration both legally and psychiatrically.

But before this problem can be met adequately either legally or medically, there is need for extensive studies of the frequency and the nature of offenses committed by such medico-legal offenders and of the interrelationships existing between crime on the one hand and definite recognizable forms of psychopathology on the other hand.
In an attempt to approach this problem, a general survey was made of all the case histories of male patients in the current files of the Eloise Hospital on the date of November 1, 1934. The general findings may be summarized briefly as follows:

Total case records reviewed		1,394
Case records with insufficient anamnesis		132
Total case records included in this study		1,262
Patients with history of criminality:		
Definite criminality before recognized onset of mental disorder		119
Definite criminality after onset of mental disorder		148
Crime gravely threatened or unsuccessfully attempted:		
Before onset	7	
After onset	49	
		56
Total		323

Patients with history of misdemeanors only	24
Patients with history of conviction for felony	40
Patients with history of house-of-correction sentences for misdemeanors	31

The 132 records that lacked sufficient anamnestic data to warrant inclusion in the study were chiefly records of aged patients and transients whose friends and relatives could not be located by the social-service department.

Of the 1,262 patients included in the study, 323, or 25 per cent, had a definite history of criminalistic behavior, ranging from misdemeanors to felonies. This percentage

unquestionably falls short of representing the actual incidence of criminalistic behavior among psychotic patients, for the following reasons:

1. Difficulties inherent in the securing of information often render impossible a complete history of the individual. Frequently, in the nomadic type of patient, a definite criminal history is unknown to relatives and friends, and even to the authorities. In this study, cooperation with the Federal Bureau of Identification, made possible through the routine finger-printing of all admissions to the hospital, was of material assistance in the securing of criminal histories that otherwise would have been unavailable.

2. The routine practice in Michigan, as in many other states, is either to commit directly, or to transfer, to special institutions for the criminal insane all patients with a history of criminality. Hence, the patients in this general mental hospital actually represent a selected group, from which a considerable proportion of criminalistic patients have been removed.

The incidence reported here, therefore, becomes decidedly significant as an indication of the seriousness of some of the problems to be faced in the paroling of patients.
Our findings show also that 119 patients of this group, or 10 per cent of the total group, had actually committed definite crimes before the recognizable onset of their psychosis, and often crimes of a character apparently unrelated to their mental illness, such as embezzlement, swindling, automobile theft, and so forth. In other words, 10 per cent had been crime problems before they became psychiatric problems.

In addition, 148 patients, or approximately 12 per cent of the total group, were found to have committed definite crimes at or after the recognized onset of their mental illness. Study of the individual case histories, however, indicated that frequently in these cases the offense seemed to be directly related to the existing mental disease—e.g., a homicidal attack motivated by persecutory delusions; hence the problems represented by this group appear to be more psychiatric than criminal. Particularly is this true in regard to suicidal offenses, and the exclusion of this type of behavior reduces the relative size of this group from 12 per cent to 8 per cent. Nevertheless, the fact that 8 per cent of the male patients in a general mental hospital showed definite criminality after the onset of mental disorder constitutes a serious matter for consideration, particularly when the question of parole arises.

Of the 323 patients with criminal histories, 56 were individuals who had gravely threatened or unsuccessfully attempted to commit serious offenses. In this figure are included only those patients in whose cases the attendant circumstances were such that full credence of their threats was warranted. Mere threatening or resentful utterances were disregarded; hence any error in this figure is probably in the direction of understatement.

Only 24 of the patients had a history of crime limited to misdemeanors, for which the penalty was a fine, a reprimand, or a few days in jail.

That 40 of the patients had served time in prison for felony is not in itself remarkable. This figure acquires more significance, however, when it is realized that all these felonies occurred before the recognized onset of the mental disorder, and that these patients were thus serious crime problems before they became psychiatric problems. The same considerations hold true for those patients, 31 in number, who had served time in houses of correction for various types of misdemeanors. Furthermore, a study of individual case histories discloses that the majority of these patients had a history of repeated sentences for both felonies and misdemeanors, over half of the group having served two or more sentences. Briefly, this group of 71 patients, constituting 5 per cent of the total group under study, had established themselves as definite and recognized criminal problems before commitment to a mental hospital had become necessary.

To make possible an evaluation of the various forms of antisocial or criminal behavior represented in one group, the patients were arbitrarily divided into six general categories, as shown in Table 1. Four general types of offense are particularly significant-namely, sexual offenses; homicide, alone or combined with suicidal offenses; physical assault; and miscellaneous felonies. No particular discussion will be attempted of narcotic addiction because of the small number of cases and their essentially psychiatric nature, nor of the minor offenses and misdemeanors because of their relative unimportance as well as low incidence. The question of suicidal behavior also will not be discussed for the reason that it is essentially a psychiatric rather than a legal problem. The table is as follows:

TABLE 1—OFFENSES REPRESENTED 1N GROUP of 323 CRIMINALISTIC PATIENTS

	No. of patients	Percentage of criminal group	Percentage of total group
Sexual offences	66	20.4	5.2
Homicidal and suicidal offenses			
Homicidal alone	84		
Suicidal alone	47		
Homicidal combined with suicidal	18		
	149	46.2	11.8
Physical assaults	50	15.5	3.9
Miscellaneous felonies*	28	8.6	2.3
Narcotic addictions	6	1.8	0.4
Minor offenses or misdemeanors;			
Disorderly conduct and drunkenness	16		
Miscellaneous offenses**	8		
	24	7.4	1.9
Total	323	100.0	25.5

* Forgery, embezzlement. robbery, and so forth.
** Vagrancy, non-support, and so forth.

It should be explained that in making up this table patients with a varied criminalistic history were classed according to the offense that had the greatest immediate psychiatric significance for this study. This accounts for there being only 28 patients under "miscellaneous felonies," despite the fact that a total of 40 patients had served time for felonies. Also, patients with a history of homicidal offenses or physical assault in

addition to sexual offenses were included only under "sexual offenses," emphasis being placed upon the type of crime that has given rise to the present public interest in the entire problem.

The term "homicidal offense" was used only for offenses in which the actual intent was to kill. In those instances in which it was difficult to decide between a physical assault and a homicidal attack, the offense was classified as a physical assault. In practically every instance, the homicidal offense had been unsuccessful, since for the most part only those patients who had failed in their homicidal attacks had been sent to this hospital.

Again, in the group of suicidal offenses, only those patients who had made definite attempts to kill themselves were included. Mere threats or suicidal gestures were excluded unless study of the individual social-service history warranted full credence of the threat.

The various items in this table will be discussed in detail later. Here we will call attention merely to certain general considerations. First, there is a definite tendency in this group toward offenses directed against persons rather than against property, contrary to the trend among criminals in general. In the average criminal population, offenses against property usually comprise over 60 per cent of all offenses, while sexual offenses and other offenses against persons range from 10 per cent to 15 per cent each. In our group of psychotic criminals sexual crimes comprised 20 per cent of the total, and other offenses against persons, excluding the suicidal group, amounted to 45 per cent. Hence the generalization is warranted that a disposition toward mental disease may be reflected in an increased tendency toward sexual crimes and other crimes against persons.

In all probability, the trend toward these types of offense in the criminal behavior of persons either already mentally ill or disposed toward mental disorder reflects the inherent tendency of such personalities toward simpler and more primitive responses in the meeting of difficult or strongly emotional situations, the incapacity or lessened capacity for self-control in immediate situations of social conflict, and lack of the proper integration of intellectual and emotional responses during periods of mental stress.

Another general consideration concerns the extent of criminality found in this patient population as compared with the general population. Unfortunately, no statistics are available as to the incidence of criminalistic behavior in the general population, but it is a reasonably safe assumption that it would fall definitely short of the incidence in this mental hospital population, a group from which a portion of the criminal element had already been eliminated by legal processes.

In considering possible cause-effect relationships between the mental disorders of these patients and their criminal behavior, an effort has been made to differentiate between offenses committed before and those committed after the onset of the mental disorder. The findings are summarized in Table 2.

TABLE 2—OFFENSES COMMITTED BEFORE AS COMPARED WITH THOSE COMMITTED AFTER RECOGNIZED ONSET OF MENTAL DISORDER

	Number of patients	
	Before onset	After onset
Sex offenses	33	33
Homicidal offenses	15	33
Both homicide and suicide attempted	3	9
Physical assault	10	26
Suicidal attempts	0	47
Narcotic addictions	6	0
Miscellaneous felonies	28	0
Misdemeanors only	24	0
Total	119	148

*The 56 cases in which crime was unsuccessfully attempted or merely gravely threatened are not included in this table.

In compiling this table, the individual case histories were carefully studied, and in every instance of doubt, the patient was classified as manifesting criminality after the onset of his mental disorder. It should be stated further that "time of onset" means not the date of commitment, but rather the time at which relatives and friends became aware of serious personality changes in the patient. Often this time of onset antedated the actual commitment by a year or more. It was believed that from the point of view of our study this time of onset was more significant than the more or less chance date of commitment.

CRIMINALITY IN MALE PSYCHIATRIC PATIENTS

In 119 of our group no direct relationship was apparent between incidence of criminal conduct and time of appearance of mental disease. Nevertheless, it is entirely probable that in many of these cases there was a relationship between a developing or incipient mental-disease process, not yet advanced to the point of being recognized, and antisocial behavior.

In regard to criminality occurring after onset, no definite conclusion can be drawn as to cause-effect relationships, since if the suicidal offenses are excluded, the number of patients who manifested criminal conduct before the onset of the mental disorder actually exceeds those who manifested it after, indicating the probability of a concomitance in individuals of two different social problems. To be sure, in a large proportion of the after-onset cases, the criminality appeared to be directly related to psychotic symptomatology, such as persecutory delusions and hallucinations. But on the other hand it must be remembered that fully as large a group in the population of this study suffered from persecutory delusions and hallucinations without manifesting criminalistic behavior. The assumption seems reasonable, therefore, that criminality among mental patients is not due directly to mental disease itself, but that it is dependent upon other factors in the personality. A further corollary of this assumption, which this study in general indicates as reasonable, is that the personality defects that lead to the, development of mental disease may also contribute to criminality.

In considering specific items of Table 2, however, a definite difference is to be noted between the types of offense committed before and those committed after the onset of mental disorders. Offenses committed after onset were all of a type directed against persons, while of those committed before onset only about half were of this character. The probable interpretation is that the onset of mental disorder tends to favor not so much the development of criminalistic trends as the manifestation of those trends in certain types of antisocial behavior.

It is of interest also that the number of sexual offenses was the same before and after onset. Despite the relatively small number of cases involved, this constancy, not apparent in the case of the other offenses, raises the question whether there is any relationship either direct or indirect between mental disorder and sexual delinquency-whether, on the contrary, sexual delinquency does not represent a problem complete in itself, although the existence of a state of mental illness may be conducive to a more frequent manifestation of this offense. We will consider this question further in our discussion of the sexual offenses.

The data on threatened criminality in relation to time of onset are summarized in Table 3.

TABLE 3—OFFENSES THREATENED BEFORE AS COMPARED WITH THOSE THREATENED AFTER ONSET OF MENTAL DISORDER

	Number of patients	
	Before onset	After onset
Threatened homicide	6	30
Threatened homicide and attempted suicide	1	5
Threatened physical assault.	0	14
Total	7	49

Though the group is too small to be of much significance statistically, the findings are suggestive of a direct relationship between mental disorder and seriously threatened crime in which the attendant circumstances warranted the giving of full credence to the threat. Two examples may be cited: one a threatened homicide by a man who locked his family in a room, called an undertaker and stated that he was planning to kill them, and was found by the police using an axe to batter down the door which the family had barricaded against him; and the other a threatened physical assault by a man who pursued a young boy down the street in a rage, menacing him with serious physical harm, and who was overpowered with difficulty by the police before he could catch his intended victim. But the validity of this apparent relationship between threatened criminality and mental disorder is open to question since the study revealed an even larger number of patients who had made equally serious threats, but who had never attempted to put them into action and whose threats had never been taken seriously by those to whom they were made. The general conclusion reached was that the apparent relationship between the threatened criminality and mental disorder was in reality only an indication of the release of criminal tendencies as a result of the mental disease-that is, that the onset of mental disorder permitted the manifestation of previously controlled antisocial tendencies and that the mental disorder was not in itself the cause of, but merely the agent in the discovery of, previously existing criminalistic trends. Again the assumption seems to be warranted that the criminalistic mental patient really represents two types of social

problem, the criminal and the psychiatric, and that the psychiatric aspect serves often only as an agent in the disclosure of the criminal aspects. Hence the conclusion seems justified that the disposition of this type of mental patient calls for extreme care and consideration, with serious weight given to the history of criminal behavior.

Sexual Offenses—For purposes of comparison, the 66 sexual offenders were divided into those whose sexual offenses involved some manner of actual assault upon another person and those who committed perversions such as bestiality, public masturbation, scopophilia, and homosexuality by mutual consent. There were 41 in the first group and 25 in the second. The 41 were subdivided into those who offended against minors and those who offended against adults. Some of the more significant data with regard to these three groups are presented in tabular form below:

	Against minors		*Against adults*		*Of perversion type*	
	Before Onset	*After Onset*	*Before Onset*	*After Onset*	*Before Onset*	*After Onset*
Number of patients committing offence	16	11	7	7	10	15
Hospital admissions:						
First admissions	15	9	7	7	10	10
With two or more admissions	1	2	…	…	…	5
Average age in years:						
At time of admission	35	49	35	44	34	40
At time of study	37	52	39	48	37	45
Average years in hospital	2	3	3	4	3	5
With history of imprisonment	5	0	3	0	1	1

We see from this that 27, or 40 per cent, of the 66 sex criminals had offended against minors, 16, or well over half of them, having committed the offense before the onset of the mental disorder. The sex perverts make up roughly another 40 per cent of the group, with 25 cases, in 15 of which, again well over half, the offense had been committed after the onset of the mental disorder and hence would seem to have been directly related to it. Only 14, or about 20 per cent, of the entire group had offended against adults.

Of the 16 who had committed offenses against minors before the recognized onset of the mental disorder, 5, or about one-third, had a history of penal servitude, indicating that their criminalistic tendencies had been recognized, but inadequately dealt with. Of the 7 who offended against adults before the onset of the disorder, 3 had a history of imprisonment. That these numbers are too small to serve as the basis for any general conclusions, is readily admitted, but we believe that they do indicate trends of sufficient significance to warrant serious consideration in the development of social measures for dealing with such patients.

Another trend consistently apparent in this entire group of sex offenders is the lower average admission age of those whose offenses were committed before the onset of the mental disease as compared with those who offended after the onset, the difference averaging ten years. This earlier manifestation of delinquency is suggestive of a greater seriousness in the antisocial tendencies of the younger patient, and of the possibility that

increasing age and the onset of mental disorder released criminalistic tendencies previously controlled in the older patient.
Another interesting aspect of the problem of sexual offenses is the combination of such offenses with other types of criminality. A summary of our findings on this point is given in Table 4.

TABLE 4—OTHER TYPES of CRIME COMMITTED BY SEX OFFENDERS

	Sexual offenders against minors		Sexual offenders against adults	
	Before onset	After onset	Before onset	After onset
Actual homicidal offenses	5	2	5	1
Threatened homicide	…	1	…	…
Actual physical assault	2	…	1	…
Miscellaneous felonies	7	…	4	…
Total:	14	3	10	1

This table shows that 28 of the 66 patients who had committed sex offenses had a history of other criminal conduct, and that 24 of these, about 36 per cent of the entire group, had shown definite criminality other than sexual before the onset of recognizable mental disorder. In other words, approximately 40 per cent of the sexual offenders had demonstrated criminality in other regards, thereby emphasizing the seriousness of the social problem they represent.

Of further significance is the fact that of the 16 sexual offenders against minors before onset, 14 had offended in other regards. Only 3 of the 11 who had offended sexually against minors after onset had a history of other offenses. Of the 14 offenders against adults, 11 had committed other offenses. It is also of particular interest that of the 25. patients with a history, of perversions, none had a history of other types of criminality.

Homicidal and Suicidal Offenses—The data on the homicidal and suicidal offenders may be summarized as follows:

	OFFENSES COMMITTED				
	Homicidal		Homicidal with Suicidal		Suicidal
	Before onset	After onset	Before onset	After onset	All at or after onset
Total number of cases	15	33	3	3	47
Hospital admissions:					
First admissions1	14	31	2	8	44
With two or more admissions	1	2	1	1	3
Average age in years:					
At time of admission	44	40	55	50	42
At time of study	47	44	57	55	47
With history of imprisonment	5	…	…	…	…
With history of misdemeanors	7	1	1	…	3

OFFENSES THREATENED

	Homicidal		Homicidal combined with suicidal	
	Before onset	After onset	Before onset	After onset
Total number of cases	6	30	1	5
Hospital admissions:				
First admissions	5	22	1	5
With two or more admissions	1	8	…	…

	Homicidal		*Homicidal combined with suicidal*	
	Before Onset	*After Onset*	*Before Onset*	*After Onset*
Average age in years:				
At time of admission	30	41	52	48
At time of study	31	45	55	51
With history of imprisonment	5	…	…	…
With history of misdemeanor.	1	5	1	1

These data show an increased criminality after the onset of mental disorder. No other significant differences are apparent, with the exception of the high incidence of previous prison sentences and previous misdemeanors in the relatively small group of patients with a history of actual homicidal offenses before the onset of the mental disorder, which indicates some social recognition of the problem represented by these patients. There seems to be some differentiation in the average ages for the various groups, but the relatively small number of cases precludes the placing of any validity on these differences. However, in contrast to the sexual offenders against minors and adults before onset there is a sharp difference in average ages, the sexual offenders being decidedly the younger.

Physical Assault Offenses—The data on the offense of physical assault are as follows:

	Actual physical assault		*Threatened physical assault*
	Before Onset	*After Onset*	*All after onset*
Number of cases	10	26	14
Hospital admissions			
First admission	9	23	13
With two or more admissions	1	3	1
Average age in years			
At time of admission	47	38	38
At time of study	51	43	42
With history of imprisonment.	1	..	..
With history of misdemeanor	8	6	2

This offense appears to differ considerably from those previously considered in that the greater incidence occurs after the onset of the mental disorder, and in that the average admission age was less for those who manifested this behavior after onset. However, the relatively small number of cases precludes the drawing of definite conclusions.

4. Miscellaneous Felonies—About the 28 patients who committed miscellaneous felonies there is little to be said. All committed the offense before the onset of the mental disorder, and all but two were first admissions. Their average age on admission was thirty-nine years, and their age at the time of the study, forty-two years.

While all of these patients had committed felonies, many of them had been sent directly to the hospital and not to the criminal court. It is worthy of note, however, that of these 28 patients, 12 had actually served one or more terms in prison for previous felonies. One general comment to be made on this group is that their average admission age far exceeds the age of the average criminal offender of this type, and hence that they may represent a different aspect of the crime problem from that represented by the average felon.

Distribution of Psychiatric Diagnostic Types—Another question concerning these patients has to do with the distribution of psychiatric diagnostic types among them. This is given below, the distribution for the entire group being included for purposes of comparison:

	Percentage of criminal group	*Percentage of entire group*
Schizophrenic reaction types	38	41
Alcoholic psychoses	14	12
Manic-depressive psychoses	12	14
General paresis	10	13
Senile and arteriosclerotic psychoses	7	10
Psychoses with mental deficiency	5	2
Psychopathic personalities	3	2
Epilepsy	3	1
Miscellaneous diagnostic groups	8	5
	100	100

It is apparent that there are essentially no significant differences between the two groups so far as concerns the frequency of occurrence of any particular psychiatric diagnostic type, and that the general distribution of diagnostic types corresponds fairly well with that of other general mental hospitals. The slight differences may be accounted for wholly on the basis of the relatively small size of the criminalistic group.

In the distribution of psychiatric diagnostic types for the different categories of offense, certain variations in the frequency of diagnostic types were found. These variations only are given here since the general distribution in other respects followed essentially that of the two larger groups:

Of the sexual offenders, 12 per cent had psychoses with mental deficiency as compared with 5 per cent of the criminal group as a whole and 2 per cent of the entire group.

Of the homicidal offenders, 16 per cent had alcoholic psychoses as compared with 14 per cent of the criminal group and 12 per cent of the entire group.

Of the suicidal offenders, 34 per cent had manic-depressive psychoses as compared with 12 per cent of the criminal group and 14 per cent of the entire group.

Of those who combined homicidal with suicidal offenses, 22 per cent were schizophrenic reaction types as compared with 38 per cent of the criminal group and 41 per cent of the entire group; another 22 per cent had manic-depressive psychoses as compared with 12 per cent of the criminal group and 14 per cent of the entire group; and 17 per cent had senile and arteriosclerotic psychoses as compared with 7 per cent of the criminal group and 10 per cent of the entire group.

Of the physical-assault group, 54 per cent were schizophrenic reaction types as compared with 38 per cent of the criminal group and 41 per cent of the entire group.

Of those who committed miscellaneous felonies, 14 per cent had psychoses with mental deficiency as compared with 5 per cent of the criminal group and 2 per cent of the entire group; and 8 per cent had psychopathic personalities as compared with 3 per cent of the criminal group and 2 per cent of the entire group.

Of those who had committed minor offenses and misdemeanors, 34 per cent had alcoholic psychoses as compared with 14 per cent of the criminal group and 12 per cent of the entire group.

No particular comment can be made on these variations other than to say that they are in accord with the general findings in the fields of psychiatry and criminology, and that they possess no special significance for this study.

General Facts of Hospitalization—The general data on hospitalization for the various types of offender were briefly as follows

The average percentage of patients with two or more admissions ranged from 10 to 15 in the various groups, with the exception of the homicidal group, in which it was 20 per cent, and the suicidal group, in which it was 2 per cent.

The average age at admission ranged from forty to forty-four except in the case of the sexual offenders who committed their offenses before the onset of the mental disorder, for whom it was thirty-five; the patients who combined homicide with suicide, for whom it was fifty; and the narcotic addicts, for whom it was thirty-five.

The average duration of the period in the hospital was from two to four years, except in the case of the suicidal patients, for whom it was five years.

With the exceptions noted, the findings for each of the various categories of offense were essentially the same. Within the individual groups, as we brought out in discussing them, certain variations in age did occur, but the groups are too small to warrant the drawing of definite conclusions.

One general observation that may be made, however, is that the average age on admission of the criminalistic mental patient far exceeded the average age of twenty to twenty-four years found consistently in the general criminal population. The admission age for the group under study is of course an index rather of the age at the onset of the mental disorder than of the age at the time the crime was committed; nevertheless, it does suggest that the criminality of those predisposed to or actually suffering from mental disease represents a social problem pertaining to a later age level than does criminality in general.

SUMMARY

1. Of 1,262 patients, the male population of Eloise Hospital, a general mental hospital, 323, or 25 per cent, were found to have a history of criminality, despite the general practice of sending mentally disordered criminals to special institutions for the criminal insane, and despite, further, the difficulties involved in securing complete case histories.
2. A history of definite or actual criminality before the recognizable onset of the mental disorder was found in 119 cases, or 10 per cent of the total population.
3. A history of definite criminality after the onset of the mental disorder was found in 148 cases, or 12 per cent of the total. One-third of these 148, or 47 patients, had committed suicidal offenses, leaving 8 per cent with a history of other criminalistic behavior.
4. Of the 323 criminalistic patients, 56 had a history of having gravely threatened criminal conduct.
5. Only 24 of the group had a history of criminality limited to misdemeanors.
6. In 40 cases a history of prison sentences for felonies was found, and 31 patients had served sentences of varying lengths in houses of correction.
7. Study of the types of offense disclosed a high frequency of sex crimes and of other crimes against persons, the incidence being 20 per cent for the sex crimes and 45 per cent for the others, as compared with 10 to 15 per cent each for the general criminal population.
8. With the exclusion of the suicidal offenses, more crimes were committed before the onset of the mental disorder than after—119 as compared with 101. Of the former, half were directed against persons while all of the latter were directed against persons.
9. The number of sexual crimes committed before and those committed after the onset of mental disease was the same, being 33 in each case.
10. Of these 66 sexual crimes 27 were against minors, 16 having been committed before the onset of mental disease; 25 were in the nature of perversions, 15 having occurred after the onset of mental disorder; 14 were against adults, 7 having been committed before and 7 after the onset of mental disease.
11. Five of the 16 sex offenders against minors before the onset of mental disease, and 3 of the 7 sea offenders against adults before onset had a past history of prison sentences.

12. The average admission age of sex offenders before the onset of the mental disorder was within the fourth decade and was ten years less than that of similar offenders after the onset.
13. Of the sex offenders, 28 had a history of other criminality. None of these were offenders of the perversion type.
14. More of the homicidal, suicidal, and physical-assault offenses had been committed after the onset of mental disorder than before.
15. There was a high frequency of felonies and misdemeanors among the actual homicidal offenders before onset of mental disease.
16. The homicidal and suicidal offenders were on the average ten years older than the sex offenders.
17. Physical-assault offenses had occurred more frequently after the onset of the mental illness, and the average age of these offenders was thirty-eight years, in contrast to an average of forty-seven years for this type of offender before the onset of mental disease.
18. The distributions of psychiatric diagnostic types were essentially the same for the total hospital group and for the criminalistic group.
19. The distribution of psychiatric diagnostic types for the various classes of offenders showed some variations from the general distribution, but they were not of any particular significance from the point of view of this study.
20. The average percentage of patients with two or more mental-hospital admissions ranged from 10 to 15 per cent for the various groups of offenders, with the exception of the homicidal offenders, for whom it was 20 per cent, and the suicidal offenders, for whom it was 2 per cent.
21. The average age for the criminalistic group ranged from forty years to forty-four years for the various categories except in the case of the sexual offenders, whose offenses were committed before the onset of the mental disorder, and the suicidal and narcotic-addiction groups, the average ages of which were respectively thirty-five years, fifty years, and thirty-five years.
22. The average duration of stay in the hospital up to the date of this study ranged from two to four years for the various subgroups with the exception of the suicidal patients, who averaged five years.

Though the various groups included in the study are too, small to serve as a basis for general conclusions, the fact that a history of criminality was found in 25 per cent of this selected group, from which a considerable proportion of criminalistic patients had been removed by legal means, indicates the seriousness of the problem of mental disease combined with criminality.

Problem of the Definition and the Dynamic Values of Psychiatric Concepts

Milton H. Erickson, M.D.

Reprinted from the *Medical Record,* February 2 and March 2, 1938.

GENERAL CONSIDERATIONS

The growth of dynamic trends in modern clinical psychiatry has resulted in a constantly increasing need for a critical evaluation of accepted psychiatric concepts for the purpose of determining their delimitations, their proper usages, and their correct immediate and remote applications. Many of the most useful concepts of the present time were formulated originally to meet the needs of descriptive psychiatry but have since acquired new meanings through modern clinical developments. Nevertheless, the usages of these concepts and the applications of their corresponding terms have lagged behind the advances in conceptual significances.

Too often a concept has acquired dynamic meanings while its application has remained at a descriptive level. An example of this is the concept of "flight of ideas". Originally, this concept signified merely the rapid utterance of more or less complete ideas, and it possessed only a descriptive value for the immediate behavior of the patient. Now, however, modern clinical psychiatry has accorded it the significance of purposeful though distorted behavior serving definite needs of the personality which are remote from the immediate situation, and has recognized such speech as being characterized by certain types of dynamic associations existing between the individual parts of the stream of ideas. Nevertheless, despite this acquisition of increased meaningfulness, the actual practical usage of the term remains essentially unchanged from its original descriptive status.

In consequence of the addition of new meanings to original significations, there has developed a confusing admixture of dynamic and descriptive values for many psychiatric terms and concepts, rendering impossible a definite, clearly understood account of psychiatric findings without a mass of additional clarifying explanations, and causing the use of the same psychiatric terminology to define widely different but superficially similar manifestations, Thus, critical study of several mental examinations performed by capable psychiatrists on as many different types of psychotic patients will disclose that the symptomatology found in each instance, to judge from the terminology employed, is strikingly similar.

For example, we find that the psychoneurotic patient, the manic-depressive, and the schizophrenic, may all be "mildly depressed". The paranoid and the catatonic patient are both "affectively rigid". The hebephrenic and the simple precox are "apathetic," while the

manic and the excited catatonic are both "overactive" and "overtalkative", and the "agitated" depressive and the "agitated" schizophrenic are both "apprehensive". As these technical phrases are read, their meanings are not to be sought in the terms themselves, despite the fact that each of them possesses definitely both dynamic and descriptive values. Rather, it is the context of the whole description, the sequences of behavior, and the relationships existing between the various manifestations that serve to provide the connotations, the nuances of meaning, and the general complexion of the whole mass of data, which enable the psychiatrist to determine the various dynamic or descriptive imports necessary to formulate an opinion. And such an opinion is generally recognized as being based more on "clinical experience" than on the bare factual or descriptivistic material presented for consideration.

To describe a patient as depressed, ritualistic, over-active, agitated, or apathetic means nothing so far as the understanding of what is meant is concerned, and too often it means little in the actual definition of the manifestation. The depression that occurs in the manic-depressive patient is qualitatively if not quantitatively different from the depression shown by a psychoneurotic, and the depressions shown by both of these are markedly different from that shown in schizophrenia. To describe the manifestation as one of depression is only suggestive until many other considerations have been described in addition. That there is a qualitative difference is readily recognized and it is frequently expressed in some such fashion as follows: "The depression was of a psychoneurotic type rather than of a manic-depressive type." One often hears in psychiatric discussions, of the "psychoneurotic cast" to schizophrenic symptomatology, the "manic characteristics" of the catatonic, the "paranoid coloring" shown by the hebephrenic. In brief, one hears of mixed or combined psychosis, and psychoses with peculiar admixtures of symptoms presumably belonging properly to various other psychoses. That there may be mixed or combined psychoses is possible, but the present development of psychiatric thought does not warrant such an assumption. Rather, it implies the necessity for a more adequate evaluation of psychiatric concepts instead of the predication of more than one type of psychosis in a single patient.

Furthermore, for a psychiatrist to make a diagnosis of mixed manic-depressive psychosis and catatonic dementia precox because the patient shows periods of catatonic stupor, flight of ideas, and overactivity, is questionable in itself since these terms are no more than crudely descriptive and are lacking in definitive values. To describe as a flight of ideas the overtalkativeness of a patient may be correct, but overtalkativeness in itself does not constitute a flight of ideas. Neither is it correct to assume without a clear definition of the concept that a flight of ideas constitutes only a manic characteristic, as is the general practice. To validate this practice, qualitative and quantitative analyses need to be made of the overtalkativeness of the patient suffering from the manic phase of manic-depressive psychosis as well as of the overtalkativeness found in other psychoses.

At present, the definition of a flight of ideas, as culled from a dozen accepted current psychiatric textbooks, may be stated as follows: "A flight of ideas is a disturbance in the thinking processes characterized by increased rapidity in thinking, lack of dominant and goal ideas, increased associations, and susceptibility to chance associations which may be

either external or internal in type, and a rapid succession either in thought or more commonly in speech of superficially related or even of unrelated ideas which may be complete or fragmentary." Such a definition, however, is scarcely more than informative concerning the verbal structure of the manifestation, and permits no determination of the quantitative or qualitative values of its expressiveness for the personality nor any indication of its dynamic significances in application to the individual patient. Yet, in each of the textbooks from which this definition was culled, the concept of flight of ideas is used to signify by connotation certain dynamic factors inherent in the manic-depressive psychosis, and the general clinical significance of this concept is related to the purposive aspects of the disorder.

Yet, at the same time, this concept is used frequently to identify the overtalkativeness of the catatonic patient. However, its usage tends to be somewhat different since it is applied almost entirely to the form of the symptom itself, and does not carry the dynamic connotations characteristic of its use in, manic-depressive psychosis. A recognition of this fact is to be found in the frequently used qualified phrase, "catatonic flight of ideas". That there is any identity between a "manic" and a "catatonic" flight of ideas other than the apparent form or structure of the symptom is as yet a question. The probability is that the general broad use of the concept is as unsound psychiatrically as the use of the concept "fever" was formerly unsound medically. In all likelihood, there is no more fundamental identity in the overtalkativeness of a catatonic patient and that of a manic patient than there exists in the febrile reactions arising respectively from bacterial infection and toxic absorption processes. That the symptom of overtalkativeness serves different though not yet understood purposes in the two psychoses is a matter of general clinical acceptance. Nevertheless, no provision has been made as yet for the evaluation and definition of this concept in any direct relationship to the various psychosis in which it may appear. Furthermore, the use of the concept of flight of ideas should depend not upon the manifestation of a flow of speech, but rather upon differential criteria based upon a critical study of the type, nature, and purpose of the ideas themselves with further differentiation made between internal and external, remote and immediate associations, all in relation to the general state of the patient and his personality.

To illustrate further, no better example can be given than the accepted and accredited use of the word "circumstantial" in describing the stream of talk of the garrulous senile, and of the meticulous, communicative paranoid patient. Yet, even to a neophyte, the circumstantiality of the one resembles in no way the circumstantiality of the other. Nevertheless, the one term is used for both types as well as for other types of such behavior, an any differentiation made must based on an analytic consideration of the data itself, and, in addition, on still other types of data. To say that a patient is circumstantial in his speech adds nothing to an understanding of that patient nor of the symptom itself until additional data are given. At best, such a statement serves only as a point of orientation with any formulation of opinion to be corrected, altered, and redirected with each bit of additional information.

This application of a general and only crudely descriptive term to a specific symptom is strongly reminiscent of those medical days when "fever" was an accepted diagnosis and

regarded and treated as an ailment in itself. No significant medical progress was achieved in relation to the concept of fever until a differential analysis had been made of this symptom in connection with the general state of the patient and the entire descriptive concept had been broken up into a great number of apparently similar but fundamentally different reactions. Despite any absolute identity of graphic records of temperature, the processes represented may be totally different. Likewise "sugar in the urine" constituted a definite diagnosis until therapeutic and diagnostic failures disclosed the necessity for distinguishing glycosuria, lactosuria, and pentosuria. Even then it became apparent that much further analysis of the symptom was necessary to establish a final diagnosis of diabetes mellitus rather than a diagnosis of alimentary or renal glycosuria. In brief, the record of advances made in understanding the symptom of "sugar in the urine" shows clearly the absolute necessity for a qualitative analysis of the symptom in direct relationship to the general underlying condition of the patient. As a result of such analytic study, the term glycosuria now serves to report a laboratory finding while the term "pancreatic glycosuria" constitutes a significant meaningful though general clinical concept of a definite specific application.

Accordingly, psychiatry needs to adopt the analytic attitude of general medicine for the development of definitive significations and for the determination of the uses, applications, and values of psychiatric concepts and descriptive terms. The method by which this may be achieved lies in taking into consideration the dynamic as well as the descriptive aspects of psychotic symptoms. Merely to describe a symptom without indicating in any fashion its dynamic or purposive qualities is entirely inadequate and misleading, as, for example, describing a patient as "assaultive toward nurses," without indicating the dynamic considerations by adding the word "sexually". By the addition of the dynamic consideration to the descriptive term the symptom becomes clearly specific and meaningful. Particularly bas the value of dynamic considerations been illustrated by the rapid development of psycho-analysis and the fruitfulness of its contributions to psychiatry in general, enabled entirely by its emphasis and insistence upon the dynamic purposeful aspects of behavior rather than descriptive considerations.

Nor does this require the development of a new terminology but rather the adequate precise usage of the present vocabulary. The means by which such advances in conceptual significances may be achieved are both simple and difficult. Psychotic symptomatology needs to be subjected to a controlled analytic laboratory study to determine the various psychological and psychiatric significances of each symptom. Furthermore, as an initial step in such analysis, longitudinal study, as contrasted to cross-sectional, needs to be made of the psychiatric patient so that each symptom to be analyzed may be one observed over a long period of time. The recognition of the fact that a single psychiatric examination, however thorough, is often misleading and inaccurate if not actually false in many essentials, needs to be extended to the recognition of the fact that a psychotic symptom itself, even more often than the patient, requires long continued observation before a reasonably correct general classification of it may be made. Hence, the critical analysis in the psychological laboratory, after extensive longitudinal study of their clinical course of development and manifestation, of hallucinations, delusions, affective disturbances, and all the various psychotic manifestations constitutes a task of

paramount importance in the immediate development of psychiatric knowledge. By such critical study of psychotic symptomatology, one may hope to determine its exact nature and to define the essential elements comprising it, instead of stopping short by classifying it according to some general category. Only by definitive measures may the conceptual values and usages requisite for the clarification of the problems of mental disorders be determined.

AS ILLUSTRATED BY A CASE HISTORY

In the preceding section of this paper the inadequacies and fallacies inherent in purely descriptive material were discussed and emphasis was placed upon the need for dynamic treatment and long-continued observation of psychotic symptomatology. For this section, in illustration of these considerations, the following case history extending over a period of three years is reported in detail because of the clarity with which it portrays the problems involved in the utilization of inadequately defined psychiatric concepts.

Case History

The patient in question, a well-developed well-nourished white male about thirty years old, apparently a visitor in the city, was brought to the hospital by the police on an emergency order after arrest for disorderly and erratic conduct. He carried no form of identification, his name and home were never learned, and hence, no social service history could be obtained despite repeated efforts. Physical examination disclosed nothing unusual or of immediate psychiatric significance. Separate mental examinations were made on different occasions by four competent psychiatrists. In addition, the patient was presented before the hospital staff for formal consideration. The diagnostic opinion reached, separately and collectively, was manic-depressive psychosis, hypomanic phase. The mental examinations were essentially identical except in regard to thought content, but the form of this was rigidly constant, and the findings of these examinations may be summarized as follows:

Summary of Mental Examinations

In attitude and general behavior, the patient was alert, overly energetic, interested, keenly responsive to all forms of external stimuli, extremely animated in action and facial expression, and constantly engaged in a succession of well-coordinated purposeful activities conducted in an excited, exaggerated, hyperactive fashion with a marked pressure of speech and action. His general mood was one of cheerful, over responsive friendliness, with definite elation and euphoria, but he was easily irritated and angered, from which emotional states he would recover with equal suddenness. Occasionally there would be repeated prolonged rages, particularly in the afternoon, with, however, sudden prompt recovery, but these rages always seemed to be in response to external provocation. Self-care was good except for restlessness at night and a tendency to eat too hastily.

His appearance was tidy except for marked decorativeness of a neat precise systematic character. The decorations were comprised of three patches of paper pasted on his forehead above his nose, two patches located distally and laterally to the alae nasi, and neat fringes of dirty string around each button-hole and pocket. Frequently there were cigarette butts thrust into each ear canal. At other times none of these decorations were present, but special examination would disclose, fastened inside the back of his vest, a rosette fashioned from rusty nails, wire, a spoon handle, broom straws, twigs, or other odds and ends, while a similar rosette was hung inside his shirt over his naval. Additionally, around each large toe was wrapped a strip of toilet paper with the ends free and twisted into small balls, while around the calf of the left leg was a string from which hung a piece of paper roughly cut in the shape of a toad and on which was written the word "toad". Originally, this ornament had been a piece of wire on which was hung the mummified flattened body of a small toad. Around the right leg, above the knee, was a circlet of cardboard and wire to which were attached bright pieces of metal, glass jewelry, and various shiny articles. These last two articles were worn with both the concealed and the visible sets of decorations; if with the visible set, they were kept outside the trousers legs, but otherwise they were concealed. An of these decorations were neatly and carefully made, were readily displayed and much pride was manifested over them. However, the concealed set was never shown except on special request and urging, and these, unlike the others, were worn only for brief periods and at infrequent intervals while the others were often in evidence for days at a time. In addition to his pride in them, the patient resented intensely any disparagement of his decorations and defended them most passionately if any attempt was made to remove them, raging and fighting if they were taken away, even though he himself might a few moments later lay them aside voluntarily.

His motor activity was essentially one of busy purposeful action in which he endeavored to conduct all of the ward activities or which was devoted to the enactments of various fantasies in which he seemed knowingly to be playing a game. In these activities he depended to a large degree upon his surroundings to support him, marshalling, for example, a group of patients and chairs together to serve as a military drill squad, while the window curtains would be designated as their tents. The various fantasy activities were persisted in at times for several days in succession, but in such a fashion that they served to dominate and to give color and form to all of the various other activities in which he participated. Thus, when engaged in the enactment of military fantasies, in addition to his military drills, all ward work, ward rounds, patients' walks, etc., were supervised by him as if they were part of a military routine. Detailed description of this behavior will be given later.

The stream of mental activity was marked by over productivity, a continuous flow of ideas, marked distractibility, sound associations, rhyming, punning, alliteration, onomatopoeia, witticism, but no other particular disturbances were noted. However, the stream of speech centered entirely around the patient's immediate activities and he was uncommunicative in all other regards. Sample utterances will be given later in the general discussion.

His emotional reactions were those of euphoria and elation with transient periods of intense rage and anger when crossed. He was decidedly egotistical and self-satisfied, keenly interested in all of his surroundings in a rather happy joyous fashion. At times he showed some tendency to become momentarily suspicious if questioned closely about his past history.

His content of thought was restricted almost entirely to immediate stimuli or his activities of the moment which were apparently the enactment of various fantasies. Two of the psychiatrists described his thought content as centering about his conception of everything around him as machinery, the operation of which he was directing. The third psychiatrist in his examination reported the patient as regarding the entire ward life as a drama in the course of production under his direction; while the fourth psychiatrist made note of the patient construing every ward occurrence into a sexual theme. Much of his time was spent in the enactment of various fantasies such as making medical rounds, supervising the ward housekeeping, directing theatrical productions, and drilling soldiers while he kept up a constant stream of talk into which was woven in fairly logical fashion comments on each little event or disturbance occurring on the ward. Thus, while conducting a military drill, he berated soundly the stuporous patient who had not heeded his commands, weaving into his scoldings comments about the examiner's amusement over the failure of obedience, advising the patient to use his ears to hear the nurse answering the telephone and his eyes to see the hole in the trouser seat of a passing patient, continuing indefinitely in this fashion without digressing completely from the original consideration.

Extensive questioning for delusional, hallucinatory and other pathological trends elicited no evidences of such disturbances, and observation of his activities suggested no such abnormal trends, except for the obviously grandiose ideas concerning himself and his immediate activities.

Investigation of the sensorium was most unsatisfactory and continued to be so throughout the entire hospital stay. Items of personal identification and remote memory, elicited with extreme difficulty, were given variously and found to be unreliable. Otherwise, he was correctly oriented, and recent memory, retention and recall were found to be unimpaired, if allowance were made for his distractibility and the difficulty of securing his full attention. Insight seemed to be lacking, although many of his comments indicated an intelligent comprehension of the condition of his fellow patients. Likewise, his judgment seemed to be good in all general matters not pertaining to himself.

In brief, the impression made upon each examiner was that the patient was experiencing an acutely psychotic episode characterized by a feverish flight into the realities, actual and conjured, of the immediate present with an extreme avoidance of everything possible related to his life previous to his hospitalization.

DISCUSSION OF SYMPTOMS

In discussion of these case findings, emphasis will be placed chiefly upon self-decorativeness, the affective disturbances, and the overactivity with its associated over talkativeness, and an effort will be made to illustrate directly the inadequacy of undefined concepts.

1. Self-decorativeness

Ordinarily in relation to the symptom of self-decorativeness, one thinks of the manic patient with ribbons in his hair and buttonholes, the flower in his lapel, the pinchbeck jewelry, and the odd bits of gay plumage scattered over his body. Or one may think of the schizophrenic patient with his erratic, peculiar symbolic types of decorations which are often such unusual character that their ornamental significance is difficult to recognize. But in this patient much more is necessary than a careful description of the decorations. One needs to know more than the fact that the three patches of paper, triangular in shape, pasted on his forehead were taken from stamps and were placed in a triangular pattern. They were always taken from stamps bearing the portrait of Washington, regardless of the color of the stamp, and were always so cut that Washington's features were discernable. Likewise were the circular patches of paper pasted on his face in relation to his nose taken from similar stamps and so cut that again the features of the "Father of His Country" were distinguishable. All other stamps were rejected. No explanation of any sort could be obtained from the patient concerning these dynamic considerations during the months this symptom was present.

Similarly, a mere description of the neat precise string fringes about his buttonholes and pockets is entirely inadequate without the additional information that these fringes were made only from strings torn from the lavatory floor mop. New mops, the ward mop, or pieces of string were never used until after they had been rubbed on the lavatory floor. It was essential, if they were to be used, to wet and soil them by contact with the lavatory floor. With the addition of this dynamic material the entire significance of the fringes changes completely; they cease to be fringes except to the eye of the uninitiated and their entire meaning derives from the dynamic aspects of their manufacture. Hence, to describe the decoration means little or nothing without the inclusion of the dynamics involved. And had it been possible to learn still more of the dynamic aspects, an even more extensive and perhaps different conception of this manifestation could have resulted.

Similar is the situation in regard to the cigarette butts thrust into his ear canals, always butt end first. Fresh cigarettes offered him for that purpose were readily accepted, but before use, had to be lighted, a puff or two of smoke taken, following which they were extinguished and inserted. Occasionally dead matches were used, with the charred end innermost, and fresh matches were first lighted before they could be used.

Obviously, for these decorations, the ornamental effect, despite his seeming pride in displaying them as such, was only secondarily such, and their real significance lay, as far as could be determined, entirely in their dynamics. Hence, any description of them not including the dynamic considerations is misleading and uninformative. It was not the

ornamentation. But the charring of the cigarette and matches, the portrait of Washington and the soiling and wetting of the strings that constituted the primary considerations in his seeming decorativeness.

In regard to the other ornamentations, the fetishistic character is so predominant that little regard can be given to the possibility of intentional ornamentation. Except for the toe ornaments, little could be discovered concerning their dynamic values except that which could be gleaned from the wearing of the leg circlets openly with visible ornaments and secretly with the concealed set, and the rigidity of location and the manner of wearing. In regard to the manufacture of the toe ornaments, however, it was found that only toilet paper could be used. All other kinds of paper were rejected unless first cut into squares and hung in the toilet. Merely taking the paper into the toilet served no purpose: it had to be cut into squares and hung up for use. With this additional information, it becomes apparent that a pure description of the shape, size, appearance, location and construction of the article would be entirely inadequate without the dynamic fact of the original purpose of the paper used.

Not only does the inclusion of the dynamics involved for the various forms of decoration serve to clarify their nature and significance individually, but also they serve to clarify the interrelations of the various manifestations. A purely descriptive account of the string fringes and toe ornaments, aside from the possible general sexual symbolism, would fail to reveal the highly significant interrelationships disclosed by the identity of the dynamic forces entering into their construction. The psychiatrist observing the patient making a fringe from the ward mop, not knowing that it had previously been rubbed over the lavatory floor, or describing toe ornaments made from a newspaper not knowing that that piece of newspaper had been taken from the toilet, could not discover a highly significant direct interrelationship, apparent immediately upon the inclusion of the dynamic considerations.

Nevertheless, essentially the same psychiatric terms would be used in both a dynamic and a descriptive account of the decorativeness. A purely descriptive usage of the term "self-decorative," as shown by the foregoing material, is inadequate, misleading, and uninformative. There needs to be made a critical analytic study of this type of symptomatology and differential values established so that the term can not be applied alike to the hair-ribbon, pinchbeck jewelry decorations of the manic patient, the bizarre adornments of the schizophrenic, and the peculiar but equally ornamental dynamic adornment of the patient reported here.

2. "Flight of Ideas" and Overactivity

Regarding the patient's over talkativeness and over activity, these were described consistently as flight reactions. He was extremely responsive to all external stimuli and these were woven into his stream of talk and action. Witticisms, puns, rhymes, alliterations, clang associations, and onomatopoeia were so frequent as to characterize his speech. He made rounds with the physician, supervised the ward work, gave running accounts of all ward events, organized glee clubs, armies, classes in calisthenics, usually

with a stuporous patient or two and some chairs constituting his army, etc., while he himself both issued and obeyed commands, talking in a continuous stream during all of these activities. However, over a long period of time it was to be noted that the content of his speech was characterized by three types of vocabulary until the ward personnel came to make the comment, "this is Joe's machinery (or sexual or theatrical) week." During the "machinery" periods, ideas related to machinery fitted into almost every response he made to external stimuli. In his comments in making rounds with the physician, this patient's "gears" were "grinding," the nurse walked on roller bearings, a contrivance was suggested and model made of paper and string for throwing back the covers of the beds, his army must march with "machine-like precision" and was divided into the "piston corps", the "rod detachments," the "brake bands," the "cylinder head" and the "spoken radius". The sun shone in "rods" and "beams" to be fitted with "elbow joints" and "vibrators" and supplied with "elbow grease". During a theatrical week, the running commentary in making rounds concerned miens, attitudes, poses, and expressions, and interpretations were placed upon everything that attracted his attention, The army "sup-posed," "posed," and "reposed" and was divided into the "heavy corps," the "dress parade" and the "ticket detachment," Calisthenics were performed to commands of "disdain," "longing," "fear," "yearning," "glee," "refusal", etc., although during the machinery week the commands were "thrust," "rotate," "spin," "mesh," "wheel," etc. And during the "sexual" week, the running commentary on ward rounds described the patients as "presenting," "invitatious," "withdrawing," "drained," "loaded," "hard," "hot." The army was commanded to "present," "charge," "recharge," "shoot," "thrust" "retreat," "assert" "insert" and "resert." Calisthenics were directed by such commands as "erect," "up," "down," "go limp," "wiggle," "squirm," "relax," "sigh," "grasp," "thrust." A paper dropped on the floor was "excited," "aquiver," "ashiver," "aflutter," and a ball bounced would elicit an immediate comment such as "beating with anticipation—pashen—en—pay as you enter."

During each of these three general periods the content of the patient's behavior and speech changed constantly but the context or significance and the form were invariably the same. Ward rounds would be transformed into housekeeping and inspection tours, the theatrical troupe became a printer's organization and the army became a school. A catatonic patient or a row of empty chairs was all that was necessary to set the scene while he gave commands and executed them himself. In cross-sectional study, there was no apparent order or rhythm to his behavior and no activity was persisted in for more than a few days at a time. However, upon the longitudinal study made possible by continued observation for many months, it soon became apparent that each period was strictly limited to the one general type of behavior and that the speech and behavior of the "machinery week" never entered into the "sexual" or "theatrical weeks". As months passed it became evident that there was a rigidly regular succession of periods of a stereotyped pattern, masked, however, by his responsiveness to external stimuli.

3. Affective Disturbances

Mention was made in all four of the mental examinations of the patient's tendency to become easily enraged for transient periods, with occasional intense rages of longer

duration but apparently in response to external provocation. Such observations were correct so far as could be determined by cross-sectional studies. Continued observation over a considerable period of time was necessary to disclose a striking peculiarity in his rages, and this finding was made only through the careful study of ward notes. This peculiarity consisted of an absolute regularity and rhythm in the occurrence of his rages. Apparently always in response to an unwelcome request by doctor, nurse, or attendant, interference with his activities by ward personnel or patients, or some untoward event on the ward, nevertheless, it was found that every afternoon between the hours of two and five o'clock three sudden outbursts of intense violent rage would occur, with their form and content apparently determined entirely by the immediate situation which he seemed to be resenting. These would last five to ten minutes and would be spaced by intervals of his normal good-naturedness lasting from fifteen minutes to an hour, with the final outburst succeeded by a return to the general affective state characteristic of his morning behavior. This manifestation occurred regularly for eight months, and developed even when the patient was secluded to prevent the possibility of external provocation. The seclusion itself was utilized as the external provocation.

Furthermore, deliberate experimentation disclosed that an act ordinarily inoffensive to him, would, during the proper hours, precipitate the temper outbursts, but that after the third outburst the act would again become inoffensive and remain so until the proper time the next day.

Accordingly, it is apparent that the external provocation constituted merely a minor part of a stereotyped form of emotional behavior, and the rigid character and form of the emotional disturbance indicates that it was a function of the personality as a whole rather than a function of the personality-response to an immediate situation.

Hence, the essential information concerning these emotional outbursts is not to be found in any detailed description of the behavior itself, but rather in the dynamic considerations of the time of occurrence, the rhythm and the number and interrelationships of the outbursts. To report these rages in purely descriptive terms is to conceal their significance since their form and immediate content were determined by the apparent realities of the situation and hence did net betray their rigidity, stereotypy, and automaticity.

CLINICAL COURSE AND DIAGNOSTIC CONSIDERATIONS

The eventual outcome for this patient is equally significant regarding the actual nature of his mental disease. After about eight months of active, ever-varying but rigidly limited behavior, it was noted that he was becoming increasingly less responsive to external stimuli and correspondingly less active and talkative. At first, a few hours or an occasional day might be spent sitting about in an inert unresponsive fashion. Gradually this type of behavior came to predominate. The wearing of decorations slowly came to be more and more infrequent, and the affective disturbances becan1e increasingly less frequent, although the actual time and number of temper outbursts remained unchanged, until finally the patient had become too apathetic to do more than to sit quietly about the ward.

About a year after his admission vague delusions appeared for the first time and gradually developed into bizarre somatic delusions of cows in his stomach, horses in his knees, absence of viscera, etc. At the same time, vague hallucinations of noises, voices, and images developed slowly but of no particular character of quality so far as could be ascertained since the patient never explained more than to say, "They're talking to me," or, "They're making noises," or "I see things there," as he sat about, apparently listening and watching, smiling in a silly preoccupied fashion. About a year and a half after admission, he presented the typical appearance of the silly, grimacing, untidy, deteriorated hebephrenic praecox, often incoherent and irrelevant but more often unresponsive in speech, apathetic in conduct and behavior, and inaccessible to mental examination. This condition persisted until his death from an intercurrent infection three years after his admission. Although a complete autopsy was performed, the only significant findings obtained were those in relation to acute lobar pneumonia.

Diagnostic discussion of this patient constitutes an exceedingly difficult problem despite the final development of the mental disorder into the classical textbook picture of hebephrenic dementia praecox. Consideration, however, of the symptomatology found in competent cross-sectional study, characterized as it was by an absolute flight from personality situations into immediate realities, by the cyclical recurrence of the psychotic phenomena, and by the textbook manic characteristics of the individual symptoms, serves to confirm the original diagnosis of hypomania. Yet, at the same time, without there having occurred any change in the patient or in the character of his symptomatology, the limitations upon the personality, the absolute restriction to certain forms of self-expression, the peculiar rigidities of the behavior patterns, the stereotypes of thought, action, and affect, the fixed ritualisms of conduct and the peculiar dynamic qualities of the symptoms, discovered only by longitudinal study, suggest a diagnosis of schizophrenia. To assume that there was a mixed manic-schizophrenic psychosis or that the psychosis was manic originally and exhaustion of the personality led to a schizophrenic deterioration serves only to avoid the difficulties involved in the diagnostic problem. In all probability, the essential criterion should be the eventual outcome of the mental condition, with the possibility of an exceedingly sudden acute disorganization of the personality following years of rigidly exercised self-enforced adjustments accounting for the peculiar character of the early psychotic behavior.

SUMMARY

In brief, while this case report presents a number of interesting problems concerning psychiatric diagnosis and interpretation, the purpose in citing it has been for the illustration it affords of the difficulties entailed in the utilization of a vocabulary, originally developed to meet the needs of descriptivism, now vitiated in its applications by the development of psychodynamic trends. That the psychotic manifestation described by any chosen term or concept remains unchanged is readily admitted and the applicability of the descriptive concept as such is not to be questioned. However, there remains the fact that psychiatric emphasis is now placed not upon the descriptivistic aspects but almost entirely upon the underlying dynamic considerations, and that this

change in emphasis has not been reflected in any modification in the use of the original concept.

Accordingly, there needs to be performed a most difficult task of defining present day psychiatric concepts, determining their limitations, establishing their applications, ascertaining their dynamic connotations and assigning to them new conceptual significances in harmony with the conceptual significances which have been acquired by the phenomena to which they are applied.

One may summarize the entire problem by stating briefly that the further advancement of psychiatry rests upon the task of refining the linguistic tools essential in securing any understanding of psychiatric problems. The whole field of psychotic symptomatology as now generally classified needs to have each item analyzed as an individual problem involving both descriptivistic and dynamic aspects. In brief, by such an analysis, the application of present psychiatric terms and concepts could be brought into harmony with the advances in conceptual significances which have accrued in consequence of dynamic developments.

“Arrested” Mental Development

Milton H. Erickson, M.D.

Published in the *Medical Record*, October 20, 1937

The relationship between the mental age and the chronological age, as determined by intelligence tests, is generally presumed to be of a definite and constant character, with any agreement of, or disparity between, the two essentially permanent both in nature and degree. Hence, the conclusion is drawn that, aside from unusual happenings, a state of normal intelligence constitutes a permanent condition and that feeblemindedness is ordinarily present in a constant degree throughout life.

However, there is a clinical psychometric finding, made with some frequency among children with less than normal intelligence, which is apparently contradictory to this relationship between the chronological age and the mental age, and which is illustrative of the frequent unreliability for diagnostic or classificatory purposes of even valid psychometric findings. This finding is the peculiar condition usually termed “arrested” mental development. It may be generalized to include all intellectual spheres or it may be limited to certain aspects of intellectual growth. It is characterized by a constantly increasing disparity between the mental and the chronological ages resulting from a failure of proper increase in mental age in accord with chronological development, and it is reflected in a constantly decreasing intelligence quotient. Two factors determining the rate and extent of this decrease are the age at which the anomaly in development first appears and its extent, whether complete or partial.

To illustrate these various considerations two clinical case histories are reported, each having a psychometric intelligence test disclosed a mental age of three years, ten months, or an intelligence quotient of 61. A year later she was seen by the same psychometrist who reported an increase in mental age to four years, four months, but a decreased intelligence quotient of 58. Two years later, upon retest by the same examiner, an increase of only eight months in mental age had occurred.

Further retests were made at ages ten and eleven and on these occasions her mental age remained as found on the third test-five years exactly. Thus, apparently, her mental age had remained at a constant level for three years. More than three years elapsed before she was again tested, when an increase of ten months in her mental age was found although her intelligence quotient was now only 40. She was removed from the special grade and committed to the state home for the feebleminded.

Two years later, at the age of sixteen years, a seventh and final test was administered at which time her mental age was found to have decreased six months and her intelligence quotient to have decreased to 33.

At the present time, at the age of seventeen, she is somewhat undersized and obese but otherwise there are no definite physical abnormalities. Mentally, she is dull and apathetic, childish in her interests, and markedly inactive. She cannot read, write, spell or count, but she is able to feed and to undress herself although she requires assistance in dressing. Medically, the only diagnosis warranted is simply "imbecility".

The following table summarizes her test findings:

Results of Tests

DATE OF TEST	CHRON AGE	MENTAL AGE	I.Q.	PM*
Oct. 6, 1926	6 yrs. 4 mo.	3 yrs. 10 mo.	61	A
Nov. 7, 1927	7 yrs. 54 mo.	4 yrs. 4 mo.	58	A
Oct. 14, 1929	9 yrs. 4 mo.	5 yrs. 0 mo.	54	A
Aug. 18, 1930	10 yrs. 0 mo.	5 yrs. 0 mo.	50	R
June 20,1931	11 yrs. 0 mo.	5 yrs. 0 mo.	45	B
Jan. 29, 1935	14 yrs. 7 mo.	5 yrs.10 mo.	40	C
Apr. 23, 1937	16 yrs. 9 mo.	5 yrs. 4 mo.	33	D

* PSYCHO-METRIST

Discussion

Since only two cases are reported, direct discussion, despite the relative frequency of this type of clinical finding, must necessarily be limited. Instead, emphasis may be placed upon the clarity with which these cases illustrate two types of defective development of intelligence, and attention directed to certain general considerations of the problems of feeblemindedness and psychometry as illustrated by these clinical findings.

Of particular interest, because of the freedom from any discoverable medical complications, is the first case, since the absolute arrest of mental development at a fixed level, permitting a change in intellectual status from normal intelligence to low grade feeblemindedness, demonstrates that growth or development processes may be fully as important as original endowment in the production of mental deficiency. Whether this type of mental deficiency, because of the period of normal or nearly normal intelligence, differs, in the ultimate, from that type manifestly present from infancy constitutes a question of definite interest needing further investigation. Clinical experience indicates that the "arrested development" type of mental deficiency may be found with the greater frequency among delinquent children, a finding which suggests the increased difficulties of environmental adjustment occasioned by the constantly lowering level of possible adjustment. At all events, differential studies of this type of mental deficiency are warranted as a measure of establishing better classificatory groups among the mentally deficient. Such studies should include a history, beginning at infancy, of repeated psychometric examinations, since, as these two cases demonstrate, a single intelligence test, however valid in itself, may nevertheless be most misleading.

Another consideration of this same problem deals with the well-recognized phenomenon of "range," sometimes termed "scatter," or the failing of tests below and the passing of

tests above the actual mental age level. This occurs commonly in the psychometric examination of subjects of less than normal intelligence, particularly the feebleminded. Actually, this range frequently constitutes an evidence of "partial arrested development" and serves to demonstrate an irregularity both in the rate and the degree of mental growth for various intellectual spheres, differing from total arrest of development by being less inclusive and less complete.

Whether or not a distinction should be drawn between feeblemindedness characterized by a wide divergence in the developmental levels of individual abilities and that with little or no range may be as yet an academic question. However, the equating of psychometric findings because of identical intelligence quotients, regardless of range of the individual test scores, constitutes a most unsatisfactory measure in the classification of feeblemindedness and emphasizes the inadequacy of the psychometric test when applied to conditions other than the normal.

In addition to the cessation or arrest of mental development, there is also the phenomenon, shown in the second case, of continued mental growth but to a degree and at a rate markedly decreased from the normal. Like arrested development, this delayed or retarded mental growth is a relatively frequent clinical finding, of greatest occurrence among "problem" or delinquent children, possibly because of the difficulties entailed for the individual in the continuous shifting of possible adjustment levels. Not infrequently, delayed development may be found limited to certain individual abilities, thus causing the appearance of a significant range in the scores of the individual tests of the psychometric examination. In such instances, particularly of children of less than normal intelligence and past the age of puberty when this delayed development first becomes manifest, the time of actual maturity may be delayed beyond the accepted age of fourteen to sixteen years. Hence, there occurs a continuance of slow growth processes beyond the usual age of maturity permitting a gradual correction of the deficiencies originally causing the range in the psychometric findings. This, in turn, constitutes an improvement of intellectual status that may be sufficient to warrant reclassification in a higher intelligence group.

In children below the age of puberty, the greater period of time that must elapse before maturity can be expected, serves to increase the probability of a delayed development eventuating in an arrested development, thus augmenting the disparity between mental age and chronological age. Hence, as is shown in the two cases cited, the shift in classification is from a higher to a lower intelligence group. Such changes in classification indicate not inaccuracy of previous test results but rather the inadequacy of the entire measure as a diagnostic procedure. They suggest the need for critical study of the peculiarities of mental development illustrated by the second case, and more particularly, the absolute need of repeated and long continued psychometric studies before an adequate understanding of the individual case may be reached.

Finally, mention may be made concerning the actual frequency of occurrence of these clinical conditions. Personal experience, chiefly with orphans and delinquent children, suggests that these conditions are not at all uncommon, but that "delays" and "arrests" of

mental development are most frequent among juvenile delinquents of less than normal intelligence. In the literature mention has been made repeatedly of significant changes in the intelligence quotient after the lapse of a year or more. Usually, however, such studies have been restricted to one or two retests, and have tended to emphasize gains rather than losses, but even so, their findings suggest the desirability of studying anomalies and variations in mental growth and development by repeated psychometric examinations over a long period of years. Particularly do the case histories reported here illustrate the significant values of a long psychometric history.

Summary

Two clinical case reports, each having a psychometric history extending over six years, are cited to illustrate two types of defective development of intelligence. In the first case, illustrative of a complete arrest of mental development, the mental age, first determined at the chronological age of eleven, remained constantly at eight years, ten months with the consequent change in status from *dull normal intelligence* with an intelligence quotient of 80 at eleven years to *low grade moron* with an intelligence quotient of 55 at the age of sixteen.

In the second case, which illustrates partial arrest with retarded development eventuating in a complete cessation of mental growth, there was a change in status from *high grade moron* with an intelligence quotient of 61 at the age of six years to *imbecile* with an intelligence quotient of 33 at the age of sixteen, despite there having been a slow increase of the mental age from three years, ten months at six years to a final mental age of five years, four months.

In discussion, attention is directed to, 1, the need for long-continued psychometric studies to determine the actual clinical frequency of these types of defective development of intelligence; 2, the possible inadequacy and misleading character of valid psychometric findings as a diagnostic or classificatory measure; 3, the general significance of these clinical findings to the problems of differentiation and classification of subnormal intelligence and feeblemindedness; and 4, the possible significance of these findings to the problems of the growth and development of intelligence, particularly in relationship to the phenomenon of range or scatter.

Psychological Factors Involved in the Placement of the Mental Patient on Visit and Family Care

Milton H. Erickson, M.D.

Published in *Mental Hygiene*, Vol. XXI, No. 3, July, 1937, pp. 425-435

One of the primary considerations in the return of the mental patient to normal social life is the proper psychological preparation of the patient himself, of his relatives, and of the community. The failure to provide such preparation accounts in many instances for the short duration and the futility of the visit, the failure of the patient to adjust in the home or in the community, the development in him of increased or of new psychotic difficulties, and the eventual discouragement, through misunderstanding or lack of understanding, of all those concerned in his restoration to normal social life.

The successful extramural placement of a patient, either in the original home or in a foster home, is not the simple procedure of selecting a suitable patient and arranging for his discharge on visit. In addition to dismissing the patient from immediate institutional care, there is the equally, if not the more, important objective of continuing him on visit, of enabling him to adjust himself in the community, and of teaching the community to accept him. A hostile or even an indifferent neighborhood militates against the patient almost as much as do his own difficulties. Accordingly, an absolute prerequisite to the successful placement of the patient on visit consists of a certain preliminary education of the community, leading to the development of social attitudes favorable to the patient, to his difficulties, and to the hospital itself.

For purposes of discussion, the problem of the preparation of the patient and of his relatives for his return to the community may be divided into two approaches. The first of these, which may be termed the *indirect approach*, consists of the development of a socially constructive relationship between the hospital and the community. The second, which may be called the *direct approach*, concerns the relationships of the hospital and its staff with the patient and his relatives as individuals.

For an adequate discussion of the first method of approach, it will be necessary to consider the hospital, its administration, and its possibilities of so functioning that it may influence the development of a favorable attitude on the part of the community toward the return of the mental patient. It is well recognized that the mental hospital reflects to a large degree the levels, the standards, and the attitudes of the community it serves. But since the hospital is an organized unit of the community, it bears a definite burden of responsibility in the formulation of public attitudes concerning mental disease. Too often the mental hospital serves merely as a custodial institution, to which the patient is brought and in which he is kept while his relatives merely visit him, little or no effort being made to acquaint the public with the aims, the purposes, and the potentialities of the institution. Instead, the lack of hope and the feeling of helplessness engendered in the

family by the development of mental disease continue in the attitudes taken toward the hospital, and only the more aggressive of the public ever make the effort necessary to secure an adequate understanding of the entire situation.

At a limited number of state hospitals, in recognition of the need for a concerted effort to educate the public toward the development of a more intelligent understanding of mental disease, and toward increasing the possibilities of placing the patient on visit, a definite effort has been made to draw the public into cooperation with the hospital by informing them of the nature of the institution, its purposes, its goals, and its needs.

The measures used have been various in character. One of the more successful, that which is being employed extensively by the Worcester State Hospital, with which the writer was formerly affiliated, revolves chiefly around a systematic correspondence with the relatives and the friends of the patient. When this measure was initiated, its value was not fully appreciated; but with the passage of time, results have been secured that more than warrant the relatively small amount of effort required. The first of these correspondence measures is the immediate sending of a general informative letter, worded and typed as a personal communication, to the relatives of the newly admitted patient. This letter anticipates many of their questions, informs them officially of the actual situation, makes a formal appointment for them to visit at the hospital and to interview the physician and the social-service worker, and gives them an opportunity to develop a favorable attitude toward the hospital by virtue of the special interest signified by the letter. Innumerable relatives have expressed a feeling of gratitude for this measure of acquainting them with the hospital and enabling them to realize the definite interest taken in the welfare of the patient. Furthermore, this letter serves to impress upon them the fact that their cooperation with and understanding of the hospital are essential. Judged by the remarks of many relatives and friends, this letter has been of material aid in correcting their misapprehensions of mental hospitals as purely custodial institutions.

A development of this systematic correspondence has been the writing of letters periodically to acquaint relatives with the actual condition of the patient, either favorable or unfavorable, to urge the relatives to make visits, and to recommend various measures on their part which would be conducive to the welfare of the patient and to his readjustment in the home. Relatives, friends, and neighbors of the patient have all expressed repeatedly to the writer and to his colleagues their appreciation of these letters, thereby indicating that there has been an effective growth of public confidence in the hospital and of that favorable attitude on the part of the community which is essential to the successful restoration of the patient to normal social life.

Another measure employed by a number of state hospitals with which the writer is acquainted is the yearly examination of each patient in the hospital for the express purpose of determining his suitability for a home visit or for placement in family care. After this examination, a letter is sent to the relatives of each patient who is found to be sufficiently improved to warrant a trial visit at home, informing them of this fact and making a definite appointment for a conference with the psychiatrist to arrange for such a visit.

Also, the relatives and friends of patients who have neglected to visit at the hospital receive letters tactfully insisting upon such visits and making formal appointments as a measure of compulsion, thereby doing away with the idea that the hospital is a custodial institution whose inmates may be permanently forgotten. Even the neighbors of negligent relatives have expressed their appreciation to the writer and to his colleagues for such letters sent to these relatives to compel them to take an active interest in the patient's welfare. On the research service of the Worcester State Hospital a letter-writing routine was established by which the relatives of every patient were periodically counseled and educated as to how they might be of service to the patient, to themselves, and to the purposes of the hospital. With the help of these letters, systematic appointments were made, interviews were conducted, and adequate arrangements were completed for the extramural placement of patients. Through utilization of this correspondence measure, more than one patient who had not had a visitor for years had the interest of his relatives reawakened, with subsequent placement on visit.

Another comparatively recent measure, which is being adopted increasingly by various hospitals, is the printing of an institutional newspaper. This type of publication has been found, in actual practice, to serve the purposes of acquainting the relatives and the general public adequately with the growth and progress of the hospital and with the establishment of improved services, and of giving them a thorough understanding of their own role in the therapy of the patient and in his placement on visit. A frequent experience at these hospitals is the request of friends, relatives, and neighbors of patients' families to be placed on the mailing list of the publication. The hospital newspaper has proved to be a most effective measure in the development of a cooperative spirit with regard to the institutional care and to the extramural placement of the patient, much as the various trade journals serve to promote good will for commercial firms. Furthermore, it is a most effective measure in disseminating educational material, and in correcting the misapprehensions of the public in general regarding the nature and functions of a mental hospital.

Still another method by which a mental hospital can establish a favorable community attitude toward itself and toward its problems is the practice of encouraging the public to visit the hospital and of conducting clinics for the express purpose of giving lay groups a better understanding of mental disease. At Eloise Hospital, with which the writer is now affiliated, this practice of conducting clinics has been particularly developed. The number of clinics held at Eloise for lay groups and organizations averages more than one a week. In addition, a considerable number of public lectures are given by various members of the staff. On these occasions every effort is made to give the public an adequate understanding of what may be accomplished for the welfare of the mental patient, of the problems to be solved, and of the social implications of mental disease. Thus, a foundation is laid for the development of social attitudes favorable to the readjustment of the patient in the community, as well as a better comprehension of the needs and problems of the hospital itself.

To summarize, the *indirect approach* of the hospital to the problem of discharging the patient on visit consists of the development of a proper social attitude in the community toward this problem by various educational measures. These measures are aimed at the promotion of good will toward and of confidence in the hospital, the instruction of friends and relatives of the patient and of the general public concerning the actual nature and purposes of the hospital, the correction of the general misapprehensions concerning mental disease and mental hospitals, and the development of an individual and a community sense of responsibility for the mental patient.

Concerning the second approach, the *direct approach*, to the relatives and to the patient as individuals, one of the first considerations is the actual administration of the hospital in relation to the patient. In the vast majority of hospitals, under the present type of organization, provision is made formally for only two types of patients-the newly admitted and the chronic institutional type. A few hospitals recognize a third category of patients, the convalescent. But usually so weak is this recognition that it fails to permit the effective differentiation achieved for the newly admitted and for the chronic patient. To clarify this point, just as the hospital needs an admission service and a chronic service, so does it need a convalescent service which would be convalescent in actual practice rather than in name only. Likewise, the convalescent service should be provided with a special staff similar to that which is usually provided for the admission service.

An actual convalescent service, with its own special staff, would constitute a significant force in securing a more rapid and a more successful selection of patients for discharge on visit, as has been the experience at those hospitals that have met this need. At present, in too many hospitals, the question of discharge on visit or of extramural placement of the patient is left to the accident of request by relatives or by the patient himself, or to the chance observations of the physician, already burdened with routine duties, in charge of the general wards, or even to the sheer necessity of making room for new patients. Yet every hospital has a sufficient number of convalescent patients to populate fully more than one ward. A physician whose only duties are the care and supervision of such wards can handle this major problem of discharging mental patients in a decidedly more effective manner than is accomplished by the unsystematic procedures now generally in use. The institution of such a measure would serve to centralize and to organize the problem of discharging the patient either on visit or in family care, and to establish within the hospital a definite responsibility for this important function.

In place of a convalescent service, some hospitals have employed various measures of grading or classifying patients. An example is the grading system reported by Erickson and Hoskins.[1] However, such measures are usually only unsatisfactory substitutes for a convalescent service, since the latter functions more effectively in two particular regards. One of these is the psychological effect of such wards, not only upon the patient himself and upon his relatives by virtue of the official recognition of an improvement in his condition, but also upon the hospital staff through the stimulation afforded through realization of specific accomplishment in therapy. The significance of this effect upon the staff in relation to the promotion of psychotherapy cannot be overemphasized. Equally important is the second advantage of a convalescent service provided with a special staff-

that it permits the development of organized, continued, and effective psychotherapeutic measures, as well as the adequate preparation of the patient and of his relatives for his return to the community.

Concerning the actual work with the patient and with his family relevant to their psychological preparation for the return of the patient to his home or for his placement in family care, the measures may be divided into two categories. The first is the systematic interviewing of relatives at regular intervals throughout the entire hospital stay of the patient who has a favorable prognosis, or, more practically, throughout the patient's stay on the convalescent ward. The second is the systematic graduation of the duration of the patient's home visits. The practicability of the first procedure may be questioned; but those hospitals which have instituted a definite convalescent service permitting such intensive work have found the difficulties to be more apparent than real. According to the writer's personal experience, only the first few interviews prove to be difficult and time-consuming. Under proper administration, the services of one physician are fully adequate for a minimum of one hundred patients.

The benefits to be derived from this procedure lie in the opportunities that it presents for the education of the public, for the development of good will and understanding, for the securing of more adequate information permitting better psychotherapy, and for the effecting of gradual changes in the immediate home situation to which the patient must return. All of these advantages serve significantly to increase the number of discharged patients, and, of even greater importance, to prolong the period of normal social adjustment for the individual patient.

Placement on visit should not terminate the series of interviews by the psychiatrist with the patient and with his relatives. Rather, they should be continued at periodic intervals determined by the peculiarities of each case. According to the writer's experience and that of his colleagues, the most effective procedure was found to be interviewing first the relatives, then the patient alone, and finally relatives and patient together. Thus, the general supervision of the patient can be directed, immediate problems evaluated and adjusted, and impending difficulties anticipated. The sense of security thereby engendered both in the patient and in his relatives serves materially to further a normal adjustment of the patient and to meet problems that could not be handled otherwise except by the readmission of the patient to the hospital.

The second type of procedure, the systematic graduation of the lengths of the patient's visits at home, is developed in the following manner: The patient who has convalesced sufficiently to warrant being placed on visit is allowed first to go for a drive or a walk with relatives. Perhaps the next week he is allowed to go home for a day. Next, he is allowed to go home for two or three days, and gradually, depending upon the patient's adjustment to the home situation, the visit is increased from a few days to a week or two weeks or even to a month. Upon each return from a limited visit, extensive interviews are conducted, problems of adjustment are faced, and every effort is made to give both the patient and his relatives insight into their particular situations. Finally, the patient is

dismissed on an "indefinite visit," with instructions to return at stated intervals to report his progress and adjustment according to the previously discussed system of interviews. By virtue of this cautious, systematic graduation of the length of visits, with opportunities to discuss adjustment problems as they arise, and to exercise a direct and continuous supervision over the general home situation and the care of the patient, it becomes possible to send out on visit the patient who had previously been unable to adjust at home, and, by obtaining the confidence and the full cooperation both of the patient and of his relatives, to teach him how to make a good social adjustment. This type of procedure implies a constant, systematic supervision of the patient's daily routine life that can be achieved best on a convalescent ward. Furthermore, such close supervision and intimate contact can serve to exert only favorable influences upon the condition of the patient, which should be the constant aim and purpose of the hospital regardless of the work entailed thereby.

In regard to patients placed in foster homes, an extensive discussion of which has been given by Thompson,[2] the procedure must be slightly different, but the same general psychological principles apply. In the selection of a family-care home, the personalities of the members of the foster family are evaluated in essentially the same fashion as is done in the case of the relatives of patients. A similar evaluation is made of the personalities of the patients already placed in the home. Finally, the type of home is selected with regard for the patient's general cultural level. A detailed discussion of the entire problem of the selection of the family-care home may be found in Crockett's report.[3] Since placement in a foster home renders impractical repeated visits at the hospital for interviews with the psychiatrist, these patients are visited regularly by a social worker, and with equal regularity, but less frequency, by the psychiatrist. In the writer's personal experience, essentially the same procedure in interviewing was followed as with patients visiting at the hospital, with essentially the same results.

Another approach to the successful extramural placement of the mental patient, and one that may supplement, or perhaps to a certain extent be substituted for, the convalescent service, is the establishment of an out-patient clinic-or, more strictly speaking, a parole clinic-as a unit apart from, but integrated with, the hospital itself. Psychologically, the important factor in the separation of the clinic and the hospital into distinct units is the fact that such a separation has the same personal significance for the patient on visit as the convalescent ward has for the institutional patient; it is a form of official recognition that hospital care itself is no longer necessary. Thus the patient is given a feeling of hope, and is thereby stimulated to utilize the facilities of the clinic to the fullest possible extent as a measure of avoiding a readmission to the hospital, which, to his mind, represents a serious personal mishap. The prevalence of this emotional and forceful attitude on the part of the patient will be readily appreciated by any one who has had experience in such clinics.

In actual practice, the patient and his relatives report at the clinic at definite intervals for systematic interviewing and counseling. The realization that this is the official function of the clinic serves to impress upon the patient and upon his relatives the values to be derived from full cooperation. Furthermore, the patient feels more free to seek advice and

counsel on matters for which he would hesitate to disrupt a hospital routine because of their apparently trivial nature. Also, there is not attached to the clinic the same mistaken social stigma that attaches to a mental hospital, a fact that permits a more ready seeking of assistance at the clinic. Already, for example, at the newly established Eloise Hospital Parole Clinic, patients are beginning to express freely their feeling of gratification for the opportunity of receiving further aid from the clinic rather than from the hospital itself, emphasizing this feeling by voicing their sense of personal improvement and achievement in the remark, "I don't have to be a ward patient any more. I'm well enough to go to the clinic now."

Another quotation from patients and relatives may be given to summarize the psychological value of a parole clinic in regard to its specific function in post-institutional care: "Now you can go to the clinic before anything bad happens and get straightened out, instead of trying to get along somehow or other until you have to be sent to the hospital."

In brief, the *direct approach* of the hospital to the problem of discharging the patient on visit depends upon adequate personal attention, given by means of systematic interviews, to the specific problems presented by the individual patient and by his relatives, preferably through the functioning of an adequately organized convalescent service; upon attention given to the community from which the patient comes or to which he goes; upon systematic graduation of the lengths of the trial visits until assurance is obtained that the patient can continue to adjust on visit; and upon the establishment of some system of organized post-institutional care for the continuance of supervision and psychotherapy, preferably by means of a parole clinic.

To summarize the psychological factors involved in the successful extramural placement of the mental patient, they include the establishment of the hospital in an educative role for the instruction of the general public, and of the patient's friends, relatives, and neighbors, concerning the problems of mental disease, and the organization of an effective system for the psychological preparation of the patient for placement on visit, with adequate provision made for post-institutional care to insure the maximum duration and degree of success of the visit by facilitating the patient's adjustment to his situation and to the community and that of the community to him.

Opportunities for Psychological Research in Mental Hospitals

Milton H. Erickson, M.D.

Based on chairman's address before the American Psychological Association round table discussion on Research in Mental Hospitals at Ann Arbor September 4, 1935.

Within recent years there has occurred in clinical psychiatry a significant change of decided interest to psychologists and to the science of psychology as a whole. This change has been the development of an ever increasing appreciation of the psychological aspects of mental disease with a consequent broadening of psychiatric concepts to include not only somatic and neural pathology, but also disturbances both in psychological functioning and in the interrelationships between psychic and somatic states. The recognition of the psychological aspects of mental disease has been expressed in three trends, developing independently but mutually interactive in modern clinical psychiatry.

Trends in Psychiatry

The first of these trends to be mentioned is the recognition of the functional unity of the individual, originating from Adolph Meyer's formulation of the concepts of psychobiological totality. The development of these concepts shifted attention from isolated clinical aspects and functions of the individual and directed scientific thought to a consideration of the effects and interrelationships of all the various factors and forces, whether external or internal, physical or mental, social or individual, having an influence direct or indirect upon the personality. Thus, the investigation of psychiatric problems ceased to be simply a matter of clinical or laboratory study of somatic or neural pathology, or a study of isolated dysfunctions of various physiological processes. Instead, psychiatric problems were found also to have an origin in the innumerable interrelationships existing between the psyche and the soma as such, between the individual and the external world and especially between the many varying and conflicting aspects of the personality. With this new direction of thought and the acceptance of these new considerations in mental disease, many of which were predominately psychological in character, the utilization of psychological techniques and methodologies became imperative in psychiatric research.

The second trend equally important and serving to confirm various aspects of the psychobiological formulations was the development of Freud's psychodynamic concepts. These formulations served to stimulate an intense and fruitful interest in the mechanisms and manifestations of psychological processes and to direct attention to the value of intensive longitudinal studies of the entire psychic life of the individual. Thus again interest was directed to the individual as a functioning unit possessed of a meaningful

past, present, and future, rather than to questions of definite and immediate physical or mental pathology. Since this new development in psychiatry dealt primarily with the psychic life of the patient, the approach to the understanding of the many phenomena necessarily became psychological in character.

The third trend, in part independent and in part a consequence of the development of the psychobiological and psychodynamic concepts, has been the gradual recognition of the values of normal psychology in psychiatry. The changes in psychiatric thinking during recent years, the casting aside of outworn concepts and theories, and the present broadening of the concepts of mental disease have given rise to a necessity for precise definition and delimitation of the normal patterns of behavior and for their equally careful differentiation from abnormal types. The studies of Freud and Meyer in particular have caused a constantly increasing interest in behavior reactions, personality types, mental states, emotional attitudes, environmental forces, and functional unity, with the consequence that an understanding of the principles, theories, concepts, methods, and applications of normal psychology has become essential in psychiatry.

The development of these trends in psychiatry has been reflected in the changing character of psychiatric research. Formerly limited almost entirely to descriptive, clinical and laboratory studies, psychiatric research now engrosses the interest of the anthropologist, the sociologist, the biometrician, the physiologist, and the psychologist, as legitimately as it does that of the psychiatrist. Further, it is to be noted that these new fields of psychiatric interest tend to be predominately psychological in character. Even in those fields once considered entirely apart from psychology, such as physiology or endocrinology, the present tendency is to place an increasing emphasis upon their psychological aspects and implications. Perhaps the best evidence of the growth of psychological trends in modern psychiatric research may be found in the report by Whitehorn and Zilboorg (1). They reviewed and classified according to content all papers published during the decade from 1921 to 1930 in the *American Journal of Psychiatry, the Archives of Neurology and Psychiatry*, and the *Journal of Nervous and Mental Disease*. They found that during the first half of the decade, a total of 817 pages on psychological studies had been published in contrast to 1622 pages on clinical studies. For the five years from 1926-1930, however, they found that the total of pages on psychological studies had increased to 1923, while those on clinical studies had decreased to 1492. The authors comment further that there has been in addition “a definite and ever growing tendency toward a more intensive study of the individual and a somewhat decreasing regard for purely diagnostic problems.” Consideration of the more recent literature confirms this impression. The significance of this growing proportion of psychological studies in psychiatric research is apparent. Not only is the value of psychology recognized but there is a tendency to give it preference over purely clinical work.

Likewise contributing to the possibilities of psychological research in psychiatry has been the gradual shifting of emphasis by psychologists from the purely academic phases of their science to the more clinical and social aspects. Memory, recall, recognition, learning, thinking, reasoning, forgetting, inhibition, sensation, perception, attention—all

once academic considerations—are now acquiring a new significance in relation to social behavior as a whole and to the functioning of the individual as a social unit. This change has been reflected by the growth of emphasis in the psychological literature on personality studies and clinicopsychological investigations and the increasing number of experimental laboratory studies on behavior patterns and personality types.

Progress in Psychiatric Research

Accordingly, the problem now before psychologists as a whole as well as psychiatrists is the important task of utilizing psychology most advantageously in furthering psychological and psychiatric knowledge. Hitherto progress has been made almost entirely by virtue of individual initiative rather than as a result of an organized body of opinion. Nevertheless, as indicated above, that progress has been sufficiently great to alter materially the character of psychiatric research, and in addition, it has served a noteworthy purpose in directing the attention of psychologists to the fruitfulness of research in clinical psychology in contrast to research on purely academic and routine problems.

Since the individual interest and initiative already exist, the immediate task is the development of an organized body of opinion essential for the full sanction and promotion of such individual research. The means by which this may be achieved is relatively simple and easy if the experience of a few centers of psychiatric research may be taken as a criterion. The measure to be employed is simply an establishment of a bona fide affiliation between departments of psychology and available mental hospitals. By bona fide affiliation is meant something more than the usual arrangement which provides for one or two theatrical demonstrations of psychotic types to students. Rather the affiliation should be such that it serves the two significant purposes of giving *direct instruction* and of promoting actual investigative work.

Considering the first of the purposes, that of instruction, there should be developed an arrangement whereby such courses as abnormal psychology, clinical psychology, psychopathology, psychology of personality disturbances, and similar related courses based fundamentally upon clinical material could be taught, at least in part by hospital staff members acting in the capacity of special instructors and lecturers for the particular college. As it is under the present system, these subjects are all too often taught in a classroom with a minimum of clinical material and usually by teachers having at best little more than an academic background. As a consequence, the average psychologist is painfully naive and inadequate and requires special orientation when confronted with actual clinical material concerning which he has been adequately trained academically. Not only would such an arrangement, whether complete or partial, be of value to the student, to the college and to psychology as well as psychiatry, but the hospital and its staff members would also reap material benefits through the raising of professional standards and the promotion of stimulating work and contacts.

In regard to the promotion of actual investigative work, a number of mental hospitals have demonstrated the worth and feasibility of such a venture. One such institution with

which the author is well acquainted, namely, the Worcester State Hospital, has been able to develop a number of significant research projects by virtue of its practice of inviting to the hospital advanced psychology students and research workers in special fields. There, under the auspices of the hospital and in the capacity of "special," "guest," or "volunteer" workers, they engage in research of interest to themselves but pertinent to psychiatry, using the hospital and its facilities as a laboratory and receiving from their particular university scholastic credit if needed for their work.

The results of this practice in the few hospitals where it has been tried warrant its extension. In each instance both the hospital and the particular college concerned have benefited—the hospital by virtue of the credit received in publication, and the stimulation afforded by the development of research work, and the college by having gained entree to a most fertile laboratory, by the production of significant work and by the increased training of its students. Those who have had a part in such affiliations feel strongly that both mental hospitals and psychology departments are losing valuable opportunities if they fail to make affiliations whereby capable students can develop investigative work on a credit basis. Further, such credit recognition secures the official sanction necessary for the development of an organized body of opinion essential to the promotion and development of psychological research in mental hospitals.

Psychological Techniques

The next consideration arising from the question of psychological research in mental hospitals is the problem of the proper evaluation and adaptation of psychological techniques and the determination of the more suitable types of problems for such specialized study. The changes in psychological and psychiatric thought, the broadening of existing concepts and the formulation of new theories have caused both sciences to place a new emphasis upon the individual as a functioning social unit. In consequence of this emphasis, the scope of investigative work has become more inclusive, and research work has been modified to include at once both psychic and somatic data, with perhaps some isolated aspects of the personality, or selected physiological functions, or some special physical state constituting the point of departure in the analysis of the problems involved. In addition to data of a personal nature, that of an impersonal character is fully as essential in the determination of the factors at work in the individual.

Accordingly, a large part of the investigative work essential to the elucidation and development of many of the modern clinical theories and formulations becomes a question of the analysis of interrelationships between the many types of data derived from environmental, anamnestic, somatic, clinical and psychological studies. Here it is that the psychologist can serve, either independently or in collaboration, in the analysis of the relationships between physical data and psychological data, most particularly in the analysis of the intercorrelations of mental and emotional states and attitudes, psychic experiences, behavior patterns, personality types, and mental activities and processes with physical states and activities, somatic conditions, physiological functions and endocrinological states and processes, and in turn, both jointly and separately, all of the foregoing types of data with the various factors, forces, and influences of special and

general environments. For this type of work the psychologist is adequately qualified and it constitutes an exceedingly fertile field for investigation.

Concepts

Another problem to which the psychologist can contribute significantly is that of the definition of concepts. There is probably no other field of scientific endeavor in which terms and concepts are so ill-defined and so crudely, loosely, and inaccurately used as in psychiatry. Even the official classification of mental disease types is arbitrary and is recognized everywhere as unsatisfactory. In all probability this unfortunate situation arises from the fact that there has never been a systematic approach to the task of defining and delimiting the fundamental concepts upon which classification systems must be based. For example, "depression" is a phenomenon which may occur in paresis, manic-depressive psychoses, schizophrenia, psychoneuroses, and psychoses with brain tumor. In each instance, the term is used as an adequate description of the state manifested despite the fact that to the clinician the "depression" of a schizophrenic patient and that of the psychoneurotic are totally different phenomena, possessing only a superficial resemblance.

Likewise is the case in regard to the "flight of ideas" which may be manifested by a manic patient or a catatonic, the "retardation" shown by depressive patients and those with neurological disease, and the emotional intensity and egocentricity shown by the paranoid patient or the patient suffering from an epileptic psychosis. In each instance these phenomena are described in the same general terms, although clinically they have a different significance, origin, and effect. In brief, the same general terms are used throughout psychiatry to describe innumerable conditions and symptoms which bear only superficial resemblances.

A parallel of this may be found in the history of general medicine. At one time, "fever" was a well-recognized medical concept and patients were treated for that condition. No significant progress was made, however, until the general concept of "fever" had been cast aside and a differential analysis bad been made of febrile states. Likewise it is fair to assume that no great progress can be made in psychiatry until the existing usage of terms has been corrected by the careful analysis and differentiation of concepts. To describe a patient as excited or depressed or over-active or retarded means as little as it does to say that a patient is sick or febrile or suffering, and such descriptions will continue to be meaningless until a careful differential analysis has been made of the state such terms supposedly describe.

This task of defining, clarifying and determining the application of the general concepts of psychiatry constitutes a problem well within the realm of psychological analysis and it is a labor essential to much further progress in psychiatry.

Closely related to the task of defining concepts and actually constituting an integral part of it is the problem of evaluating objectively and classifying properly psychiatric symptomatology. To study the general type, frequency of occurrence, and the general

interrelationships of various symptoms means little unless the individual symptoms themselves have been quantitatively and qualitatively analyzed and classified. Thus. the proper study of delusions as such would require as thorough a differential analysis as would the study of anemias. It would require taking into consideration not only the general type, number, content and fixity, but also the individual character, origin, purpose, means of expression, effect on conduct, duration, intensity, degree of coordination with the rest of the psychic life as well as many other features for each delusion concerned in the study. In the whole field of objective evaluation of symptoms little work has been done. One excellent example of the psychological approach to this problem of objectively evaluating psychotic symptoms is to be found in Angyal's study of somatic delusions in which he demonstrates clearly the value of the psychological approach (2). More such work needs to be done in the entire field of symptomatology.

Correlation of Psychological and Psychiatric Concepts

Still another opportunity for the psychologist lies in the correlation of known psychological laws and concepts with psychiatric concepts. Essentially this is the application of normal psychology to psychiatry in a direct and systematic fashion, a medical parallel of which may be found in the application of the principles of normal histology to pathology. Just as the knowledge of histology constitutes the essential foundation for an understanding of pathology, so may the correlation of known psychological principles with psychiatric hypotheses constitute the means of determining fundamental differentiations, and of establishing the laws and conditions governing the development of abnormal states. To illustrate, the laws and conditions of normal learning have been established to a considerable extent. The application of this knowledge to the learning processes involved in the development of a psychoneurosis might conceivably yield valuable information. In a similar manner, the existing knowledge of the conditioned response could be applied profitably to the investigation of psychiatric problems as is indicated by work already under way in one psychology department affiliated with a mental hospital. Further, a great part of the laboratory and experimental work that has been done satisfactorily on the normal subject needs to be repeated on the abnormal subject and such repetition would serve to advance not only the knowledge of the abnormal but also the knowledge of the normal. To illustrate, the marked accentuation of personality characteristics in mental patients should render easier the task of analyzing the factors determining personality types than would be the case in normal subjects. In brief, all work done on normal subjects needs to be repeated on abnormal subjects because of the advantages offered by the increased or decreased presence of various characteristics permitting thereby a differential analysis of the factors influencing or determining the particular phenomenon under study.

Conclusions

In conclusion, to discuss all of the opportunities for psychological research in mental hospitals is not possible within the limits of this paper nor is it necessary. A few that have been mentioned indicate the wealth of possibilities in this field for psychologists. The situation may be summarized briefly with the statement that psychologists and

psychology as a whole can offer material assistance in the solution of every psychiatric problem.

Summary

The trends in modern clinical psychiatry are becoming increasingly psychological in character. The development of psychobiological formulation of Meyer and the psychodynamic concepts of Freud has been accompanied by a gradual growth in the recognition of the values of normal psychology in psychiatry. Present trends in psychiatric research show an increasing preference for psychological studies, while psychological research is marked by a growing interest in the more clinical aspects of psychology. These factors favor greatly the development of psychological research in mental hospitals. A measure contributing greatly to such research would be the establishment of affiliations between mental hospitals and psychology departments which would be conducive to active instruction and original investigative work. The utilization of "guest" or "volunteer" research workers would also aid greatly. A few particular problems discussed offering definite opportunities for psychological research were: 1, the analysis of the intercorrelations of environmental, anamnestic, somatic, clinical, and psychological data, 2, the definition of psychiatric concepts: 3, the objective evaluation and classification of symptoms: and 4, the correlation of known psychological laws and concepts with psychiatric concepts.

The Concomitance of Organic and Psychologic Changes during Marked Improvement in Schizophrenia: A Case Analysis

Milton H. Erickson

Published in *American Journal of Psychiatry*, Vol. XIII, No. 6, May 1934

This paper embodies a study of concomitant psychic and organic findings in a case of schizophrenia, catatonic reaction type, which progressed from a condition of profound stupor to a state of apparent social recovery. The material is presented to portray the relationships, whether causal, resultant, or merely coincidental, existing between physical and mental states. The case studied is peculiarly fitted for such a portrayal inasmuch as there occurred in the clinical course of his illness three definite psychiatric pictures with each of which was obtained a cross-sectional psychological study extending over a period of a month. This case is the only clear-cut instance of the sort among a total of 63 schizophrenic patients studied by the Research Service, where extensive concomitant studies have been made during the actual periods of clinical change. The method of study was that of the Seven Months' Study Plan.[1] This comprised a social service history, determination of the initial mental and physical states, the clinical course with detailed longitudinal psychiatric study, and periodic physiological cross-sectional studies. The purpose of this method was the study of fluctuations, changes, and constancies, both physical and mental, with regard to temporal relationships-particularly those of concomitance—as a means of determining ultimate sequences. From such an investigation as this, in conjunction with other similar studies, it may be possible to secure the information that will lead to the progressive differentiation of sub-entities in schizophrenia.

The history and the findings on this patient are given below.

The patient, G. F., No. 175, is an unmarried white male of Irish descent, now 24 years of age, who was admitted to the Boston Psychopathic Hospital on May 31, 1931, and discharged to the Worcester State Hospital five days later. The physician's certificate on admission described him as mute, resistive, and depressed.

The *family history*, which is inadequate, reveals a relatively high incidence of cardiovascular disease on both sides of the family. The paternal grandparents died of "shock " and the maternal grandparents died of "heart trouble." The patient's father, aged 65, suffers from nephritis and arteriosclerosis, and is in the Worcester State Hospital with an organic psychosis. The mother, aged 57, complains of "high blood pressure." The patient is the fourth of five children. An older brother died of "bleeding from the lungs" in 1927 and an older sister died of "stomach trouble " in 1928.

The *home situation* has always been on a marginal economic level. The parents complained interminably and indulged in frequent derogatory comparisons of the home situation with that of the original home in Ireland, which they left when the patient was three years old. After the age of 12 the patient had little happy contact with any members of the family except his youngest brother. Incessant quarreling, bickering, and general dissatisfaction constituted the home atmosphere.

The *personal history* of the patient is deficient in many regards. His birth, considered normal in character, occurred February 13, 1908 Childhood development is reported to have been normal until the age of eight or nine, when a period of obstinacy and incorrigibility was noted. This behavior difficulty was associated at least chronologically with " growing pains " in the legs, causing some acute suffering. At about the age of 14 *pavor nocturnus* occurred, characterized by terrifying dreams of being taken away to some unknown place. At about the same time there occurred a period of rapid growth. His educational achievement was "average" until he failed in the first year of high school at the age of 15, when he withdrew to attend night school. There his performance lagged far behind his expressed ambitions.

His *industrial history* indicates good ambition and drive, but poor powers of work adjustment and a tendency to become easily dissatisfied with the work and his fellow-workmen.

The *medical history* reveals attacks of measles and of pertussis at about the age of four or five years, "growing pains" at eight or nine years, and a broken nose from a blow with a baseball bat at the age of 12 or 13. This was followed later by breathing difficulty, supra-orbital headaches, and a nasal discharge. The breathing difficulty and the nasal discharge were relieved by an operation in 1929, but the headaches have continued. At the age of 14 rapid growth occurred, accompanied by a tendency to become easily fatigued and a marked appetite for sweets.

The *psychosexual history* is scanty. The only information obtained concerned a brief caution about " self-abuse" some years ago and limited contact with the opposite sex because of his feeling that he was too handicapped financially for any social activities.

The *present illness* is believed to have become evident first in a change of personality occurring at the age of 12 years. Previously the patient was even-tempered, friendly, active, extraversive, and likeable. He was looked upon as a normal, happy boy. After the age of 12 he became seclusive, fearful of competition, cheated at games, was selfish, obstinate, surly, unfriendly, unhappy, and profoundly dissatisfied with his total situation. At the age of 16 increased irritability was observed and he seemed to have ever-increasing difficulty in adjusting with everybody. He became more and more dissatisfied with his home situation, his ancestry, and the social status of the family, and was imperious and demanding in his attitudes and complaining in behavior. His vanity and conceit became overweening and he expressed inordinate ambitions about becoming a wealthy landowner, a millionaire, a singer, an artist, and a "crooner." Most of his energies were absorbed by these rather grandiose ideas. At the age of 20, in 1928, he

became depressed and discouraged, apparently because of the family's temporary dependence upon charity. In January, 1931, the patient complained greatly of fatigue and headaches, and again became much depressed and discouraged, and " nervous and irritable." He quit work in May because of this condition. On May 17 he was noted as quiet, inactive, and unresponsive. He suddenly declared, "I'm not going to die. I'll live this time." He complained of a strange, overpowering feeling of weakness and sickness. He was taken to the Cambridge Relief Hospital, where he is said to have been accused of masturbation. Following this his speech became halting in character and he stood about rigidly, seemed confused, and finally appeared to lose the ability to speak. He was sent to the Boston Psychopathic Hospital on May 31, 1931. There he explained, "I've been a fool in everything. I thought I was dead. I've done too much for anyone to help me." Mental examination otherwise revealed a mute, apparently depressed, agitated, and pre-occupied patient. On June 4, 1931, he was transferred in an essentially unchanged condition to the Worcester State Hospital with a suggested diagnosis of dementia praecox.

Physical examination upon entrance revealed some dehydration, motor retardation, and resistiveness, but otherwise there was no definite evidence of physical disease observed or disclosed by the laboratory procedures.

Mental examination shortly after admission revealed him to be practically mute. He told very briefly of hearing voices say unpleasant things and he was found to be disoriented, but otherwise he was inaccessible. He was seclusive in behavior and his appearance suggested mental retardation and depression. A *psychometric examination* was attempted on July 16, 1931. He was mute, dazed, stuporous, and uncooperative, and his performance was unsatisfactory. On the Kent-Shakow Formboards a questionable mental age of five years, four months was obtained, but otherwise results were negligible. Except for an increase in his stuporous state, no marked change in his condition occurred to the date of his admission to the Research Service July 23, 1931

The *mental examination* made at this time was summarized as follows: "He was untidy, incontinent, and accustomed to stand about mutely for long periods of time in a rigid posture. He required feeding, dressing, and similar care. He was resistive to attempts to move him, and made little or no response to pin pricks or other stimuli. When asked to shake hands he responded by slight pressure with his fingers. He passively permitted movements of his limbs. The muscles of his neck and upper extremities were relaxed while those of the legs were somewhat rigid. His hands were cold and cyanotic. No *cerea flexibilitas* was noted. His facial expression was blank and his eyes were staring in expression. He executed simple commands slowly, showing both initial and executive retardation. No evidence of emotional response was noted or elicited, nor was any interest manifested in his surroundings."

At a diagnostic staff meeting on July 24, 1931 the patient was diagnosed as suffering from *schizophrenia, catatonic reaction type*, and given a *prognosis of social recovery*; *i.e*., sufficient recovery to warrant return to the community.

Until August 16 the patient continued essentially as described on July 24. In addition, salivary retention was noted and there was also a slight increase in weight. On August 16, 1931 the first study period of the Seven Months' Plan was begun. No essential change was noted in his mental state during this entire period. He was passively submissive to the tests, mute, untidy, passively seclusive, inactive, and incontinent. He seemed out of contact with his surroundings and was unresponsive to stimuli. He was given a *psychometric examination* on August 17, 1931. He was preoccupied, rather stuporous, and his performance was unsatisfactory and invalid although representative of his mental state. A "performance" test mental age of seven years, six months was obtained. No language tests could be given. On September 8 he was noted to do a little swabbing in a mechanical fashion. He went to the occupational therapy shop upon request where he made some feeble, ineffectual attempts at wood-working. He continued throughout this period to require constant supervision. Essentially no information was elicited or noted regarding his ideational content, since rapport could not be established.

Physical examination disclosed a stooped youth, 1806 cm. tall, with disproportionately long arms, somewhat under-nourished. One pupil was found to be oval but otherwise the eyes were normal. The thyroid by palpation showed a slight diffuse enlargement. Reflexes were very much diminished, but equally so. Roentgen ray examination of the head showed asymmetrical sinuses, with the right smaller than the left.

The average oxygen consumption rate (Table I) during this period was 83 percent of the standard normal. The range was 78 percent to 90 percent, with the lowest rate probably the most representative.[2] Systolic and diastolic blood pressures averaged 115 and 84 respectively, with minimal levels of 108 and 74. The pulse rate varied between 54 and 66. The rectal temperature was low, ranging from 96.8° to 97.2° F.

The urine studies (Table II) are difficult to evaluate. The volume for the first period averaged 2750 cc., but the low total nitrogen and the minimal creatinine nitrogen values for the second collection suggest an incompleteness of the sample. Nevertheless the patient showed a urine output double the average volume of our normal controls living in a similar environment, namely, 1328 cc. The urinary findings otherwise were not remarkable except for their variation. The total nitrogen indicated a fairly satisfactory level of protein metabolism.

TABLE I
OXYGEN CONSUMPTION STUDIES

Table III, which includes other physiological studies, reveals in the tabulations under "First Period" the following findings: The galactose tolerance was 20 gm., which, according to Rowe,[3] is at the lower level of normality. Study of the gastro-intestinal tract activity revealed an atonic stomach and a moderately delayed emptying time of 96 hours for the colon. The morphological findings of the blood were normal, as was also the

sedimentation rate, indicating absence of infections or organic destructive processes. The chemical constituents of the blood and the blood gases were all within normal limits, but the fasting blood sugar at 86 mgm. in both of two tests was near the lower limit of normality. Afternoon blood pressure and pulse rate were normal. The patient's weight was 23 per cent below the Metropolitan standards for his height and age. The bromsulphthalein test indicated normal liver function within the limitations of that test. The dynamometer test showed low values, possibly because of lack of cooperation.

The *inter-test* period extended from September 13 to November 7, 1931. During this time slow, gradual improvement was noted in his ward behavior. He seemed to develop a little more contact with his surroundings, to respond more promptly to stimuli, and to stare a little less. This improvement was most noticeable in the last week of the period, when be became more tidy in his personal habits and began replying briefly in faint whispers to questions and looking about him as if somewhat interested. Also, during the second month of the period he began to work a little in the occupational therapy shop, but performed in a mechanical fashion, although during the last week he seemed to show some interest and pride in his work. No additional psychiatric data were obtained.

The *second study period* extended from November 8 to December 5, 1931. At the time of the mental examination during the first week he was noted as markedly improved. There was some spontaneity of speech and he answered a few questions in a whisper, but without giving very much information. He showed more affective response, smiled a little, and seemed pleased at the opportunity of talking to the examiner. He was noted as swabbing on the ward and working in the occupational therapy shop. His urinary and fecal incontinence in large part had disappeared. He showed interest in his surroundings, although he was still somewhat retarded and slow in his movements and he did not participate actively in the ward activities. On November 9 and to a *psychometric examination* was given. Mental ages of 10 years, 4 months and of 13 years, respectively, were secured on the Otis S. A. Intermediate and the "performance" tests. His powers of attention were fairly good and he showed good persistence and some degree of autocriticism. Comprehension was fair, but responses were slow. However, the test results were not considered valid, but were regarded as indicating marked improvement over the previous findings. Throughout the period he was cooperative on test procedures and he became increasingly active and alert, manifesting feeble tendencies to mingle socially with the other patients. His work performance improved and he began assuming responsibility for small tasks, although he was not persistent. He became more interested in wood-carving, but worked slowly and ineffectually at his task. He was oriented correctly and seemed to be in good contact with his surroundings. At times he manifested a considerable amount of insight. There were brief periods of a depressive character noted throughout the study period when he spoke in a low tone and seemed unhappy. His response to family and other visitors indicated fair interest and pleasure.

TABLE III

	First period.	Second period.	Third period.
Mental state	Stuporous	Improved	Approximately recovered
Mental age	7 yrs., 6 mos. (perform.)	10 yrs. 4 mos. (Otis) 13 yrs. (perform.)	16 yrs. 4 mos. (Stanford) Superior (perform.)

Blood sedimentation rate, mm. per minute	0.15	0.00	0.04

* Probably due to dehydration.

At the beginning of the second period *physical examination* disclosed cyanosis and coldness of the extremities. He was still undernourished but the nutritional index had improved slightly from 77 per cent to 80 per cent of normal.

The oxygen consumption rate, however, had decreased from an average of 83 per cent to one of 77 per cent of normal. The lowest rate of the second series was also lower than that of the first, the respective values being 78 and 74 per cent. The blood pressure had dropped from an average of 115/84 to 97/52. The pulse was also somewhat slower. At the same time the body temperature of the patient showed an increase. The average was 98.2° as compared with the preceding 97.0° F. This apparent contradiction between the increase in the temperature and the lessening of the oxygen consumption rate, blood pressure, and pulse probably means that there was a nearer approach to basality of the test conditions than had been achieved in the first period.

The polyuria previously noted had disappeared, with a normal 24-hour urinary output. However, the first collection appears incomplete, as judged by the creatinine nitrogen value. The urinary constituents otherwise were all within normal ranges.

The red blood cell count dropped to an average of 4,26o,ooo, but the leucocytic and differential counts and the sedimentation rates were normal. The constituents of the blood showed a distinct drop in the total nitrogen from the previous values of 33 mgm. to 24

mgm., the lower limit of normality. The blood uric acid was definitely increased from 3.6 mgm. in the first period to 4.3 mgm. This latter finding was slightly higher than our normal average of 3.9 mgm. The total blood volume was found to be 3645 cc., with a value of 62.6 cc. per kg. of body weight. These findings are definitely low, but the possibility of defective circulation may have precluded accurate findings. The venous oxygen was found to be 7.23 volumes per cent as compared with the text-book normal values of 10 to 18 per cent and the average value of 11 per cent for our own controls living in a similar environment, and the finding of 12.77 volumes per cent for the stuporous state. We have noted similar or even lower values in other cases of schizophrenia. This finding also is suggestive of a sluggish peripheral circulation. The arterial oxygen was also low but the blood gases otherwise were normal. The resting afternoon pulse rate had increased from 6o to 66 and the blood pressure from 109/78 to 132/94. Galactose tolerance was not satisfactorily determined. The results of the bromsulphthalein test were again normal. Readings of the dynamometer test had increased, though they were still below the normal values. Rectal temperature taken on the ward during this period was approximately normal in its range. The colonic stasis had disappeared, with an emptying time of 24 hours as compared with the previous 96 hours.

The *second inter-test period*, extending from December 6, 1931 to January 30, 1932, showed a slow, steady continuance of the patient's improvement, until by the end of January he had apparently reached what appeared to be a complete recovery from his catatonic stupor. The end of the period found him alert, cooperative, in good contact with his surroundings, pleasant and sociable, but rather unwilling to work and interested only in drawing pictures, writing in his diary, composing stories and poems, and working on his autobiography. He was given parole during the first of January and spent his time on parole wandering about the grounds either alone or in company with another patient much younger than himself. He continued his work in the occupational therapy shop, where he exhibited much pride and interest in his work but nevertheless was an irregular attendant. He was considered to work only about half as well as the normal workman. When interviewed he was responsive to approaches but in general tended to be withdrawn and seclusive, and to lapse into states of pre-occupation. He showed much interest in social activities, attending dances and taking part in a minstrel show. He was observed usually to be cheerful, complacent, and good-humored, although occasionally he seemed depressed and spoke about feeling unhappy about his situation. He also gave an account of his ideational content during his stuporous state. He described this stuporous state as a dreamy condition, at which time he had believed himself surrounded by important people in a scientific institution, specifically the Babson Statistical Institute. He told of feeling himself hypnotized and of being fastened to the floor by some strange attraction so that he could not move. He also experienced a thirst that distressed him and compelled him to drink much water, although strange forces and voices tried to make him endure the thirst. He related imagining himself to be a king, a prince, a great man, with a large retinue of serving people, and whenever he looked out of the window he could see pageants of gaiety, all conducted for his benefit. In the ward personnel he identified Einstein, the King of England, the President, all the great men of the age, and he expressed the belief that he had built up a fantasy life in which he could live all the grandiose day-dreams of his prepsychotic period. As time passed he gradually reached

the realization that he was in a hospital, coming to this realization by hearing announcements over the ward radio that the broadcast was coming from Station WSH (Worcester State Hospital.) He also told of some persecutory delusions and of numerous auditory hallucinations. As he narrated these ideas he exhibited an excellent insight, but at the same time he manifested a continuance of his grandiosity about his personal talents and potentialities, and his judgment in relation to himself was considered not to be very discerning. Although he had discarded the fantasies of his stupor state, he entertained the belief that by hard work and earnest application he could acquire a fortune of $5o,ooo within the space of a few years. Also, he expressed the belief that the fiction and poetry he was writing would set a new style in American literature, and he was not receptive to criticism in these regards.

The *third study period* extended from January 31 to February 27, 1932. During this time his general conduct continued much the same as it had during the preceding inter-test period. He took a little more part in the social activities, working well in the occupational therapy shop. He was less self-satisfied, superior, and grandiose in his attitude. During the *mental examination* he protested about the repetition of the test procedures and expressed the belief that he was entitled to special privileges. He was unwilling to work and spent much of his time out-of-doors or else drawing and writing, holding himself aloof from all except the better grade of patients. He was friendly with the physicians and psychologists, but not very cooperative with the nurses. He seemed indifferent as to personal appearance. He talked readily and freely but was evasive when questioned closely and seemed distressed by any topic relating to his psychosis. His mood was one of contentment, cheerfulness, and self-confidence, with some boastfulness. Occasionally he manifested some anger and depression, but these were appropriate to the occasions. He reviewed his recollections of the fantasies related to his stupor and seemed to have a good degree of insight. On the whole, the psychiatric findings for this period suggested that the patient had reached his normal pre-institutional level. The *psychometric examination* revealed a Stanford mental age of 16 years, 4 months, with an intelligence quotient rating, on the 14-year basis, of 117. The “performance” mental age was “superior” and the Wells “memory quotient” was 111 per cent. The patient was cooperative, attentive, and comprehended well, and the results of the examination were considered representative and valid. Subsequent examinations have verified this.

Substantially the same findings were made in the *physical examination* of the third study period as in previous periods with the exception that nutrition was improved and that his weight had increased from 80 per cent to 89 per cent of the Metropolitan standards.

Oxygen consumption rates showed a marked increase, ranging from 94 per cent to 107 per cent, with an average of 101 per cent. Basal blood pressure averaged 113 systolic and 65 diastolic, with a range of 94 to 13o and 40 to 78 respectively. The average basal pulse rate was 62, with a range of 58 to 64. The basal rectal temperature ranged from 98.4° to 99.2° F., with an average of 98.9° F. These findings all suggest a normal physiological state.

Catheterized 24-hour urine specimens were obtained for this period. A polyuria exceeding that of the first period and amounting to 4527 cc. was found. The creatinine nitrogen values were both 067 gm.-a high value for his weight of 149 pounds. Otherwise the urinary findings were within normal ranges.

The galactose tolerance was again 20 gm. as in the first period. The secondary anemia noted previously was found to persist but was somewhat less extensive than in the previous period. The rest of the blood morphological picture was again normal. The total blood volume, however, was found to be markedly increased to 5475 cc. as compared with 3645 cc. for the second period. Blood volume per kg. of body weight had increased from 62.6 cc. to 84.2 cc., an increase Of 34.5 per cent. This rise with no significant change in the cell count suggests a marked increase of activity in the hematopoietic system, since otherwise the count would have been reduced by dilution. However, no conclusions are warranted because of the possible unknown factor of defective circulation during the second period. There was a rise in the total nitrogen of the blood to the level of the first period, with blood uric acid remaining at a slightly elevated level Of 4.2 mgm. Venous oxygen was still low but the other blood gases and pH were normal. The liver function, as shown by the bromsulphthalein and McClure tests, was apparently normal. The increased readings for the dynamometer test indicated good strength and cooperation. Colonic emptying time was 48 hours.

From March to November, 1932, the patient's mental state has remained essentially the same as it was at the close of the last study period. He has shown much insight into the nature of his previous delusions and hallucinations but he has tended to continue the grandiosity in his self-evaluation. At first he considered himself superior to work, but gradually consented to do a minimal amount of labor in return for parole privileges. His work performance has been that of a 12- to 14-year-old-boy, and he works only under supervision at simple tasks. Whenever questioned about his ideational content he tends to be evasive, uncommunicative, and to complain that he is not properly appreciated, that he is very sensitive, and that everyone should be careful not to hurt his feelings. He expresses rather grandiose ideas about his abilities and hopes to make a fortune of $50,000 in the course of two or three years.

During the past few months he has become slightly more communicative, particularly in regard to abnormal mental trends. He admits that he has continued to experience auditory hallucinations more or less continuously since the onset of his psychosis. He tends to look upon them as imaginary and as his own thoughts, but he describes them as voices that give him simple commands, such as to sit down or to stand up. No visual hallucinations are admitted. In general, he has become very well contented with his situation in the hospital and seems satisfied to remain. He associates freely with certain of the better-class patients, but tends to avoid contact with the employees and to assume a haughty and superior air toward them. In brief, he remains at a constant level, and his mental state appears to be essentially the same as that previous to the acute development of psychosis.

Shortly after this paper had been submitted for publication the patient was sent home on an indefinite visit. Six months later he returned for an interview with the examiner. He reported that he had been living on a farm with his brothers where they were clearing cutover land. His nutritional state was good; he was deeply tanned and his hands were thickly calloused. His appearance was neat and he was normally friendly and sociable, and manifested appropriate affective responses. A careful mental examination elicited no psychotic symptoms nor were any noted. The auditory hallucinations formerly so persistent had ceased about five months previously. He summarized a fairly extensive account of his psychotic experiences in the following words

"I guess I just let my wishes and my day-dreams run away with me until I couldn't control them. I didn't keep a holt on reality and I was just helpless."

Regarding his previous grandiosity he declared "Making a big fortune—just a kid idea—what I am aiming at now is working hard, earning a decent living; just keeping happy with my feet on the ground; no more big ideas for me."

In brief the patient appears to have made and to be continuing a fairly complete social recovery.

DISCUSSION

The reader will note that no apparent significance has been accorded the first 23 years of the patient's life. This seeming oversight has been intentional in this paper. The fact is well recognized that his developmental history might account in part or in full for his present condition, but it is not within the scope of this paper.

In summary, during the period of acute stuporous catatonia the patient showed evidence of mental retardation, poor capacity of response in psychiatric and psychometric examinations, and several deviations from organic normality. He was under-weight, had an atonic stomach, moderate colonic stasis, diminished oxygen consumption, reduced body temperature, and a fairly well marked polyuria. His fasting blood sugar and galactose tolerance were at the lower extreme of normality. Blood pH and blood volume were not determined during the first period. Otherwise he seemed to be physiologically normal.

During the second period his psychiatric condition was definitely improved. He was more accessible in psychiatric examination and psychometric test results were notably better, but again the results were largely indeterminate because of lack of good cooperation. In the organic sphere body temperature increased slightly more than a degree, a datum probably indicating a lessening of the hypometabolism which characterized both the first and second periods. The actual oxygen consumption rate as well as the blood pressure and the pulse rate decreased, hence the evidence as regards hypometabolism is thus equivocal unless it is granted that the patient was probably more nearly in a true basal state for the second determinations. The nutritional state improved somewhat

and the colonic stasis disappeared. The urine output was reduced to normal, with a normal composition. A mild secondary anemia became apparent despite an apparently sub-normal blood volume. The venous and arterial oxygen contents of the blood were definitely low. The total nitrogen of the blood dropped from 32 to 24 mgm., a datum which cannot yet be explained. In general, our patients have shown normal blood nitrogen values irrespective of the depth of psychosis.

Further improvement in the clinical picture was noted in the third period. Psychiatrically the patient had attained a level of recovery warranting return to the community. In the sphere of the psychometric examination he was found to have superior intelligence, both on language and performance tests, and the findings were considered valid and representative. In the physiologic sphere the hypometabolism had disappeared and the blood pressure, pulse rate and temperature were in accordance with his normal oxygen consumption rate. On the other hand, the urine volume, determined from catheterized specimens, showed a marked increase, with the only questionable abnormality of the constituents in the creatinine nitrogen values, the significance of which is not known. The blood morphological findings showed even less anemia than in the previous period, but the count was still under the text-book normal. The blood volume per kilogram of body weight showed a marked increase of 34.5 per cent over that of the previous period, with no significant change in cell count. This relative constancy of the cell count suggests either a more accurate blood volume determination as a result of improved circulation or a marked increase of activity in the hematopoietic system. Venous oxygen was still definitely low. The total blood nitrogen had again returned to the normal level of the first period. The nutritional state showed definite improvement which correlated well with the oxygen consumption rate. In other regards the patient's physiologic state appeared to be normal.

In brief, this study has served to exclude a considerable number of physiological functions as significantly correlated with the psychiatric condition, at least in this patient. The constituents of the blood in general have remained within normal ranges throughout, which has been true of the chemical constituents of the urine.

The possible relationship of the pituitary to the psychosis presents an interesting problem. The history of the patient indicates evidence of over-activity of this gland at about the age of 14. As is well recognized among endocrinologists, over-activity is frequently followed by a functional depression as is shown, for example, in the later stages of acromegaly. The rather striking polyuria manifested during the first and third periods supports the idea of a pituitary deficiency, fluctuating in character. However, there was lacking the high blood uric acid and the high galactose tolerance that Rowe[4] includes as characteristic features of the pituitary deficiency. Furthermore, both the polyuria and the blood uric acid were highest in the third period when the patient was least psychotic. These metabolic findings, as a matter of fact, could be ascribed equally well to hypothalamic disturbances. In view of the close functional relationship between the hypothalamus and the pituitary, perhaps the safest assumption would be that both were in a measure physiologically abnormal.

The possibility of pituitary involvement is substantiated further by special Roentgen ray examination made of the patient's head and anthropometric measurements taken in a study conducted by Dr. Hector Mortimer. He discovered an increased thickness of the skull tables, increased size of the frontal sinus and of the maxillary and mental processes, and increased ossification at the skull sutures, but the sella turcica was normal. The anthropometric measurements show disproportionately long upper extremities with a relatively poor development of the torso and of the osseous framework, as may be noted in the accompanying photographs. The sitting height index, however, has a normal value of 0.526. These findings, in conjunction with a history of head trauma, personality changes, sudden rapid growth, and an excessive appetite for carbohydrates at about the age of puberty are suggestive of a period of over-activity of the pituitary.

In conclusion, we have presented the psychiatric, psychologic and physiologic findings over a period of seven months in a case of schizophrenia, catatonic reaction type. Changes and fluctuations have occurred concomitantly in the observations made in each of the three fields. The mental picture shows three definite phases first, stupor; second, a recovery from the stuporous state; and third, a condition of approximate recovery from the psychosis. Concomitant with the study of the mental states there are three physiological cross-sections. Tables of findings show the nature and extent of the measured physical and psychological changes.

For the greater part, the organic data were within the normal range. However, the classification of these laboratory data as normal or abnormal gives rise to a most important question in the study of such physiological data in mental disease, namely, what may be considered "normal"? May it not be that "normal" physiological findings are not normal by virtue of the failure of proper systemic response, an illustration of which is the "normality" of the white blood cell count in certain infectious diseases? May not malfunction in one system occasion a secondary failure in another, or even prevent a proper physiological response to a disturbing factor and thus lead the observer astray by the "normality" of his findings?

The data obtained reveal coincidental deviations in the psychic and physiologic states of the patient and this suggests the possibility of significant correlations between the organic and psychic changes. However, whether this concomitance is causal or resultant or merely coincidental cannot be determined until more studies of this nature have been made. In brief, for an adequate study of dementia praecox careful consideration must be given to an analysis of all inter-relationships, parallelisms and contrasts in the physical and mental data obtained. The method of approach illustrated in this case analysis permits a precise study of the phenomenological nature of dementia praecox or schizophrenia as it is found in the patient as a whole. It affords a comprehensive view and a perspective of the whole problem impossible of attainment by investigations, however intensive, of individual aspects such as thyroid studies on one group of patients, ideational content on another, and blood vascular system on a third. In brief, only by some method of study which allows the simultaneous investigation of many aspects of the disease can a satisfactory approach be made to a determination of temporal sequences and functional interdependence.

SUMMARY

Detailed psychiatric, psychologic and physiologic studies were made for a period of seven months on a patient suffering from schizophrenia, catatonic reaction type.

Three distinct psychiatric states—namely, stupor, recovery from the stupor and a condition of apparent recovery from the psychosis—were found, for each of which a physiological cross-sectional study was made.

During the stuporous state he was under-weight, had diminished oxygen consumption, reduced body temperature, polyuria and delayed colonic emptying time. Other physiological findings were essentially normal.

During the second period he had recovered from the stupor, had gained weight, manifested a slight, equivocal decrease in his oxygen consumption rate, a slight increase in body temperature, mild secondary anemia, a questionable low blood volume and low venous and arterial oxygen content. Other findings were within normal ranges.

During the third period the patient appeared to have reached the level of his pre-institutional mental state, had gained weight and manifested a normal oxygen consumption rate, with normal body temperature. Except for a marked polyuria and low venous oxygen content, the physical data showed no apparently significant deviation from the normal.

There is evidence suggestive of a pituitary over-activity manifested at about puberty, according to the history, and followed by evidence of deficiency during the periods of study. However, the fluctuations noted could likewise be attributed to an abnormal functioning of the hypothalamus.

In brief, coincidental with the changes in the psychiatric and psychological spheres, there have been corresponding or opposite fluctuations and variations in the organic sphere. Also, in some instances, an apparent independence has been indicated by physiologic constancy. Accordingly, when more studies of this nature have been made, an answer to the question of functional interdependence may be achieved.

Published in the *Archives of Neurology and Psychiatry*, August, 1933, Vol. 30, pp. 388-401

Despite the fact that schizophrenia has been known under one or another name for centuries, the nature of the disorder even at the descriptive level remains in no small measure yet to be determined. It is true that there is a voluminous literature describing the multifarious deviations from psychologic normality and no small number of publications dealing with organic variations. But the question is stall open as to which of the deviations are essentially characteristic of the psychosis. In the picture as presented by the patient we have to deal with pathologic phenomena of several different categories. The abnormalities may comprise the effects of bad hygiene, the effects of habituation, the effects arising primarily out of the fundamental cause or causes of the disorder and the defects arising from secondary operations of the primary causal factors. The need remains for an adequate definition of the psychosis. This definition should, of course, delimit it from all other disorders; it should be broad enough to include all of the subvarieties; it should include none but characteristic attributes.

The literature on schizophrenia as now available, while profuse in qualitative material, is defective in its content of accurate quantitative information. But an even more significant defect is the lack of homogeneity of the data as they exist.

These data have been obtained by many investigators using different techniques on a variety of patients living under dissimilar environmental conditions. They are of correspondingly limited utility for the purpose even of formulating a technically satisfactory definition. In large part they are entirely unusable for the type of studies of correlation that is needed for the analysis of the problem as a problem. There is need, then, for the collection of an extensive body of descriptive data on a fairly large number of patients studied under uniform conditions. This topic has been discussed at greater length in another communication.[1]

While it is true, as has been emphasized elsewhere, that the mere enumeration of traits is a research method of strictly limited utility, it is likewise true that attempts to carry out research on a problem that has not been accurately set are likely to result in numerous ineptitudes.

Even at the descriptive level, certain substantial accomplishments can be hoped for. At this level can be studied the question as to whether schizophrenia represents a disease entity or whether, like fever or headache, it represents a variety of essentially different disorders. The detection of disease entities has not infrequently been accomplished at this

level. For example, myxedema was so discovered. In principle, this sort of discovery amounts to the detection of consistent syndromes.

Schizophrenia may well represent a variety of syndromes. Given a sufficient body of homogeneous data, such syndromes should be detectable by the use of systematic statistical methods. The detection of a syndrome, however, does not in itself afford any evidence of causality. To continue the previous illustration, the mere fact that deficiency of the thyroid gland was discovered as a characteristic concomitant of myxedema served merely to delimit the problem of causality. The causal relationship of the defect of the thyroid gland to the disorder had to be proved experimentally. This was done in two ways. Surgical removal of this gland for goiter was shown to be followed by myxedema, and the symptoms of myxedema were shown to be ameliorated by the administration of thyroid substance.

In the case of schizophrenia the approach to the problem of causation will presumably necessitate three steps. The accumulated data must be tested, as indicated, for the existence of characteristic syndromes. The items making up the syndromes may stand in casual, consequential or concomitant relationships to each other. The next step is to test empirically for consistency of concomitance. It must be determined which features of the syndrome vary *pari passu* with changes in the clinical condition of the patient. In principle, this method serves to differentiate the essential from the fortuitous elements in the picture. Finally, among those features that vary in step with the clinical condition, causation may be sought.

For the detection of causation we have in principle two empiric methods of procedure. One is to make frequent cross-sectional determinations of the physiologic and psychologic characteristics of the patient, ideally before and during the onset of the psychosis, or, less satisfactorily, during an attack and through a remission of the psychosis. For this aspect of the research, the most valuable type of patient is one who passes rather promptly through episodic acute attacks, with approximate normality between exacerbations. Thus the events might be placed in temporal sequence. Those invariably occurring early may be expected to include the causal factors of those arising later. The second method is the experimental. This amounts in effect to the arbitrary augmentation or reduction of any suspected factor and noting the consequences as mirrored in the clinical state of the patient. Commonly, therapeutic studies, when based on rational "leads," have a certain value in the determination of causation. Without further elaboration of the philosophic aspects of the problem, suffice it to state that these are the two general methods by which etiology is commonly determined. This paper embodies the description of an experimental project that has been evolved in the light of the foregoing considerations.

In the earlier years, the studies consisted of a series of tests of the vital functions, psychologic tests and rather conventional psychiatric studies.[1] As the work progressed, more and more difficulty was experienced in interpreting the data because of a rather high degree of variability among the test findings of the individual patients. In 1931, it was determined to concentrate attention for the time being on variability as such. A so-

called seven months' plan was formulated, and the work of the entire staff for a year was devoted to carrying it out. The plan has been briefly described elsewhere.[2]

The purpose of the plan was to collect observations on a considerable number of physiologic, psychologic and psychiatric variables for about seventy-two schizophrenic patients. This required four weeks of testing for each patient; each was then given two months' rest during which, however, studies of the action of certain pharmacodynamics and of the spinal fluid were made. The tests were then repeated and another period of rest interposed. Finally, in the seventh month the tests were made again. Thus each patient was studied rather elaborately three times without the complication of treatment other than unavoidable situational influences.

The entire environmental setting was kept as constant as possible, though absolute constancy is impossible in a hospital for mental illness. For example, every significant change in the clinical state of any patient constitutes a change in the environment of the others.

The schedule of studies is indicated in the accompanying table. An attempt was made to conduct the study under conditions that would secure the maximum utility of the data for purposes of correlation. Especially was it desired to secure observations of the psychiatric status coincident with the application of physiologic tests that might be modified by the emotional condition of the patient. In this we were not always successful owing to the limitation of personnel, but in general the psychiatric and other observations were so timed that major defects in the data were avoided.

Schedule

First Week

Monday:	9:00 a.m.	Psychometrics		1:00 p.m.	Physical and Psychiatric examination
Tuesday:	9:00 a.m.	Psychometrics		1:00 p.m.	Physical and Psychiatric examination
Wednesday:	9:00 a.m.	Psychometrics if necessary		1:00 p.m.	Physical and Psychiatric examination
Thursday:	7:30 a.m.	"Basal metabolism," including rectal temperature, pulse rate, blood pressure, weight and height; sample of blood collected for quantitative analysis and phytotoxic test		1:00 p.m.	Psychiatric examination
	9:30 a.m.	Breakfast			
Friday:	7:30 a.m.	"Basal metabolism"		1:00 p.m.	Diagnosis by admitting staff: psychiatrist's note
	9:30 a.m.	Breakfast			
Saturday:	7:30 a.m.	"Basal metabolism"		p.m.	Mental note

Second Week

Sunday	a.m.	Rest		p.m.	Rest
Monday:	9:00 a.m.	Experimental psychology		1:00 p.m.	Psychiatric observations in ward
				3:00 p.m.	Photography – two nude poses
Tuesday:	9:00 a.m.	Experimental psychology		1:00 p.m.	Psychiatric observations in ward
Wednesday:	9:00 a.m.	Experimental psychology if not previously complete		1:00 p.m.	Psychiatric observations in ward
Thursday:	8:00 a.m.	Oculocardiac test		1:00 p.m.	Psychiatric observations in ward
	9:30 a.m.	Breakfast		1:30 p.m.	Dental examination and roentgen studies of skull, chest and gastro intestinal tract
Friday:	a.m.	Blood volume, plasma volume, hemoglobin, blood gases, blood pH, blood morphology		3:00 p.m.	Schneider test of vasomotor efficiency: psychiatric observations in ward
Saturday:	8:00 a.m.	Period of rest; recheck of Friday's observations If necessary		p.m.	Rest

Third Week

Sunday:	7:00 a.m.	Start 24-hour collection of urine		p.m.	Collection of urine
Monday:	7:00 a.m.	Finish collection of urine		2:30 p.m.	Blood pressure
	8:30 a.m.	Inject phenolsulphonphthalein: collect specimens			
Tuesday:	7:00 a.m.	Start collection of 24-hour urine		1:00 p.m.	Psychiatrist's note
	7:30 a.m.	"Basal metabolism," lung volume			
	9:30 a.m.	Breakfast			
Wednesday:	7:00 a.m.	Complete 24-hour collection of urine		1:00 p.m.	Psychiatrist's note
	8:30 a.m.	Inject phenolsulphonphthalein: collect specimens			
Thursday:	5:00 a.m.	Galactose tolerance control sample		1:00 p.m.	Psychiatrist's note
	6:30 a.m.	Collect samples for chemical analysis of blood and blood counts			
	7:00 a.m.	Galactose tolerance test			
Friday:	5:00 a.m.	Repeat galactose tolerance test		1:00 p.m.	Psychiatrist's note
Saturday:	5:00 a.m.	Repeat galactose tolerance test		1:00 p.m.	Psychiatrist's note

Third Week

Sunday:	p.m.	Rest		p.m.	Rest
Monday:	8:00 a.m.	Fluoroscopic gastrointestinal studies begun: psychiatrist's note: Internist's note on physical status		p.m.	Gastro-intestinal series
Tuesday:		Gastro-intestinal studies continued; psychiatrist's note			
Wednesday:		Gastro-intestinal studies continued			
	8:00 a.m.	Blood sedimentation test: bromsulphthalein; test for hepatic function; psychiatrist's note			
Thursday:		Gastro-intestinal studies continued		p.m.	Psychiatrist's note

METHODS

The various items are mostly self-explanatory. Standard methods were used throughout. A history of the case was obtained, as discussed in a later section. A thorough physical examination of each patient was made, partly by way of eliciting data bearing on constitutional diagnosis, but especially for the purpose of detecting organic disease that would serve as a fortuitous complication of the study. Any patient showing evidence of disease beyond such passing afflictions as colds or minor ailments was excluded from the series. In short, our aim was to confine the study to subjects free from significant organic disorders.

Patients were included for study only when the research psychiatric staff was able to classify the cases as schizophrenic beyond a reasonable doubt. Patients were excluded on the following grounds: (1) over 50 years of age (chiefly because of the liability to organic changes frequently occurring with advancing age); (2) coexisting disease discoverable by the usual diagnostic methods; (3) adequate histories unobtainable; (4) marked language difficulties; (5) inclusion of feeblemindedness with the schizophrenic picture; (6) symptoms predominantly those of psychoses other than schizophrenia; (7) recent chronic alcoholic or other intoxication.

For purposes of further description, the activities of the various cooperating departments will be dealt with separately.

ORGANIC STUDIES

The determinations of the basal metabolic rates were made on Thursday, Friday and Saturday of the first week and on Tuesday of the fourth week. The patients were taken to the laboratory without breakfast and were put to bed for thirty minutes before being tested. After the period of rest the oxygen consumption was measured for two six minute intervals by the Benedict-Roth method. The results were calculated according to the Harris-Benedict and the Aub-Dubois standards, and the mean of the two values was taken as the basal rate. If superficially "satisfactory" conditions of basality were not secured, the tests were recorded but marked with an asterisk and not subsequently used for statistical purposes. Extreme care was taken to exclude technical error. The machines were tested daily for leakage and for failure to absorb carbon dioxide due to spent soda lime. Tests were recorded as "satisfactory" only when the patient remained quiet during the period of rest and showed no overt evidence of tension during the tests. If, as was usually the case, two consecutive tests differed significantly in the rate of oxygen consumption, the lower was regarded as more likely representative and was used for subsequent studies of correlation. The details of the study (on a large group) and a critique of results have been published elsewhere.[3] After the rate of oxygen consumption was determined, the patient's weight, standing height, sitting height, rectal temperature and blood pressure (systolic and diastolic) were determined. The results of the last mentioned study have also been reported.[4]

Front and lateral full length photographs were made of each patient in the nude at a standard distance of 6 feet (1.8 meter) and before a coordinate screen. A standard mercury vapor lamp served for illumination.

Oculocardiac Test.—The degree of vagus irritability was determined by a quantitative oculocardiac test. The pulse rate was recorded before and during the application of varying grades of pressure to each and to both eyes through an oculocompressor, following the Roubinovitch method.[5] The pressures used were 125, 150 and 175 mm. of mercury.

As a supplement to the physical examination a thorough dental examination was made. If indications appeared, x-ray plates were made of the teeth.

Roentgenograms.—X-ray plates were made as a routine measure of the skull—lateral and frontal exposures—the chest and the abdomen and pelvis after a barium sulphate meal. A consultant roentgenologic specialist interpreted each plate as to the condition of the sella turcica, sinus, lungs, stomach and intestines.

Weight.—This was obtained with the patient unclothed. By comparison with the Metropolitan Life Insurance Company height-weight-age tables, corrections having been made for shoes and clothing, a nutritional index was calculated.

Blood.—The volume was determined by the Congo red method.[6] In brief, a known volume of 1.5 per cent solution of Congo red equal in milliliters to one fourth of the patient's weight in kilograms was injected intravenously, after 10 milliliters of blood had been removed for the preparation of the standard. After mild exercise for three minutes and before the end of six minutes a second 10 milliliters of blood was taken. Five milliliters of the blood was added to each of two graduated centrifuge tubes containing 1 milliliter of 1.6 per cent oxalate solution. The control sample of blood was treated in the same way. All four tubes were capped with heavy finger cots and centrifugated for thirty minutes. At the end of this time the total volume and the corpuscle volume were read for each tube. The concentration of the dye in the serum was determined by reading in a colorimeter against a 1:200 dilution of the dye containing the same amount of serum taken from the control tubes. The volume of the plasma was then calculated, and by dividing this value by the percentage of plasma in whole blood the volume of the whole blood was determined.

The hemoglobin was determined in grams per hundred milliliters by means of the Haden-Hausser hemoglobinometer. The value of 15.6 Gm. per hundred milliliters was taken as normal.

Samples of blood were taken from the radial artery and the median basilic vein for determination of the gases and the pH. The samples were taken directly in glass syringes to which a finely powdered sodium oxalate and sodium fluoride mixture was added. and then the syringes were capped. All venous samples were taken at least thirty seconds after removal of the tourniquet to allow for reestablishment of the normal circulation and to

prevent stasis. Exposure to air was completely prevented by handling the blood in the syringes in which the samples were taken. Evidence that this technique was satisfactory will be reported in detail in a subsequent paper.

The arterial and venous oxygen and carbon dioxide were determined in a Van Slyke manometric apparatus. The pH of the arterial and the venous whole blood was determined by the glass electrode and the electron tube potentiometer of Stadie.[7] All measurements were for whole blood at 38 C.

The morphologic study of the blood included a red cell and a leukocyte count, and a differential count on 200 cells. Both the conventional and the Schilling criteria were used.

The vasomotor efficiency was studied by the method of Schneider.[8]

Renal Function.—The rate of excretion of phenol sulphonphthalein was determined for two of the three test periods, but was then discarded as not significant for patients on whom extensive analyses of the blood and urinalyses were being made.

The urine was collected for two twenty-four hour periods in each of the three test months. At least two and in some cases all of the specimens were obtained by catheterization at the beginning and the end of the collection, with voluntary voidings in between. The patients were under surveillance throughout the entire time of the collection. The volume and specific gravity were measured, and from these values the total solids were calculated. Each specimen was centrifugated and the sediment subjected to microscopic examination. Qualitative tests were made for indican, albumin, sugar, bile, acetone and urobilinogen. An aliquot portion of each sample was analyzed for total nitrogen, urea, uric acid, creatinine and ammonium nitrogen. The residual nitrogen was determined by subtracting the sum of all the determined bodies from the total nitrogen.

Volume of the Lungs.—This was determined by the use of a spirometer in which was measured the total forced expiration after a forced inspiration. In psychotic patients this datum is significant when the volume is equal to, or above, prediction. Subnormal values are obviously of dubious significance because of the dependence of the datum on the cooperation of the subject.

All samples of blood for chemical analysis were taken in the morning before breakfast. The nitrogen of the urea, amino-acid, uric acid, creatinine and creatine fractions was determined, and this was subtracted from the nonprotein nitrogen to give the residual nitrogen. Except for the urea nitrogen, which was obtained by the method of Looney,[9] and the uric acid, which was at first determined by the method of Benedict and Franke, all determinations were made by the methods of Folin. Cholesterol was determined in the whole blood by the method of Myers and Wardell and blood sugar by the method of Folin.

Phytotoxic Index.-As previous studies[10] had demonstrated that the serum of certain psychotic patients was toxic to the growth of seedlings of Lupinus albus, the “phytotoxic

index" was included in the study. This index is obtained by dividing the average elongation of the root of the seedling of Lupinus albus in a solution of mixed salts[11] to which 1 per cent of blood serum has been added by the elongation obtained in the same concentration of the same solution alone. From 10 to 25 seedlings were used for each test. The results of this study will be published in detail later.

Sedimentation of the Blood.—The rate was determined by the method of Rourke and Ernstene.[12] This, with the Schilling index, was relied on to supplement the ward observations of the nurses and internists in the detection of intercurrent infections. As a further precaution, morning and evening rectal temperatures and resting pulse rates were recorded as a routine measure each day and the weight once a week.

In the routine studies, standard methods were used throughout. These will be discussed more fully in subsequent reports on the different phases of the research. Suffice it here to state that the more difficult procedures were carried out by thoroughly trained chemists and physicians and the other procedures by well-trained technicians under constant supervision. The work was checked at frequent intervals by carrying out the technical procedures in duplicate so that the analytic error in all determinations was kept to the minimum for the specific test.

Pharmanodynuzmic Tests.—In addition to the routine studies, each patient was subjected to special pharmacodynamic tests during the interval between routine test periods to determine the functional condition of the autonomic nervous system. The details of these tests will be reported separately.

Galactose Tolerance.—The test of Rowe[13] is was used as an index of carbohydrate metabolism.

Gastro-Intestinal Function.—Roentgenographic studies included pictures of the abdomen or abdomen and pelvis immediately and at six and twenty-four hour intervals after the ingestion of 180 Gm. of barium sulphate. Plates were made with the patients in the supine position. Fluoroscopic examinations were made with the patients in the erect position. The final progress of the barium through the tract was determined by fluoroscopic examinations repeated daily until evacuation was completed. In connection with the gastro-intestinal studies, each patient was reexamined by a physician to exclude intercurrent physical disorders that might render the findings noncharacteristic. Likewise, each received a special examination by the psychiatrist each morning of the tests as a control on the emotional factor.

Hemato-Encephalic Barrier.—This was tested for permeability by Hauptmann's modification of Walters' bromide method, as used by 1falamud and co-workers?[14]

The test consists in feeding the patient bromide for several days and then estimating the ratio between the bromide in the serum and that in the cerebrospinal fluid from the color produced by gold chloride.

Hepatic Function.—Tests were made by the methods of McClure for the determination of cholesterol, bile pigments and bile acids in the bile obtained from duodenal drainage after stimulation with oleic acid. Bromsulphalein determinations of hepatic function, the van den Bergh reaction, the icteric index and Graham tests were also made.

Forty-eight patients were studied before and after the feeding of tyrosine for changes in the phenol content of the blood and urine in relation to the uric acid of the blood. These studies were highly technical, and further discussion of them will be deferred until the data are systematically reported.

Control studies on various features were made on a group of physicians, medical students and laboratory workers.

PSYCHOLOGIC CONTRIBUTION TO THE STUDY

For its part of the study, the psychologic department used a battery of tests and experimental procedures aimed at obtaining samples of the psychologic and psychophysiologic characteristics of the patients. These ranged from reflex responses through various motor and intellectual functions to complicated personality traits and attitudes. The nature of these can be seen from the list of items to be given. The attempt was made to touch on a fairly comprehensive group of functions in order to enable us to study the intercorrelations of these and their connection with the physiologic and other characteristics studied during the same period. It was also desired to study the variability in these functions over the period.

In this paper we shall not discuss the possible effects of previous examinations, the order of items in the psychologic schedule and the effect of other, nonpsychologic studies made in the same period. The consideration of such problems must be left for future papers, as must also the discussion of the question of controls, the attitude of patients and examiners and other problems.

It might be stated, however, that the general program was so arranged as to have the psychologic part of the study carried out at times when there was the least likelihood of the results being affected by other procedures, especially those often unpleasant to the patient, such as blood tests. The psychometric examinations came at the very beginning of the month of study, in the mornings and afternoons of the first two days of the first week. If the examination was for some reason or other not completed during the first two days, the third day of the week was used for this purpose. During the second week the major part of the experimental psychologic procedures were gone through on the corresponding days of the week. After the first period of study, additional experimental procedures were introduced, but because of the fullness of the schedule it was necessary to place these in what was called the “zero” week. This was the week preceding the first week of repeated study, i.e., the last part of the last week of the two-month period of rest. The schedules used are herewith presented. They were modified in only a few cases. The figure in parenthesis preceding the item refers to the number of times it was, as a general

rule, given during the seven month period.[15] After each item is given the reference to the sources for the techniques so far as it is possible to give them.[16]

Psychometrics
- Week I: First Day
  - (3) K-S clinical formboards [17]
  - (3) Stanford-Binet test[18]
  - (3) Otis S. A. intermediate test (alternate forms) [19]
  - (3) S-K symbol-digit test [17c]
  - (3) Writing test [17c]
  - (3) Drawing test [20]
  - (1) Freyd occupational interests [21]
- Second Day
  - (3) Worcester 2C formboard [22]
  - (3) Army Alpha (alternate forms) [23]
  - (3) G. E. pinboard [24]
  - (3) Kent-Rosanoff association [23]
  - (1, 2) Thurstone [26] or Bernreuter [27] personality inventories
  - (1) Heilbronner test [28]
  - (1) Memory test [29]

Experimental Schedule
- Week II: First Day
  - (3) Steadiness [30]
  - (3) Prod [31]
  - (2) Knee jerk [32]
- Second Day
  - (3) Pursuit [33]
  - (3) Reaction time: simple visual, choice visual. simple auditory [17c]
  - (3) Tapping
  - (2) Galvanic threshold [34]
- Third Day
  - (1) Luria “Motorik” [35]
- “Zero” Week
  - (1, 2) Observation [36]
  - (1) Interruption [37]
  - (1) Rorschach [38]

On a few occasions it was necessary to change the regular psychometric schedule owing to foreign language difficulty or to lack of cooperation. Under these circumstances tests such as the following were substituted: Army Beta, Witmer cylinder, Witmer formboard, ship, Kent-Kohs color cubes, Woodworth-Wells substitution, Porteus mazes and Healy picture completion.

PROGRAM OF PSYCHIATRIC STUDY

The psychiatric study of patients on the research service was made in accordance with an established schedule. Admission to the service followed a diagnosis of schizophrenia by the ward physicians and a recommendation as to suitability. On admission the patient was assigned to one of the four staff psychiatrists for thorough study to determine the reaction type. An extensive mental examination, consisting of an elaboration of the Kirby schema, was made over a period of four days. On the fifth day the psychiatric findings, together with social service history and the results of the pertinent psychologic examinations, were presented to the diagnostic staff, consisting of four psychiatrists, three or more internists and two psychologists; both of the latter groups were well versed in practical psychiatry. After an adequate discussion of the findings and an interview with the patient, classification was made as to diagnosis, subtype and suitability for further study as determined by the criteria cited earlier in this article. In the classification of the cases of the patients into various subtypes of schizophrenia, the kraepelinian system was used for clearcut types; otherwise the cases were designated as "mixed," "unclassified" or "late indeterminate."[39] The terms were regarded as merely roughly descriptive, not as connoting nosologic differentiation. Unanimity of opinion as to subclassification was not considered essential. When once accepted as suitable, throughout the rest of the period of study the patient was interviewed daily by the psychiatrist, and careful daily notation was made of his mental state and behavior, especially in relation to the procedures of study. In the second and third periods of study, precisely the same order of psychiatric routine was followed. This included even the diagnostic procedure, in order to insure a reasonable validity of diagnosis and to correct any errors made. During the periods of rest no intensive psychiatric study was conducted, but the patient was seen daily and often interviewed by the psychiatrist. The information was recorded in the form of weekly notes. In order to supplement the material obtained directly by the psychiatrists, a daily conference between the nurses and the psychiatrists was held at which an account was given of each patient's activities. The nurses and attendants also recorded independently the usual ward notes in accordance with a standard established by the psychiatrists. Further, under the direction of the chief psychiatrist, two ward observers took notes on selected aspects of the patient's behavior.

STATISTICAL ASPECTS OF THE STUDY

During the progress of the study about five hundred thousand quantitative observations were made. Means had to be adopted to insure the recording and organization of the material. The achievement of four principal aims was undertaken: (1) assuring from the outset of the project the statistical validity of the data; (2) safeguarding the completeness of the data; (3) consolidating the records emanating from various departments; (4) analyzing and presenting the results.

It was believed that a statistical department should not defer functioning until after the figures had been produced, but should take an active part in devising the experiments and the record forms, thus making it more probable that an ultimate statistical analysis would really lead to a clarification of the problems in question. Consequently the statistician and his staff were in constant contact with the various research workers, discussing with them

such points as numerical requirements, control groups, control of interfering variables and experimental and observational errors. Each subproject was "set up" in preliminary outline, considering: (a) the objects of investigation. (b) the justification of the project, (c) the methods to be utilized, (d) the records and reports required, (e) enumeration of the personnel and its duties, and (f) the estimated cost of the undertaking.

Such outlines were submitted by each research worker to the various members of the group, including the statistician, for criticism before starting to work on the problem.

The problem of safeguarding the completeness of the data necessitated a comprehensive checking system to make certain that all reports due from the various workers were received.

The consolidation of the mass of experimental data coming from many sources constituted one of the major practical problems in the statistical set-up. Our purpose was to combine facilitation of statistical analysis with accessibility of the data to the various workers. We wished to present the raw data in a form which permitted quick scanning and which would give a longitudinal and cross-sectional picture of a patient at a glance. Obviously a coding system would not serve this purpose. Besides, we were working with an unusually large number of variables but a relatively small number of patients on whom not single but frequently repeated observations were made at short intervals. Thus the conventional punch-card system was not applicable.

A special system of consolidating and recording was devised. For each of the major branches of the research a separate soft paper card, l0½by 6 inches (25.4 by 15.24 cm.), was used. The cards had twelve lines, providing space for observations over one year, the number of columns depending on the number of variables involved in the study to which the card referred. One card with twenty-seven headings was devoted to social history; one card with fourteen headings dealt with the chemical composition of the urine. The chemical composition of the blood and the blood counts were recorded on two cards with a total of forty-two headings one card with ten columns contained the data on basal metabolic tests. Psychometry and phychologic experiments appeared on three cards, with a total of fifty-five columns. Miscellaneous clinical data relating to the temperature, the pulse rate, the weight, the gastro-intestinal studies and the galactose tolerance were given on one card of twenty-six columns. Therapeutic data were recorded on one card under twenty-nine headings. This card included, in addition to results on medication, data on physical activity in terms of hours spent in work and play, the number of visitors received by the patients and the like. Lastly, there was a card on which the positive findings of the physical, dental and roentgen examinations were recorded.

At the bottom of each card a descriptive title summarized the kind of data to which the card was devoted. The cards were placed in overlapping arrangement, showing the bottom label, on a division sheet and bound in a so-called "straight-post visible binder," from which either the whole case or a single card could be taken out at any time with the greatest facility.

The binder had a capacity permitting the inclusion of the history of each of thirty-three patients for twenty-five years and giving space for the records of five hundred variables. A given month was always kept in the same horizontal line on all cards, so that by placing cards side by side paired values for correlation studies could be easily picked. It should be mentioned that the transferring of the data to these consolidation forms was subjected to a triple check. Simultaneously with this consolidation scheme all observations were coded, and as soon as a period for a given patient was completed the coded values were scored into frequency tables.

This system made it possible to compute descriptive averages such as arithmetic means and standard deviations at any given phase of the study. Frequency distributions of each variable were prepared according to the following scheme: distributions of all values per period, distributions of individual mean values per period, distribution of individual ranges per period, distribution of individual ranges over all periods and distributions of the differences of individual means by signs between two periods.

Besides this, in instances in which the number of observations warranted, as for example in the case of bodily temperatures and pulse rates, a separate distribution was prepared for each patient. Thus, for these two and a few other variables we obtained measures of variation for individual subjects, and from these individual standard deviations we prepared frequency distributions of this constant.

Approximately six thousand frequency distributions were plotted, and their constants computed. This furnished an ample basis for the determination of variation within and among subjects. Besides this, an analysis of seasonal trends was attempted for each variable.

The correlation of the many factors constituted the greatest part of the labor in the statistical offices. Many gross correlations were computed and the relationships presented in the form of scatter-diagrams. Contingency tables were frequently compiled as need demanded.

Finally, the statistical material on many of the different aspects has been assembled, and interpretative memoranda have been prepared.

SUMMARY

A cooperative project for the investigation of schizophrenia in its several aspects is described.

The functions of the laboratories devoted to organic and psychologic features of the research are outlined.

The methods by which psychiatric observations were made is discussed.

The recording and analytic methods used in dealing with the data are recounted.

The project has proved to be practicable and productive.

Grading of Patients in Mental Hospitals as a Therapeutic Measure

Milton H. Erickson, M.A., M.D., and R. G. Hoskins, M.D., Ph.D.

Published by American Journal of Psychiatry, Vol. XI, No. 1, July, 1931.

For the past four years the Worcester State Hospital has been carrying out a research project on the etiology and therapy of dementia praecox.[1] In addition to endocrine and other drug medication, systematic attention has been given to certain types of situational therapy. Among these, a plan of grading and promoting patients was instituted, and sufficient experience has now accumulated to justify a preliminary report of results.

The idea is by no means novel. An essentially identical plan was introduced into the Irish Convict Prison by Sir Walter Crofton in 1854. He established a method of classing the convicts into grades and of promoting them from a relatively simple environment through one of increasing complexity to that of normal, social life. During this process, an effort was made to stimulate the prisoners to self-betterment. That various similar plans have been employed in more or less elaborate form in mental hospital practice is well known. The common use of parole privileges, which, from the standpoint of the patient, constitute a reward bestowed for improved conduct, is one phase of this general plan. So far as we are aware, however, the method has not been employed sufficiently extensively and systematically, under controlled conditions, to permit an appraisal of its therapeutic value.

Ordinarily, the patient comes to the hospital in a state of high emotional tension that is a result of his unsuccessful attempts to cope with an over-trying environment. During the initial period in hospital, perhaps the most valuable feature is a simplified environment that relieves him, in a measure, of the necessity for a psychotic adjustment. After a time, however, the simplified situation is likely to have an effect as detrimental as it was at first favorable. The hospital environment tends to promote conformity, obstruct individuality, and deprive the patient of personal interests. He becomes "institutionalized," and develops habits of routine behavior which, coupled with natural human inertia, tend to keep him on the level of "good ward adjustment." The time comes when the psychiatrist desires to institute a more active regimen to stimulate the patient to take up once more the problem of self-realization. He then encounters the problem of motivation. He may give any amount of good advice, but be completely baffled by a spirit of "*cui bono*."

When the patient has reached this stage there is need for introduction into the ward management of some means of actively correlating his own personal interests with the hospital situation. This should be done in a forceful but unobtrusive way, taking into account the fact that the individual patient is highly ego-centric, and may be strikingly unable to visualize himself as psychotic and appreciate his situation as similar to that of his fellows. He cannot, therefore, readily be approached on any basis of common

experience as to what is good for mental patients. Any appeal must be personal. It must be acceptable, readily comprehended, and genuinely stimulating.

Since the great majority of patients have had several years' experience in the public schools, and have become conditioned to response to schoolroom routines, less resistance is to be anticipated if situational therapy can be given the coloration of schoolroom technique. In particular, the subjects are quite habituated to promotions as a result of active conformity to imposed routine. They are inclined to accept unquestioningly the abstract justice of this, as some of their comments quoted later will show.

The plan adopted in the Research Service of the Worcester State Hospital consists in a scheme of grading based chiefly upon behavior. It is formulated in terms comprehensible to the patients, rather than appealing to the scientific sense of the psychiatrist. An explanatory statement of the scheme is posted conspicuously in the wards. It consists of a series of paragraphs, and each is displayed as a large poster. Each poster carries the line, "Patients are sent home only from Grade B." In each ward is kept posted, also, a roster of all patients on the service, classified by grades. Each week a list of promotions and demotions is posted.

In all, seven posters are used, reading as follows:

THIS WAY OUT

All patients on the RESEARCH WARDS are graded according to their progress. As they improve they are promoted. They are sent home ONLY FROM GRADE B. If you want to go home, improve your grade.

Your doctor will explain.

GRADE A—AT HOME.
Able to act like normal people.
Able and willing to work.
Able to get along with family and friends.

GRADE B—GOING HOME.
Getting well enough to go home.
Working well.
Reliable on parole.
New interests and new ideas.
Old ideas controlled or understood.
Rebuilding mental strength to stay well.

Patients are sent home only from Grade B.

GRADE C—ON PAROLE.
Working and playing well.

Getting new ideas and interests.
Making the best of everything.
Cooperating well and obeying rules.

Patients are sent home only from Grade B.

GRADE D—FIRST CLASS ON THE WARD.

Keeping neat and tidy.
Working well and playing well.
Learning to take things as they come.
Beginning to understand old ideas.
Learning to cooperate in everything.

Patients are sent home only from Grade B.

GRADE E—SECOND CLASS ON THE WARD.

Working and playing poorly.
Lazy and shiftless.
Too proud of own ideas.
Not very cooperative.
Careless of clothing.

Patients are sent home only from Grade B.

GRADE F—THIRD CLASS ON THE WARD.

Mute, resistive.
Silent or too talkative.
Excitable and disturbed.
Not cooperating.
Not working or playing.

Patients are sent home only from Grade B.

PRACTICAL RESULTS

This scheme has now been in operation about six months. The poster material was displayed, one unit at a time, over a series of weeks. The first poster was placed in a well-lighted, prominent position over a door through which all patients routinely passed. After a few days it was removed to an alcove, and the second poster put on display over the door. Thus the whole Series ultimately came to be posted in the alcove, where each could serve frequently to reinforce the suggestions. From the first, the patients manifested a marked interest in the posters. A census revealed that at least eighty per cent were giving them their personal attention. Some patients were elated over their classification; others were disappointed and argumentative, though only one or two out of a hundred showed

any definite antagonism. Various illuminative criticisms were collected from the patients. Some of these may be recounted.

F. P. —"That's like being in school. You can get somewhere in school—just go from one class to another; only here you go home."

A. T. —"I'm in Class D. I don't think I can ever get in Class A, but I know I can get in C, and I'm going to do it."

J. T. — "You've got me in C. I belong in A." This patient protested for weeks and then began asking the nurses and attendants and physicians what to do to get in Class B, calling attention to every achievement in order to win promotion.

J. F. —"How long have I got to stay in F? "He was given an explanation and shown by the chart and answered, "Oh, I can do that. I'll be in E next week." (He was.)

S. R. —This patient is untidy, soiling himself night and day. Upon coming to the ward and noting his classification, which was F, he stared at it steadily for a half hour, then asked the examiner, "Am I in Grade F?" He was told that he was, and after ten minutes more study asked, "Do I have to stay there?" Informed to the contrary, after a long pause he answered, "Well, I won't."

T. A. —"You've got to go through that like you do in school, doctor, I want to be in C and then I'm going to get in B, and then I can go home."

E. M. —"That's silly-nonsense. They've got me in Class C. I'll show them where I belong. If they want more work, I can do it. I belong in Class B."

E. D. — "Doctor, can't you show me how to get up in the next class?"

A. C. —"When I first came here, I was in F, but I just had to do one little thing and then another, and then you keep going up, and now I'm in B."

An unforeseen element of value in the scheme is its effectiveness in eliciting the cooperation of the families of the patients. They became much interested in the grades given to their afflicted relatives. Not infrequently the visitors have taken a wholesome, active part in the therapy, urging greater effort upon the part of the patients, praising them for their progress, and, on their own part, developing new interests in place of the previous hopeless attitude. Promotions in some cases have been rewarded by the relatives by special gifts. There has been a definite increase in the number of visits. One mother commented: "Albert was in Grade F so long that I lost hope, and then when he got promoted to E, I felt happy. Now he is in D, and I want to come to see him every week to see how long it will be before he is in C." While the therapeutic effect of such an attitude of the relatives is difficult to measure its reality is unquestionable.

DISCUSSION

The plan described can be related directly to the underlying principles of psychiatry. A striking feature of the schizophrenic patient is the regression to immature levels of thought and behavior. The project is definitely planned to meet the patients at the childhood levels, to evoke childhood memories, and utilize earlier conditioning. Again, the simplicity of the plan broadens its appeal both to the patient of lower grade mentality and to the patient whose interest cannot be aroused in anything requiring much mental effort because of his preoccupation with his fantasy life. Particularly, the principle of graduated achievement is theoretically sound. To many patients in the lower grades, the feat of stepping at once into the highest grade seems impossible of accomplishment. The task of improving their status by a single grade, however, appears much less hopeless, and they are accordingly more inclined to make the necessary effort.

One of the most ominous features in the schizophrenic psychosis is a malignant sense of isolation. The patient's thinking tends to be exclusively in terms of "I " and "Me." To whatever extent he can be brought to think in terms of "We " and "Us," he is on the way to a cure. The plan under discussion is of some value in stimulating a sense of group consciousness. Moreover, it introduces the principle of emulation within the group, which reinforces the attention to the plural pronoun rather than the singular.

The plan is valuable in its constant repetition of suggestion, without becoming a stale and accepted part of a meaningless routine. This follows from the fact that the patient, with each promotion or demotion, has occasion to re-orient himself and thus reconsider the whole situation in terms of personal interest.

Perhaps the most significant element in the plan is its tendency to enhance the self-esteem of the patient. In practically every case, the schizophrenic psychosis exhibits a protective reaction to a sense of personal failure.[2] Each improvement in the patient's grade gives him a sense of accomplishment.

SUMMARY

A plan is described that is in successful operation as one feature in situational therapy in a research service devoted to the study of schizophrenia. The patients are formally divided into six groups in accordance with their psychiatric status. Each group is described in terms comprehensible to the patients, and to each group is assigned a grade letter. Patients are promoted or demoted from grade to grade in accordance with changes in the mental condition. All promotions and demotions are given ward publicity. This is an effective method of motivating efforts toward self-improvement and of stimulating hope in the individual patient. The method is widely applicable to state hospital practice, and yields excellent therapeutic results for the effort expended.

Evolutionary Factors in a Psychosis*

Milton H. Erickson, MA., M.D.

Published in *The Medico-Legal Journal*, May-June, 1931, Vol. 48, No 3.

* Material obtained from the records at the State Hospital for Mental Diseases. Howard, Rhode Island.

Introduction

The following case is presented for consideration for two reasons, first, because it shows the gradual evolution of a psychosis from definitely recognizable psychogenic strains and stresses and personality frustrations having their beginning in the patient's infancy and continuing without interruption by force of chance and circumstances throughout life; second, because it illustrates so well, in the author's opinion, the utter inadequacy of the present official system of classification of mental diseases. No diagnostic tag given this patient's psychosis can give any understanding of it. It is an affective disorder occurring at the age of menopause, but it is comprehensible neither as involutional melancholia nor as manic depressive, but only as the culmination of a life-long series of events and situations which the personality could not combat. In giving the case, only significant, positive data are presented.

Reason for Commitment

The patient, P. E., a white female 43 years of age, of German extraction, was committed to the State Hospital on March 24, 1930, because of a determined attempt to kill herself and her son by means of illuminating gas.

Family History

The familial history reveals sound ancestral stock. The parents were members of the wealthy class, well educated and cultured. The marriage, however, was most unhappy, separation occurring during patient's infancy, and divorce despite the Catholicism of the family during patient's years of puberty.

Personal History

Her birth and early development were normal, and her childhood was physically healthy. Her personality was described as that of a shy, sensitive, timid, cheerful person with a strong social urge and an attractive nature.

Her early home life was most unfortunate. Neither her father nor her mother desired her, and the role of an unwanted child was thrust upon her from the beginning. She was early sent to live first with one relative and then another, staying comparatively short times at each home, and none of the relatives were seriously interested in her. Her childhood life was barren and secluded and she was not allowed to play with other children. What few contacts she did establish were always interrupted by the transiency of her visit.

When about eight or ten years of age she was sent to convent schools for an education, but even then was not allowed to become well established in any one school but was periodically sent to another. She was, however, exceedingly clever in her academic work, and by the age of fifteen had received the equivalent of two years of high school. Her mother's divorce and subsequent remarriage when she was thirteen added further difficulties to her adjustment in the convent since she was looked upon with considerable askance by the other pupils, and her own intense religious training there made her mother's religious dereliction a source of considerable conflict.

Upon the completion of her convent education she was received into her mother's home but treated as a servant, since her mother disliked her and the step-father's attitude was only one of pity. She was restricted in all her pleasures, and her social contact of any significance was limited to a brief, surreptitious, innocent flirtation with a young man in the neighborhood. After two unhappy years at home she was sent around to the homes of various of the nobility related to the family, where she played the role of poor relation or acted as governess in return for her care.

Then at the age of nineteen, because she could get neither happiness nor satisfaction out of her situation, she decided to come to America. The money was loaned her by her grandmother, a debt which she later repaid to the last cent. Upon arriving in America she immediately took out citizenship papers, lived with an uncle in New York for a while, attending night school to improve her knowledge of English, and looking for work. She shortly secured a position as governess with a wealthy New York family and remained with them for somewhat over a year, teaching the children languages. She lost this position when the family decided to go abroad, securing another, and losing that very shortly through similar circumstances. A third and fourth position were likewise secured, but each time circumstances terminated her position and she was often hard-pressed economically.

After being in America for several years, she met a young man at a church social and fell very much in love with him and he with her. However, before the romance could culminate, the young man was suddenly killed in an automobile accident. At the funeral she met the young man's father, who became interested in this attractive young woman who had meant so much to his son. This interest developed into an affection, and at the age of 23 she married this man, who was 45 years her senior. Her marital life in general was very happy, but she played more the role of nurse and housekeeper to her husband than that of a wife. One child resulted from the marriage, a boy now 18 years of age, and this child has constituted the central interest in her life. During the last ten years of her

marital life her husband was very much of an invalid, and when he died four years ago she was not greatly disturbed emotionally.

There were, however, certain seriously disturbing factors in her marital life. First, her husband's family furiously objected to her, accusing her of having married her husband for a home and his money. Second, about fifteen years ago, she and her husband made unsound speculations, losing somewhere around, $16,000. This business loss forced her husband to return to his business of manufacturing roulette wheels, but his physical incapacity compelled her to take over the management of the entire shop. The seasonable nature of the industry and an economic depression, together with limitations of their economic means, caused her very considerable distress of mind. Then, following her husband's death, she had a series of protracted law-suits with his relatives concerning some landed property which he had left her. To free herself of these law-suits she was finally forced to buy them off, and in doing so she had to place a mortgage on the two houses she was left. She then absorbed herself in the business, hoping to earn enough money to give her son all possible educational benefits. However, business became progressively worse, and in October, 1929, she was forced to sell one of the two houses. Following this she became greatly distressed and much worried about the future solvency of her business. For week after week she attempted to devise ways of increasing her business and of securing additional income, fearful that it might be necessary for her son to discontinue school and contribute to her support.

Her acute psychosis began to develop in the latter part of February, 1930. She became increasingly depressed and increasingly interested in ways and means of committing suicide. She questioned her son in detail about methods of suicide, brooded a lot, and occasionally refused to speak. A week before her admission a package of razor blades was found in her belongings. Then on March 22, 1930, seemingly unusually cheerful, she called on some friends, returning about midnight, and finding her son asleep, she closed the doors and windows so that she could fill the kitchen with gas and have it overflow into her son's bedroom. However, the smell of escaping gas awakened her son and he secured medical aid in time to revive his unconscious mother. Although she seemed entirely rational the next day, commitment to the State Hospital was deemed advisable.

Physical Examination

Physical examination and Laboratory findings upon admission were essentially negative for significant clinical findings. The menstrual history was normal until the last three years, during which time there had been a gradual decrease of the menstrual flow with practically none during the last six or eight months.

Preliminary examination upon admission revealed a somewhat poorly nourished woman of 43, whose facial expression was one of marked depression and anxiety. Her general bearing suggested great emotional tension, and she was very restless and constantly moving, although her movements were slowly performed. She answered questions readily in a low tone, and explained that she had attempted suicide because she was afraid

that if she died or was sent to a hospital for mental diseases her son would be alone in the world and that she did not want him to be so situated.

Mental examination on March 27 revealed a 43-year-old white female of German extraction whose manner was one of depression and who shed tears very readily. She was somewhat retarded in her actions and thought processes, and her speech was slow and deliberate. She was fully cognizant of her situation and repeatedly and piteously asked to be allowed to return home. She gave a complete account of herself, going into all the details of her history accurately, as was determined later through separate investigation. She emphasized in particular the insecurity of her home situation as a child, her lack of sex instruction, her deprivation of social opportunities, her barren sexual life with her husband, her economic losses, the burden of her husband's care, and the economic stresses undergone following his death.

No definite delusional trends were obtained. She manifested no particular self-accusatory trends except the single statement, "I blame myself for worrying about trying to make my boy comfortable."

The patient's affective responses were those of very considerable depression. Connation and action were decreased. Associations and stream of thought revealed some slowing of her thought processes, but no actual blocking. No amnesia noticed, and there was no disturbance of her native powers of judgment. Her fund of information was entirely commensurate with her educational opportunities. Insight into her condition, however, was faulty, and she explained her conduct by saying, "I was upset when I did it. I know I was. I know it was wrong, but I was not insane."

Clinical Course

The patient's clinical course showed fairly rapid improvement in her condition. At first she was considerably depressed and agitated on the ward, asserting vaguely that the future was dark and foreboding, that she could see nothing but troubles and worry. She gradually began to improve, become smiling, cheerful, and agreeable. She took much interest in Occupational Therapy and in ward activities. Within a month she seemed to have entirely recovered from her depression. After six weeks she was allowed to go out for short visits during the day with her son, and on each occasion she adjusted excellently. About the middle of May, her son took her out for a ride one Sunday afternoon, and she cheerfully asked him to take her to their home for a short time. There, according to him, she began acting queerly, and looked through the medicine closet. Fearful of her intentions, he immediately took a bottle of iodine and some razor blades out of the closet and went out in the garden and buried them. When he returned a few minutes later his mother was gone. Neighbors and the police were called and all searched for her, but she was not found until the next morning where she had hanged herself in the basement after slashing her wrists deeply.

Diagnosis

Purely for classification purposes she was diagnosed *Involutional Melancholia*, with a differential diagnosis of *Manic Depressive, Depressed*. The former diagnosis was considered the more suitable since she was of proper age and since she had never shown the more or less characteristic cyclothymia of the manic depressive temperament.

Interpretative Summary

The evolution of this psychosis seems to be fairly apparent. Her entire life history is one of insecurity, deprivation, obstruction, and defeat. In her own subjective review of her life, she felt that everything that she had firmly desired had been denied her. Born in a disrupted home, discarded by her father, rejected by her mother, and forced from early infancy to find her home among intolerant and unwilling relatives, she was denied that sense of security so essential for childhood development. Going from pillar to post and never being welcome anywhere, she could never achieve that sense of being an essential and stable part of her environment. Denied social contacts as a child and changing homes before she could reap the benefits of whatever brief contacts she had, a sense of social starvation resulted and she failed to secure the foundations for an adult social structure in her life. Later, when sent first to one convent and then another for her education, she found herself an alien creature. To quote her own words, "I wasn't like the other girls. They all had homes and parents and friends, and I didn't have any." Further conflict developed when, as a result of her intense religious training in the convent, she attempted to assimilate the facts of her mother's divorce and remarriage. Finding no solution to these conflicts, she absorbed herself in her studies and easily became a star pupil, but after completing her education and achieving that sense of accomplishment, she returned to her mother's home, hoping in a vague, adolescent way that life would then hold something for her. But instead of securing an opportunity to capitalize her sense of accomplishment, she was treated as a servant and as an unwanted dependent, and sent around to the homes of various wealthy relatives to play the role of a poor relation. At about the same time her normal sexual development occurred, with consequent curiosity, but because of lack of instruction, social starvation, and the surreptitious nature of her one, futile, adolescent romance, she developed only a burning sense of ignorance, of inferiority, and of nameless shame.

By the age of nineteen her sense of maladjustment was so great that it forced her to the drastic resort of seeking her inalienable human right to happiness in a foreign country, namely, America, that land of El Dorado. This severing of her home ties, the emotional poverty of her life, and the necessity of earning her living in a foreign land under the handicaps of an alien constituted a most serious strain upon her personal resources and accentuated her feeling, already great, of personal inferiority.

But even in America the fates pursued her as harshly as they had in her native land. One position after another she lost through no fault of her own. Even the young man with whom she fell in love was accidentally killed, the subjective results of which can be best expressed in the patient's own words: "What could I do?"

Marriage to a man 45 years her senior, though not consciously realized, was obviously only a solution to her life-long problem of home and economic insecurity. For this solution she paid by compensatory conscientiousness in her marital life that rendered it only a life of duty well done. But in solving this insecurity problem, she frustrated her opportunities of self-expression. She was young and starved and eager for the joys of youthful, human, physical life, but all that she could attain was the task of being nursemaid to an old man, and her only escape was sublimation of her sexual desires in interest and affection for her son.

When, through unfortunate speculations, her house of cards came tumbling down and there was a gradual development of economic distress, she found her life-long plan of sacrifice and effort to secure domiciliary and economic security defeated. Along with this loss of everything she had striven for since childhood came the dawning realization of another loss. Her son, that central interest in her life and who constituted her only means of achieving sexual and emotional gratification, would soon be lost to her by emancipation from childhood dependency. Hence, in a psychotic effort to stay the inevitable actualities of life and to secure herself from further difficulties and changes, she attempted to kill herself and her son, thereby symbolically saving her life from wretchedness, despair, and loneliness, and adding to his an everlasting continuance of mother love.

Some Aspects of Abandonment, Feeblemindedness, and Crime

Milton H. Erickson, MD.

Reprinted from *The American Journal of Sociology*, Vol. XXXVI, No. 5, March 1931.

A total of 1,5oo adult white married male criminals in Wisconsin were selected. These included 170 cases of abandonment, of which 35 per cent were feeble-minded although the feeble-minded constituted only 18.2 per cent of all criminals. Relatively, 22.3 per cent of the feeble-minded committed abandonment as compared with 8.88 per cent of the non-feeble-minded. The degree of feeble-mindedness was essentially without import. Subjective causes for delinquency in abandonment cases were essentially economic distress and ill-health, with liquor playing far less part in these cases than in other offenses. Family size appears to constitute a factor in abandonment, with the larger families occurring more frequently among. the feeble-minded. World War service, conjugal incompatibility, and individual poverty constitute factors in both abandonment and crime. The disruption of the childhood home of the individual appears to lead directly to the production of social unfits. The foreign born feeble-minded contribute 230 to 245 per cent of their proportion of crime as determined by population ratios.

This study was undertaken to investigate whether or not the offense of abandonment, including desertion, non-support, and abandonment of dependents, is more a dereliction of the feeble-minded than it is of those of normal or nearly normal intelligence. In addition it was hoped to discover, if possible, some underlying factors and distinguishing characteristics of this particular malefaction and offender, and likewise to develop any relationships bearing upon crime and the criminal in general.

The material was obtained from the examination of the inmates in the penal and correctional institutions of Wisconsin, made by the Psychiatric Field Service of the State Board of Control during the period of July 1, 1924, to July 1, 192 7. From the total number of examinations only those histories of married white males were accepted. Thus the complications of race and sex were avoided and the unmarried excluded. A total of 1,500 cases was thus obtained. From these, a selection was made of all abandonment and all feebleminded cases-numbering 382 individuals-which were divided into the three groups: (1) “Not Feeble-minded Abandonment Cases,” numbering 109; (2) “Feeble-minded Abandonment Cases,” numbering 61; and (3) “Other Feeble-minded Cases,” numbering 212. The classification of “Feeble-minded” or “Not Feeble-minded” is based upon the results of the application of the Stanford Revision of the Binet-Simon Intelligence Tests given by a qualified psychologist, with the results confirmed in many instances by a retest and by a consideration of the history. The intelligence quotient of .75, accepted by the American Association for the Study of Feeble-mindedness, was taken as the dividing line between feeble-mindedness and non-feeble-mindedness.

That there is a very decided relationship between abandonment and mental deficiency was promptly ascertained. Among all of the 1,500 offenders, 273, or 18.2 per cent, are feeble-minded; whereas, among the abandonment offenders (who number 170), 61, or 35.9 per cent, are feeble-minded. Thus, although the feeble-minded constitute slightly less than one-fifth of the total number of offenders, they are responsible for nearly two-fifths of all abandonment cases.

This relative preponderance of the feeble-minded in abandonments is seen further by comparing the number of abandonment cases in the feeble-minded and the non-feeble-minded groups. Among the feeble-minded offenders (numbering 273), 61, or 22.34 per cent, are abandonment cases; whereas, among the offenders who are not feeble-minded (numbering 1,227), 109, or 8.88 per cent, are abandonment cases. That is, abandonment among the feeble-minded group is nearly three times as great as among the group not feeble-minded.

Accordingly, the correlation of mental delinquency with abandonment is not to be doubted, but whether that correlation is direct or indirect may not be stated here.

The degree of feeble-mindedness apparently does not influence this relationship to any appreciable extent. High grade morons (I.Q. of .60-.75) number 205. Among these, 45, or 21.95 per cent, are abandonment cases. Low grade morons (I.Q. below .60) number 68, and among these 16, or 23.52 per cent, are abandonment cases. It would seem, therefore, that the amount of intelligence possessed by the feeble-minded of any grade is insufficient to enable satisfactory coping with marital duties and responsibilities, with resultant dereliction.

Subjective causative factors underlying the offense of abandonment would be looked for most naturally among the “Reasons, Excuses, or Explanations” given by the delinquent. However, it must be recognized that the criminal’s rationalized explanation of his malefaction, unless substantiated by case work, is unreliable scientifically, and conclusions drawn there from must be made cautiously. Nevertheless, the very remarkable agreement as to causative factors between the two groups of abandonment cases-the feebleminded and the non-feeble-minded-is significant. Various outstanding reasons given are presented in Table I.

TABLE I

CLASSIFICATION OF CASES ACCORDING TO CAUSES FOR OFFENSE AS STATED BY INDIVIDUAL

	Total	Economic Distress		Ill-Health		Liquor	
		Number	Percent-age	Number	Percent-age	Number	Percent-age
Not feeble-minded abandonment cases	109	25	22.9	13	11.9	10	9.2
Feeble-minded abandonment cases	61	14	22.9	9	14.8	6	9.8
Other feeble-minded cases	212	10	8.9	1	0.5	50	23.6
Criminal cases in general.	1,500	233	15.5	35	2.3	296	19.7

Other reasons given, for which no significance could be found, were drugs, bad company, fun and excitement, other, not stated.

The surprising absolute agreement in the first subjective reason between the two groups of abandonment cases, coupled with the extensive disparity between the two groups of mentally deficient offenders, is strongly indicative that economic distress is a genuine factor in the causation of abandonment, even as it is in the offense of theft.[1] Further, the fact that the feeble-minded, despite their decreased earning capacity, give no greater indication of economic distress as a causative factor than do their intellectual superiors with greater earning capacity, stamps economic distress as a purely environmental factor for this offense. Particularly is this inference substantiated by the low percentage for the group of "Other Feeble-minded Cases."

Likewise in regard to "Ill-health" the high percentages in both abandonment groups and the practically negligible percentages in other groups indicates that this explanation is not an unreliable chance rationalization but that it is a factor of very definite significance. These percentages are suggestive of the fact that the multiplication of family cares by sickness on the part of the wage-earner and the unavoidable economic distress arising therefrom constitutes a deciding factor in the production of anti-social conduct, especially among the feeble-minded. Thus it appears to be both an environmental and an individual factor.

That alcoholism is still a potent factor in the production of delinquency would be a most ready inference if the percentages given above could be accepted at face value. However, to accept those percentages without question would be a dubious procedure, for the excuse of "I was drunk and didn't know what I was doing" and similar excuses are too easily made for any great amount of reliance to be placed upon them. That liquor does play a part in individual cases cannot be questioned, but in how many cases is another matter. In Table I, the high degree of agreement between the two groups of feeble-minded cases, and the extensive variance between the abandonments and other cases all indicate very strongly that liquor plays a definitely recognizable and somewhat measurable part in the causation of delinquency as has been shown previously by Pearson and Elderton,[2] and by Howard.[3] Further, the equality of percentages for the abandonment groups designates liquor, like economic distress, as an environmental factor.

Supplementing the impressions derived from the consideration of "Economic Distress" and "Ill-health" are the data on the "Social and Economic Responsibilities" of the offender given in Table II. As may be seen, there are more large families and fewer families without children among the abandonment groups. This shows that the heavy responsibilities of family life do occur most frequently among the abandonment cases, thereby indicating the family itself as a genetic force in the offense and giving additional weight to the deductions drawn above concerning subjective factors. In an individual of weak moral fiber, the constant demands of a family and related economic stresses may serve to push the individual beyond the pale of proper social conduct.

Further, the greater number of children and the greater number of families with children occur in the feeble-minded groups. This is in accord with the well-organized opinion of

authorities in general regarding the greater fecundity of the mentally deficient classes.[4]

A history of participation in the World War plays some part in abandonments, particularly in regard to individuals not feebleminded. Also, it plays an easily recognized but difficultly measured part in crime in general. Table III is the table of military service. To evaluate properly these percentages, it must be borne in mind that the criminal population is entirely unselected as regards physical condition, age, freedom from dependents, qualifications which obtain in the selection of men for military service. Accordingly, a percentage of the unselected criminal group exceeds in actual numerical value the same percentage of the military class coming within the same grouping.

According to the Census of 1920, of the general population coming within the age limits of the offenders included in this study, 12.1 per cent saw military service in the World War.[5] This figure, however, greatly exceeds its true value at the time of this investigation, since the constituency of the general population has fundamentally changed during the time since the close of the war and the beginning of this investigation, due to the attainment of majority by large numbers of minors. Bearing these considerations in mind, two facts stand out markedly in Table III: first, the percentage of ex-service men among abandonment cases not feeble-minded is disproportionately high; second, the percentage of ex-service men among criminals in general is likewise disproportionately high. That one out of every five of the not feebleminded abandonment cases is an ex-service man is strongly suggestive of a direct correlation between that service and the offense. However, it should be recognized that hasty marriages and post-war difficulties in civil readjustment account for a certain proportion. Aside from this, the disorganization of personality attendant upon military service constitutes an unquestionable genetic factor in this offense.

The second point mentioned above, the high percentage of ex-service men among criminals, has been previously noted by Lorenz,[6] who found over 25 per cent among Wisconsin offenders. This point reveals beyond doubt the potency of military service as a factor in delinquency. It plays a part directly by virtue of the disorganization of personality consequent upon military service and indirectly as a result either of post-war readjustment difficulties or of army-learned habits and morals carried over into civil life.[7] Further, when it is considered that the age of greatest crime incidence is eighteen to twenty-four years[8] and that the median age of criminals serving a term of one year or more is twenty-eight years,[9] the disproportion of World War veterans is markedly emphasized, inasmuch as they are beyond these ages. Accordingly, delinquency, even long afterward, must be regarded as a due toll of war.

The element of conjugal incompatibility undoubtedly plays a large part in the genesis of the offense of abandonment and the extent of divorce has been taken as an indication of

TABLE IV
COMPARISON BY NUMBER AND PERCENTAGE OF CASES DIVORCED

	Total	Individuals Divorced	
		Number	Percent-age
Not feeble-minded abandonment cases	109	36	33.1
Feeble-minded abandonment cases	61	17	27.9
Other feeble-minded cases	212	31	14.6

United States general population* – while, male, twenty-one or more years of age (percentage include widowed, separated, and divorced)	…	…	6.6

* United States Bureau of the Census, *Abstract of the Fourteenth Census* (1920) pp. 216, 218, Tables 52, 53.

marital disharmony. The figures for divorce among the various groups are presented in Table IV. The extremely high percentage of divorces among abandonment cases indicates, in all probability, the role played by conjugal incompatibility. And the increase of 180 per cent in divorces among the delinquent class over and above those of the

general population may be, and probably is, an indication of the characteristic instability of the criminal classes. Also, this prevalence of divorce is strongly suggestive that the criminally inclined individual is fundamentally lacking in the personal and social qualities requisite for the maintenance of family duties.

Poverty, credited generally by authorities with having no inconsiderable part in the genesis of crime, is manifest among the abandonment cases, as is evident in Table V. In this table, the term "Poor" signifies a hand-to-mouth existence, the term "Fair" the possession of a small amount of taxable property, and the term "Good" a comfortable, secure living with educational and cultural opportunities available. Such designations, while inexact and uncertain and without much meaning in individual cases, do possess considerable value in aggregate usage. Although percentages showing the economic

TABLE V
CLASSIFICATION OF CASES ACCORDING TO ECONOMIC CONDITIONS

	Total	Economic Distress		Ill-Health		Liquor	
		Number	Percent-age	Number	Percent-age	Number	Percent-age
Not feeble-minded abandonment cases	109	105	96.4	4	3.6	0	…
Feeble-minded abandonment cases	61	59	96.7	2	3.3	0	…
Other feeble-minded cases	212	183	86.4	29	13.6	0	…
Criminal cases in general – while, male, twenty-one or more years of age	2,350	2,096	85.5	342	14.0	12	0.5

status of the general population on a similar scale are not available, it is certain that the percentage of hand-to-mouth existences would fall short of that shown by criminals, and that in general the economic status of criminals is much lower than that of the general population.[10] This conclusion is concurred in by Gillin, Garofalo, and Sutherland in their respective texts upon criminology. The greater extent of poverty among the abandonment cases enhances the value of the inferences drawn above concerning the criminogenic force of economic distress in abandonment. Also, the similarity of the percentages for the two groups of abandonment cases emphasizes the environmental nature of poverty as a factor in the dereliction of abandonment. However, it is not to be inferred that a disappearance of poverty would herald the end of crime.[11]

Disruption of the childhood home of the individual also plays a part in the production of crime, as is indicated by Table VI. As may be appreciated readily, the percentage of disrupted childhood homes is surprisingly high. Shideler has estimated, apparently soundly and conservatively, that 2 5 per cent of all children, as compared with from 40 to 70 per cent of all delinquent minors,[12] come from disrupted homes. Healy,[13] and Healy and Bronner[14] have shown that at least 50 per cent of juvenile delinquents come from disrupted homes; and Sutherland, in his study of literature, has concluded that the disrupted home occurs twice as frequently among delinquent minors as among

TABLE VI
CLASSIFICATION OF CASES ACCORDING TO HOME CONDITIONS
PREVIOUS TO INDIVIDUAL'S EIGHTEENTH BIRTHDAY

	Total	Home Broken		Homes Disrupted by Death, Divorce, Desertion, or Separation	
		Number	Percentage	Number	Percentage
Not feeble-minded abandonment cases	109	70	64.4	39	35.6
Feeble-minded abandonment cases	61	44	72.2	17	27.8
Other feeble-minded cases	219	152	71.7	60	28.3
Criminal cases in general – while, male, twenty-one or more years of age	3,000	1,755	58.5	1,245	41.5

non-delinquents.[15] And the assumption that the same conditions would hold true among adults is justified by Table VI. Further, Lorenz, in his study of three hundred ex-service men in penal institutions, found 59 per cent coming from disrupted childhood homes.[16] Thus it may be considered that the disruption of the childhood home, probably through increased economic difficulties, the deprivation of educational and developmental opportunities, and the failure of the normal guiding influences of home training, constitutes a handicap to correct social development and may lead to the causation of antisocial behavior. The decreased percentages for the feeble-minded groups suggest only the decreased value of such homes.

Another important contributor to delinquency, including abandonment to an equal extent, is the element of unselected foreign stock, as may be judged from Table VII. It is at once evident that the foreign-born stock does produce considerably more than its due quota of our specified delinquents. Particularly is this so in regard to the feeble-minded groups which show an average of 166 per cent

TABLE VII
CLASSIFICATION OF CASES ACCORDING TO NATIONALITY AND PARENTS

	Total	Native Born		Foreign Born		One Native One Foreign	
		Number	Percentage	Number	Percentage	Number	Percentage

of the expected quota of foreign parentage. Similar findings were noted by the Immigration Commission of 1910[17] and by Laughlin[18] and by the Massachusetts Department of Corrections." The inherent danger in unselected foreign stock is evident.

That the foreign-born individual of sound stock is not an undesirable is evident from Table VIII. As may be seen, both in regard to abandonment and to crime in general, the not feeble-minded foreign-born individual is responsible for no more than a fair share of crime as determined by population ratios, and is no worse than his native-born brother. But not so of the feeble-minded stock. As shown, 14.8 per cent of the population at large are of foreign birth as compared to 34.4 per cent to 36.6 per cent of the mentally deficient delinquents. This places the proportion of crime by foreign born feeble-minded offenders at 233 per cent to 247 per cent of their fair quota. The need of more extensive immigration culling is evident.

**Abstract of the Fourteenth Census of the United States* (1920), p. 97, Table 21.

SUMMARY

The conclusions reached in this investigation are as follows:

1. There is a decided relationship between feeble-mindedness and abandonment, feeble-minded abandonments occurring proportionately nearly three times as frequently as abandonments of comparable individuals of normal or nearly normal intelligence.
2. The degree of feeble-mindedness, whether high or low grade, appears to have no influence upon the tendency to commit abandonment.
3. Economic distress appears to be a very considerable factor in the causation of abandonment, and as such it is of an environmental nature.
4. Ill-health on the part of the wage-earner appears to be a causative factor in abandonment and appears to be both environmental and individual in nature.
5. Alcoholism as a causative factor in abandonment appears slight in extent and environmental in nature.

6. Abandonment cases tend to have the greater number of families and the greater number of children as compared with other offenders, thereby indicating the element of the family as a genetic factor in the offense.
7. A disproportionately high percentage of ex-service men are included among delinquents, particularly so among abandonment cases of normal or nearly normal intelligence.
8. Conjugal incompatibility, as indicated by the extent of divorce, is a generative force in abandonment.
9. Poverty of the individual seems to have a very definite part in the causation of abandonment as well as in the production of crime in general, and it appears to be entirely environmental in nature.
10. An unduly large percentage of individuals of normal or nearly normal intelligence, for both abandonment and other offenses, come from disrupted homes of childhood.
11. Individuals of foreign parentage are responsible for a definitely increased quota of crime in general, as determined by the population ratio.
12. The mentally deficient individual of foreign birth is responsible for an overwhelmingly great excess of crime over and above his fair quota as determined by population ratios, an excess ranging between a 30 per cent and a so per cent, and manifest both in abandonment and in crime in general.

An Interpretation of a Case of Biological Deviation

Milton H. Erickson, M.D.

The Medico-Legal Journal, November-December 1930. Vol. 47, No. 6.

Introduction

The following case is offered for consideration because of its social, medical, legal, and psychiatric interests. It represents a problem with which society must deal, for which clinical medicine can give no help and the law can offer only retaliative, punitive, and destructive measures, while psychiatry as yet affords only a little understanding of it and gives a small measure of hope mixed with despair.

Reason for Commitment

The patient, W. H., was committed to the state hospital following his third arrest in so many months for indecent exposure. On the first arrest he was merely reprimanded and the second time he was placed on probation, the violation of which culminated in his third arrest and commitment.

Family History

The family history was fairly adequate and revealed nothing of psychiatric significance. His forbears were all of good, substantial peasant stock. The home training was rather rigid and narrow, but not unkind or harsh.

Personal History

The patient is the second in a family of ten siblings, three of whom died in infancy from causes unknown. The others, exclusive of the patient, are living and well, and are all good substantial citizens.

The patient's birth, infancy, and childhood development were normal. He suffered the usual childhood infections, but was never seriously ill. He was alert, nervous, quick bright, and energetic in his play as a child and manifested no peculiarities or abnormalities until shortly before the age of puberty. At that time, when about ten years old, instead of becoming interested in the rough and tumble games of boyhood, he learned to bake and cook. Sweeping the floors and making the beds was part of his fun. Washing dishes, that bane of budding manhood, had greater lure than building caves or following the leader. Yet, when he did play with the boys on occasion, he held his own against them and was accepted in full fellowship.

At the age of puberty, which occurred between twelve and thirteen years, he began the practice of masturbation, accepting the practice as a matter of course. He never worried about it nor became greatly enslaved by the habit. Along with this experience a new and much more forceful sexual interest developed. This lay in staring at women's forms, commenting obscenely on their figures, and telling and listening to bawdy stories. This interest was never accompanied by any overt act, but even his interest in housework was second to it.

Patient graduated from a convent school at the age of fifteen. He was considered of average intelligence and did fair work. Following graduation, he went to work in the mills, learning the trade of weaving. He was always a capable and efficient workman, and was very well regarded by his employers, though generally disliked by his fellow workmen because of the contrast between his production and theirs. During dull seasons when the mills were closed he worked in his father's store, an occupation which greatly interested him. However, despite his daily work in the mills, he continued to do a considerable share of the housework, often arising early to anticipate his sister in the tasks.

His first heterosexual experience occurred at the age of seventeen and his part in the episode was passive throughout, the girl taking the initiative entirely. His attitude was one of mere interest and curiosity, and although he had an ejaculation, he derived no particular sense of satisfaction. His next experience occurred in a bawdy house where he was taken by some friends, who, knowing the intensity of his vocalized sexual interests, felt a need of greater sophistication in him. This experience afforded little more pleasure than the first, but it did lead him to frequent the place regularly in an effort to obtain satisfaction and to become a "regular fellow." Thereafter, he visited the bawdy house more frequently, sometimes taking his pleasure in normal fashion and striving to be like his fellows, and sometimes yielding to his unsatisfied sexual desires and taking his pleasure in the perverse form. There was gradually adding to his list of sexual pleasures cunnilingus and mutual masturbation, all of which offered him more pleasure than normal relations.

At the age of nineteen he contracted a Neisserian infection and was somewhat worried and frightened about it, though assured by his comrades that it was of little moment. A few years later he contracted syphilis and was intensely worried about it. The physician whose aid he sought outlined a course of treatments, charging him $25.00 for the first one. The patient was then plunged into despair since he could not afford further treatments, and yet he had heard alarming tales of the horrors of untreated syphilis. He paced the streets in an anxious, frightened, and tearful state of mind, wondering what to do since he was without funds and he suspected his father's stern and unforgiving attitude. As he walked along, absorbed in this problem, he met a sympathetic stranger, and was advised, since he could not pay for treatment, and that his parents would not, he could easily obtain free treatment by getting sent to jail for a few months. The patient readily accepted the suggestion and joined this stranger's crew of robbers, breaking into a store that night. The patient was easily caught by the police, and because he played a minor part, was given a sentence of six months, and at the same time free treatment for

his syphilis. Following his release from jail he continued in his former habits of life, seeking the company of prostitutes frequently and practicing perversions more often than normal relations, since he felt that such a course rendered him less likely to contract disease and at the same time afforded him infinitely more pleasure and satisfaction.

At the age of twenty-five he met the daughter of a fairly respectable and substantial family to whom he became greatly attracted. During the year of courtship that followed she successfully resisted his attempts at pre-marital relations and he confided to her that he was taking "sal hepatica" almost daily to keep away from other women. Following marriage, sexual relations were normal, though his demands were excessive, pregnancy occurring within three months, following which the patient's wife discovered that he was practicing coitus interruptus and then secretly masturbating. The patient readily admitted this to her and then explained that he derived more satisfaction from onanism than normal relations with her. During the latter part of this pregnancy the patient returned to his celibate sexual habits. Nevertheless he continued to have regular congress with his wife, lest she suspect him. In these extramarital affairs he usually resorted to perversions. This infidelity he kept concealed from his wife for the next five years, during which time he was a model husband in helping with the housework, taking care of the babies that arrived regularly every two years, and in working industriously to support the family. However, he was often harsh, disagreeable, and irritable, and at these times he was extremely inconsiderate and excessive in his sexual demands in a vain and frantic attempt to educate himself sexually to respond like other men and to escape from the cravings of auto-erotism and perverted desires.

About three years previous to his commitment his wife began hearing rumors about his sexual exploits and upbraided him concerning them. The patient ridiculed her reproaches and boastfully told her that she was helpless, that he was too smart for her, and that she could never get the legal proof necessary to send him to jail. He declared that he was entitled to sexual pleasure, and since he could not get it from her he would seek it elsewhere. Bitter quarrelling resulted and for three months they did not speak to one another. Finally their quarrels were satisfactorily adjusted and they lived fairly happily except for patient's excessive demands. Then, after some months, the wife discovered that he had again fallen back into his old habits. This gave rise to further quarrelling, and then the patient openly returned to his former licentiousness, and for the next year spent every weekend in company with some mistress and often during the week arising early in the morning and visiting some brothel before going to work. At the same time, because of his absolute insistence, he maintained marital relations with his wife, often practicing coitus interruptus followed by masturbation.

A year before admission he underwent an operation for hernial repair and appendicitis from which he made good recovery. Following this more quarrelling about his sexual habits occurred with finally a readjustment with his wife and a forsaking of his practices. Home life was then fairly happy when suddenly a period of economic distress developed because of a business depression. Work was scarce and the mills were frequently closed two or three days a week. The patient's wife had to seek employment to aid in supporting the family of five children, and often the patient was left alone to care for the family

while his wife was away at work. He worried greatly about this, since, despite his conduct, he was intensely attached to his children and his home. He tried to compensate his wife at this time for the scurvy fashion in which he had treated her. He lessened his sexual demands upon her, and expressed contrition for his misconduct, and strove in every way to merit her favor. At the same time he worried increasingly about the economic straits the family was reaching, and daily sought to secure additional employment. Then suddenly he developed the habit of going into a dark room every night and staring into the houses across the way in the hopes of seeing women undressed. Then one day he rapped on the window to attract the attention of passing school children and exposed himself, following which he masturbated in the next room. The next day he exposed himself to a woman and a girl, masturbating immediately afterwards in the next room. After several such episodes he was arrested and released with a severe reprimand. The patient's only explanation at that time was that an uncontrollable influence forced him to such conduct, and that it gave him a sense of infinite satisfaction and relief from his worries for the family. Several weeks after his first arrest he was again apprehended for a series of repeated exposures. This time he was placed on probation with drastic warning. Three weeks later he was again caught in the act, after a number of complaints, and was committed to the state hospital for observation.

Physical Examination

Physical examination upon admission revealed a French-Canadian male, thirty-five years of age, of athletic habitus, in good physical condition except for gingivitis, much dental repair work, imbedded tonsils, and old healed appendectomy and herniotomy scars.

Laboratory Findings

All laboratory findings were within normal range except the serological, which revealed a negative Kahn but strongly positive blood Wassermann.
The cerebrospinal fluid was suspiciously positive and the colloidal gold and mastic readings were respectively 1111121200 and 01332. Other findings were of no import.

Mental Examination

Preliminary examination upon admission found the patient to be friendly and agreeable, frank and accessible. He discussed his troubles and answered questions fully and completely, attributing his situation to the habit of masturbation and giggling and simpering in an exceedingly foolish fashion as he told his story. When the physical examination was made, the patient threw off all covers and demanded to know if the examiner did not think his figure lovely and perfect, giggling foolishly as he did so. Though in excellent contact with his environment he seemed to have no critical appreciation of his situation.

Formal mental examination performed five days after admission revealed an alert intelligent thirty-five year old man who discussed himself spontaneously and fully, co-operating in every way. While he seemed to have an excellent appreciation of his

situation, nevertheless he would at times giggle foolishly and ask boastfully, “I’m pretty good, ain’t I?” and then the next moment would weep bitterly, lamenting his situation and worrying about what would happen to his family. He gave a very complete account of his entire life including his sexual activities, and blaming present difficulties upon parental failure to instruct him concerning masturbation, and his native endowment with “hot blood.” His exhibitionism he attributed to an uncontrollable impulse that forced him to such conduct and the sense of relief from his worries which it afforded him. The patient’s thought processes were clear and coherent and his ideational content revealed no delusions though questioned specifically for the various types. No disorders in the perceptual field were elicited, and there was no impairment of the sensorium. As for insight, the patient’s own statement illustrates best: “I have done a shameful thing. I don’t know why I did it. But I’ve learned my lesson now.”

Clinical Course

The patient’s clinical course was one of gradual and satisfactory improvement. He rapidly lost his silliness and foolishness, and his reactions became normal in every regard. He developed a sound appreciation of his predicament and appeared to have a full realization of the utter undesirability of his social behavior. He wrote many letters to his wife expressing his contrition for the hardships he had caused her and promising complete reformation for the future. In this he appeared to be wholly sincere and there was no attempt on his part to gloss over his offenses or to minimize them in any way. On the contrary, he seemed to have a healthy sound appreciation of himself and the difficulties confronting him. He was soon given parole privileges and proved himself to be fully co-operative and trustworthy. For his luetic condition arsenicals were administered with good results. After several months he was discharged and to all information available at the present time he is adjusting satisfactorily in the community.

Diagnosis

For classification purposes, he was labeled Constitutional Psychopathic Inferior without Psychosis. No attempt was made to determine the part played by his luetic condition since the extent of such a role would be a matter of pure speculation. Further, it was believed that his conduct might well be explained on the basis of his biological deviation which led to progressive maladjustment until the situation was beyond his control. Nevertheless, the label applied to him was recognized as being wholly inadequate to describe him, but no better recognized term seemed available.

Interpretative Analysis

Fundamentally, this patient is a biological deviate whose sexual nature is disorganized and distorted by an ambivalence of interests leading to various forms of perversions and arresting the full rounded development of his powers of sexual expression.

At the boisterous age of boyhood when mother’s apron strings are galling and housework degrading, he was busy making beds and sweeping floors instead of fighting and

following the leader. But, even so, he could and often did mix successfully with his fellows, and his strength of personality compelled their full acceptance of him.

Then at the age of puberty, when girls are anathema, and the narcisstic role holds sway, masturbation had little interest for him. On the contrary, he was precociously heterosexual, staring at women, commenting obscenely upon their figures, and listening avidly to erotic stories. Yet, despite this intense erotic interest in the opposite sex, remarkably so because of the unquestionable opportunity afforded by his social status, he made no effort to express this interest actively until adolescence. Then his first experience was conditioned by his passivity and disappointment since he obtained little pleasure and no real satisfaction. He strove correct this by regularity of visits to brothels, but all efforts to secure satisfactory sexual relations in normal fashion were defeated. He turned to perversions, deriving from them infinitely more pleasure than from normal connections. At other times, endeavoring to emulate his fellows and to achieve their sense of accomplishment, he would establish normal relations, but instead of that primitive needed sense of masculine satisfaction reaped only misery and fright of Neisserian and luetic infections. He then demonstrated the innate weakness of his inhibitive powers and the faultiness of his judgment by participating in a robbery as a means of securing adequate treatment which he himself could not purchase These experiences seriously weakened his normal sexual tendencies and strengthened the trends of his biological deviation. Marriage was then essayed in an endeavor to reach the plane of sexual adjustment and contentment attained by his fellow workmen. But normal femininity in the dull placidity of average marital life could give him little. All it gave him was a continuance of his interests in domestic tasks and he shared his wife's duties, never graduating, even in that sphere, to the full masculine level. Since marital relations were unsatisfying, recourse to masturbation resulted, but even that failed to fill for him the void of sexual expression. Accordingly, he returned to his bawdy house habits, seeking, in the very perversity of his social conduct and the perversions there available, a fuller sexual satisfaction, maintaining at the same time normal marital relations, sometimes to wild excess, in a vain endeavor to establish a balance in his instinctive drives, and to achieve that sense of sexual normality and security possessed by his fellows. But rumors of his misconduct came into his home with disrupting force, threatening to disintegrate it and to rob him of his family, in which he was intensely interested, though probably more in a maternal and feminine rather than a paternal masculine fashion. Torn between conflicting desires, after a wild and reckless abandonment to sexual claims, he yielded to the burden of marital and paternal duties, forsaking his hopes in instinctual adjustment. But scarcely had he done so when a new and equally serious difficulty harassed him. Economic distress, in no wise his fault, and against which he had no defense, threatened the security of his home. The one stabilizing influence upon which he could rely was threatened. He struggled against it, frantically, fearfully, but helplessly. He had to do something, yet, what could he do? In the disorganization of his personality established by his biological deviation and the conflicts of his desires, he turned again to sexuality, exhibiting a new perversion which society could not condone.

In the quiet of a state hospital, free from the cares and responsibilities of life, he was aided to a new understanding of himself. How well he learned his lesson, and how much it will help him is entirely problematical, and the possibility of a happy satisfied life, the rightful desert of every man, is highly questionable. But at least those who dealt with him understandingly learned somewhat of the utter inadequacy of social, clinical, legal, and psychiatric measures.

Marriage and Propagation Among Criminals

MILTON H. ERICKSON, M.D.

In the preparation of this article, two previous papers have been drawn upon freely for data and interpretations with the addition of further data from the original source. The papers utilized are "Some Aspects of Abandonment, Feeblemindedness, and Crime," manuscript accepted for publication by *American Journal of Sociology*, 1929; and in particular, "A Study of the Relationship between Intelligence and Crime," *American Journal of Criminal Law and Criminology*, February, 1929, Vol. 19, No. 4, Part 1, pp. 592-635, and also, *Medico-Legal Journal*, Vol. 45, Nos. 4 and 5, 1928.

INTRODUCTION

Marriage has long been recognized generally as a significant stabilizing influence in individual and social life.[1] With apparent good reason, it has been accredited with an actual moral force in the prevention of undesirable social conduct by providing happiness and stimulating worthy activity.[2] To how great an extent it may serve as a stabilizing influence and as a preventative of unsocial or antisocial conduct is a question worthy of investigation. Accordingly, an attempt is made herewith to throw some light on this question by a study of over 3,500 criminal cases, with a view to the establishment, either positively or negatively, of the possible existence of such stabilizing and prophylactic influences of marriage upon the individual criminal. Since the possibilities of absolute and direct proofs are vague and questionable, indirect evidences of such marital influences were sought and are presented here.

MATERIAL AND METHOD

The material for this study was obtained from the case history files of the Psychiatric Field Service of the State Board of Control of Wisconsin. In these files are kept records of the routine physical, sociological, psychological and psychiatric examinations made of *all* individuals admitted to the various state penal and correctional institutions as well as those becoming eligible for parole therefrom. The institutions yielding material for this investigation were the Milwaukee County House of Correction at Milwaukee, the Wisconsin State Prison at Waupun and the Wisconsin State Reformatory at Green Bay. The time covered by this observation extends from July 1, 1924, to March 1, 1929, a period of nearly five years. From the total number of examinations made in this period, a selection was made based on race, sex and age, only white males twenty-one years of age or more being taken. These limitations were established to avoid the complications of race and sex and to include only individuals of marriageable age, thus excluding minors who may not in complete fairness be compared with adults, particularly in such a study as this. A total of 3,643 cases was obtained in this wise.

These cases were then classified first according to the level of their intelligence, i.e., whether feebleminded or not feebleminded. This classification was made to render an added significance to the findings in regard to marriage and its results among criminals. It should be stated here that the grading of intelligence was done at the time of examination by the application of the Stanford Revision of the Binet-Simon Intelligence Tests. These tests, were applied by a qualified psychometrist with the results confirmed, in many instances, by a retest. In addition, the history of the individual was always given its due weight in the diagnosis of feeblemindedness or non-feeblemindedness. The intelligence quotient, or I.Q. as it is commonly termed, of .75, approved by the American Association for the Study of Feeblemindedness, was taken as the dividing line between mental deficiency and non-feeblemindedness. Also, in accordance with the table given by Richmond[3] and agreeing with Terman's classification,[4] the I.Q. of .60 was taken as the dividing line between the high grade and the low grade feebleminded. Next, maintaining the first classification as to the level of intelligence because of the added weight given thereby to the findings in regard to marriage, the cases were secondarily classified according to marital status. Third, those married were then classified in accordance with family size. A careful analysis was made of the respective tables thus obtained, both for any intrinsic significance possessed and for any bearing they might have upon one another and upon the theme of this paper.

DISTRIBUTION OF INTELLIGENCE

Since the recognition of the utility of studying the individual criminal as such, there has been a growing realization of the necessity of understanding and appreciating the extent and nature of his mental and intellectual endowments in order to comprehend his economic and social activities. With the development of standardized psychometric tests, a valuable means of estimating the intellectual endowment of the individual became practicable. The results of the application of these tests to the offenders included in this investigation show the following general distribution

	No. of Cases	*Per cent of Cases*
Non-feebleminded (I.Q. .75 or more)	2,587	71.01
Feebleminded:		
High Grade Morons (I.Q. .60 to .75)	332	22.84
Low Grade Morons (I.Q. below .60)	224	6.15

Very evident from the above table is the astonishingly high percentage of mentally deficient individuals among criminals, if 3,643 cases may be considered a fair sample of delinquents. In this particular investigation, the percentage of feebleminded is shown to be 29. The magnitude of this may be better appreciated when it is realized that the ratio of the feebleminded in the general population has been placed at one in two hundred by a series of surveys in various states and confirmed in results by similar findings in Europe.[5] Terman, however, in a study of 1,000 unselected school children, found approximately 3 per cent with intelligence quotients below 75;[6] and Gillin, after a careful consideration of the literature on this question, has estimated a proportion of 2 per cent of the general

population as mentally deficient.[7] Thus the ratio of feeblemindedness among criminals is here shown to be at least 13 to 50 times greater than that of the general population! These findings have been repeatedly confirmed by other investigators. Kuhlmann has found an average of 29.1 per cent of the inmates of the reformatories of Minnesota feebleminded;[8] Slawson, working with delinquent boys in New York State, found 20 to 25 per cent feebleminded.[9] Anderson, after his investigations of the problem, reached a conclusion that 27 to 29 per cent of all prisoners are mentally deficient;[10] and the Psychiatric Field Service of the State Board of Control of Wisconsin, in a total of over 8,000 examinations of delinquents, has found an average of 27 per cent of all offenders feebleminded.[11] Accordingly, the genetic force of mental deficiency in the production of crime is not to be doubted. Indeed, Goddard, after his long study of feeblemindedness, reached the conclusion that every mentally deficient individual is a potential criminal.[12] The seriousness of this hardly needs mention. Whether the role played by feeblemindedness in the production of crime is direct or indirect is not a proposition to be decided here, nor does that question lessen the grave significance of mental deficiency in relation to delinquency. Indeed, this evident relationship between mental deficiency and crime intensifies the need of constructive social legislation for the amelioration of the problem of feeblemindedness and its entailed problem of criminality. It also suggests the great need of scientific investigation, particularly of the marital tendencies, status and results, of the mentally deficient and mentally defective classes with a view toward the elimination of the species.

The second revelation of the above table is that fully 20 per cent of the total number of criminal feebleminded or 6 per cent of all delinquents coming within the scope of this investigation are low grade morons. The significance of this is better appreciated when it is realized that the lack of intelligence in low grade morons is so great that authorities are agreed that they can be cared for properly only within the confines of an institution designed for that purpose.[13] Indeed, the capacity of the low grade morons for social and moral responsibility at law is nil according to Richmond[14] and Kuhlmann[15] after long study of the problem, and these investigators feel that even in regard to the high grade moron legal responsibility is frequently “debatable and subject to proof.” Yet these delinquents with such marked deficiency of intelligence and with their manifest and proved social and moral irresponsibility are allowed to serve their terms unrecognized legally for what they are. Then they are discharged and permitted to return to free society for which they are unfit socially, morally and economically, there to reproduce their kind and to continue their contribution to the crime problem. That they will is not a matter of mere pessimistic speculation, since, to the low grade moron, consideration for others, altruism, probity, and moral and ethical principles are vague incomprehensible things. In his intellectual blindness he gropes and stumbles through the social maze of life, wandering into forbidden paths all along the way, knowing no better and unable to know better. And what is worse, the road to marriage and the reproduction of kind is open to him without manner or form of restriction. The existence of the species to the extent of 6 per cent of all criminals proves the continued propagation of this socially unnecessary and destructive class which must be eliminated if any approach to the social millennium is ever to be made.

DISTRIBUTION OF MARRIAGE

Since the criminal is essentially unstable in nature and character, a decreased incidence of marriage or an increased disruption of marriage might reasonably be expected among his class. In substantiation of this inference is the report of the census bureau which states that the unmarried among criminals outnumber the married more than two times per 100,000 population of the age of 15 years or more.[16] However, this is undoubtedly a distortion of the truth since the criminal population with that age limit cannot be judged simply by mere division into married and unmarried groups. The reason for this lies in the fact that, according to the census reports of 1904[17] and of 1923,[18] the age of greatest crime incidence lies between fifteen and twenty-four years. Accordingly, the criminal population with the above age limit would include a disproportionately large number of juveniles and adolescents not yet of marriageable age. Thus the proportion of the unmarried would be illogically increased. Nevertheless, it is entirely reasonable to presume that there is a disproportion between the married and the unmarried delinquents in comparison with similar figures for the general population. In this investigation, only individuals of undoubted marriageable age, i.e., twenty-one years or over, have been taken and the findings in regard to their marital status are given 111 the following table together with similar findings for the general comparable population of the United States .[19]

	Unmarried		Married		Divorced*	
	No. of Cases	% of Cases	No. of Cases	% of Cases	No. of Cases	% of Cases
Not Feebleminded	1,118	43.22	1,469	56.78	346	23.55
Feebleminded	442	41.86	614	58.14	132	21.50
U. S. General Comparable Pop**.		25.10		74.90		9.66***

*Percentages based on total of married individuals for both criminal and general populations.
**Male, white, and twenty-one years or over.
***Includes both widowed and divorced.

As may be readily seen, there is no striking disproportion between the married and the unmarried among the criminal classes. The one status obtains almost as frequently as the other, with a majority in favor of the married. Comparison, however, with the similar percentages for the general comparable population of the country shows a decidedly lower incidence of marriage among criminals of all types. Interpretation of this phenomenon is difficult. It may signify that there is a stabilizing influence of marriage with a greater proportion of the unmarried running afoul of the law; or it may mean that the internment of the criminal often constitutes an actual physical barrier to the consummation of marriage; or it may merely denote that the fundamental constitution of the delinquent is of such a nature that he is not infrequently antagonistic toward the assumption and maintenance of marital duties and thus fails even to experience contact with any presumably stabilizing influences of marriage. At any rate, marriage, together with any of the beneficial influences it may exert upon the individual, is of decidedly less frequent occurrence among the criminal population than among the general population.

A second point of interest in the above table is the fact that the percentage of married individuals among the feebleminded is equal to that for the non-feebleminded. Evidently,

even the combined defects of criminality and mental deficiency fail to constitute a barrier to the marriage of the unfit with the consequence that the propagation of the socially undesirable classes is given opportunity to keep pace with that of the desirable classes. This fact emphasizes the need for proper recognition of this problem and provision for its solution.

Further, that over 50 per cent of criminals, feebleminded as well as non-feebleminded, are married and thus propagating their species with the sanction of society is somewhat disheartening. However, a more hopeful aspect of the matter is obtained by bringing into consideration similar statistics in regard to the marriage of college 'graduates who undeniably represent the better stock of the land. Investigation into the alumni records of Harvard and Yale for the period of 1851 to 1890 show the percentages of male graduates married ranging between 74 and 78 per cent.[20] A similar investigation at Syracuse University covering a period of 50 years reveals 81 per cent of the male graduates married[21] and similarly, Stanford University has a percentage of 73.2 per cent of the men of the classes from 1892 to 1900 married.[22] Thus, a comparison of these percentages with those of delinquents affords a hopeful eugenical outlook. Likewise, it emphasizes the lower incidence of marriage among delinquents as compared with the incidence among the better classes. The figures given in the above e table are less than their ultimate value inasmuch as more marriages will occur among the offenders herein under investigation, but the possibility of their marriage percentage ever reaching the level of that of college men is extremely doubtful since the likelihood of marriage decreases progressively with each year of life after the first half of the third decade.[23]

Another instructive aspect of the above table is the unusual frequency of marital disruption among the criminal classes as compared with the general population of the country. Divorce alone is accountable for more than twice as much marital disruption among delinquents as divorce and death together for the population at large. However, it should be borne in mind that conviction for felony constitutes grounds for divorce in Wisconsin and several other states. Though this fact does account for some of the increased disruption, it is not conceivable that it would account entirely for the markedly higher incidence of divorce among criminals. Particularly does this seem to be more tenable since the proportion of divorce is essentially the same for both the feebleminded and the non-feebleminded. This equality of percentages and the high incidence of divorce strongly substantiates the inference that the criminally-minded person, regardless of intellectual endowment, is essentially lacking in the personal and social requisites for the assumption and continuance of marital duties. Or it may be that this marked prevalence of divorce indicates the failure of the stabilizing influences of marriage and home life to react favorably upon the criminal because of his inherent instability. However, from a eugenical point of view as regards the propagation of the unfit, this high percentage of disrupted marriages among delinquents is a hopeful sign.

SOCIAL AND ECONOMIC RESPONSIBILITIES

Related in significance to the table above on the *Distribution of Marriage* is the table on *Social and Economic Responsibilities*. Data for this table, which represents only the

married cases, were obtained for 916 of the Not Feebleminded Cases and for the entire 614 Feebleminded Cases. Following is the table:

	Not Feebleminded (916 Cases)		*Feebleminded (614 Cases)*	
(Married Cases Only)		*Per cent*		*Per cent*
Without Children	246 -	26.36	126	- 20.52
With One Child	247 -	26.96	152	- 24.76
With Two Children	171 -	13.67	117	- 19.05
With Three Children	92 -	10.04	63	- 10.26
With Four or More Children (Average of Six)	160 -	17.47	156	- 25.41
Average Number of Children per Family	1.99		2.46	
Average for Entire Criminal Group	2.18			

It will be noted at once that the greater number of families with children and the greater number of children occur in the mentally deficient group. This is quite in accord with the findings of other investigators and with the generally conceived opinion of the greater fecundity of the classes of deficient mentality.[24] How serious is the fecundity of the mentally defective and deficient classes as shown here may be inferred from a comparison with similar data appertaining to other classes of society. Thus, an investigation of the families of 1,000 American men of science who had attained some degree of distinction showed 22 per cent childless and an average of less than two surviving children for each one.[25] A similar investigation conducted in regard to 1,986 prominent Methodist clergymen showed 97.44 per cent married with only 11 per cent childless, 12.5 per cent with one child, 20.4 per cent with two children, 18.5 per cent with three children, and the remaining 37.6 per cent with four or more children, an average of 3.[26] children for each individual.26 Also, an inquiry made in regard to graduates of Harvard and Yale revealed an average of 2.17 children per individual.[27] Another investigation of the Harvard graduates of 1894 revealed 20 per cent childless, 13.1 per cent with one child, 18.1 per cent with two children, 22.5 per cent with three children, and 25.5 per cent with four or more children, and an average of 2.44 children per individual.[28] This reveals the college-bred man of Harvard fully as prolific as the feebleminded delinquent and gives him a very definite lead over delinquents in general. However, it must be borne in mind that the above table does not give the ultimate or true values since more children will be born in the families of the delinquents under study. Nevertheless, when the increased infant mortality of the poorer classes is considered, likewise the greater prevalence of diseases tending to produce sterility, the markedly increased prevalence of disrupted marriages, and the separation of husband and wife occasioned by prison terms, the lead of the college-bred man in family size is more significant than appears upon casual inspection. Further, it has been estimated by Kehrer that the proportion of childless marriages for civilized countries ranges between 10 and 15 per cent,[29] which means that the ordinary middle-class citizen, taking the criminalistic and college-bred classes as the extremes, bears the burden of restocking the population. This renders less alarming the belief of the over-fecundity of the mentally unfit classes.

Nevertheless, that over 50 per cent of the criminal classes are married and tend, despite the prevalence of disrupted marriages, to reproduce themselves to the same extent almost as our leading intellectual classes constitutes an indisputable ill to society. Nor can there be any doubt of the gravity of this when it is realized that for the 38,820 adult male delinquents in custody,[30] there are only 508,714 males, minors and adults together, enrolled as students in universities, colleges and professional schools in the United States.[31] This near equality between the college-bred population and the criminal population emphasizes again the need of social intervention in the propagation of the mentally defective and mentally deficient classes in order to ameliorate the problem of criminality.

Study of the Relationship Between Intelligence and Crime

Milton H. Erickson, M.A., M.D.

INTRODUCTION

The question of delinquency, which has ever constituted a grave social problem, is arousing a constantly increasing interest as a result of the recent application of scientific methods to the study of crime in all its varied phases. Indeed, before a truly scientific interest could be developed, it was necessary that there be a development of those sciences which throw light an human conduct and behavior such as biology, psychology, sociology, and psychiatry, and particularly so this last-named science. However, the great significance of the problem is scarcely appreciated as yet, and the field of study, so wide and fertile, is relatively untouched, although significant progress has been made in some directions. Possibly, the most notable of advances made has been the beginning recognition of delinquency as a problem belonging almost entirely to the field of psychiatry rather than to the legal realm or to sociology, that field of normal human relationships. The avenues of approach for the study of this problem of delinquency and the aspects for consideration are exceedingly numerous, since every crime is the product of the complexities of human nature reacting in devious and incomprehensible ways to the complexities of the social order. Formerly, only the dull prosaic facts of social and economic existence were considered the sum total of essential knowledge concerning the criminal. Quite otherwise now, a study of crime necessitates in addition an investigation into the behavior reactions, mental attitudes, intellectual and emotional endowments, physical development, habits, predilections, idiosyncrasies, and all possible intimate and personal details of the individual offender in his daily life. Accordingly, any attempt at investigation of this question of such great moment to the welfare of society must be confined of necessity to one particular phase. Nor can any investigation hope to do more than add some small fact to the aggregate of knowledge essential for a proper evaluation and comprehension of this most complex and intricate problem of human relationships. Only in this fashion may be reached, sometime in the remote future, a solution to this serious ill of civilization.

In this investigation, realizing that the intellectual endowment of the criminal might well constitute a significant force in anti-social behavior, an attempt has been made to throw some light upon the problem of crime by a study grounded fundamentally upon the grade of intelligence possessed by delinquents. Especially was this felt to be a valuable aspect for study since a careful survey of the literature revealed that practically nothing of a detailed and systematic nature had been done to ascertain the actual force exerted by the intellectual endowment upon criminalistic tendencies. Indeed, the literature obtainable yielded nothing more than broad speculations and generalizations upon feeblemindedness and crime, with no attempt to specify or determine actual significant details and

relationships of intelligence and criminality. This has been attempted in this investigation by grouping delinquents according to the general level of intelligence possessed, and then analyzing these groups in accordance with various pertinent details concerning the individual. By so doing, it was hoped to reveal various criminological trends and tendencies together with group differences and similarities, divergencies and peculiarities, direct and indirect relationships significant either positively or negatively of the influence exercised by intelligence, or the lack thereof, upon the manifestation of anti-social behavior, or tending in any way to explain the phenomena of crime. In addition, an effort was made to note any outstanding characteristics or associated facts becoming manifest during the course of the investigation which might serve to enable a better understanding of offenders either singly or collectively.

MATERIAL AND METHOD

The material for this study was obtained from the Case history files of the Psychiatric Field Service of the Wisconsin State Board of Control. In these files are kept complete records of the routine examinations made by the Psychiatric Service of *all* individuals admitted to the various penal and correctional institutions of the state or applying for a parole therefrom. These examinations are of a four-fold nature, embracing the psychiatric, physical, psychological, and sociological aspects of each individual case, the original purpose of the examinations being the betterment of the institutional and post-institutional welfare of the individual delinquent. The institutions yielding material for this undertaking were the Milwaukee County House of Correction at Milwaukee, the Wisconsin State Prison at Waupun, and the Wisconsin State Reformatory at Green Bay. The period of time covered by this observation extends from July 1, 1926 to June 1, 1928, a period of nearly two years. From the entire number of examinations made for this period of time, a selection was made, based on sex, race, and age, and only those histories of white males twenty-one or more years of age were accepted, all duplicates being discarded. This was done to avoid the complications of sex and race and to exclude minors who may not, in all fairness, be compared to adults. A total of 1690 individual cases answering to the above specifications was thus obtained, and these cases were then divided into the four following groups

1. *Normal Intelligence Group* comprising..... 852 cases
2. *Subnormal or Low Intelligence Group* comprising..... 327 cases
3. *High Grade Feebleminded Group* comprising..... 408 cases
4. *Low Grade Feebleminded Group* comprising..... 103 cases

It may be very well stated here that the particular grade of intelligence possessed by the individual, if not obviously normal as shown by the scholastic record, was determined at the time of examination by the application of the Stanford Revision of the Binet-Simon Intelligence Tests. This was done by a qualified psychologist, with the result of the first examination confirmed, in many instances, by a retest. In addition, the history of the individual was regarded as confirmatory, and always considered in the diagnosis of the degree of intelligence possessed. particularly so in regard to the diagnosis of feeblemindedness. The Intelligence Quotient, or I.Q. as it is commonly termed, of .75,

accepted by the American Association for the Study of Feeblemindedness, was taken as the dividing line between mental deficiency and nonfeeblemindedness. In establishing this Intelligence Quotient as the dividing line, no particular weight has been accorded the present academic dispute among psychologists concerning the most acceptable and exact dividing point. Whether the dividing line is an Intelligence Quotient of .75, .70, .68, or .65, is essentially irrelevant to the purposes of this investigation, since it is desired only to determine the existence, positively or negatively, of an influence exerted by intelligence or the lack thereof upon criminality. There is neither hope nor expectation of determining the exact degree of this influence nor of ascertaining the exact weight or quality of any possible relationship. Further, when the very nature of the human material dealt with is considered, it may be conceded readily that an intelligence quotient of less than .75, combined with the manifest incapacity of satisfactory economic and social adjustment, as evidenced by conviction for criminality, justifies classification as feebleminded from medical, social, and legal aspects, if not entirely so from the viewpoint of academic psychology.

The range of the Intelligence Quotient for Bach of the intelligence levels indicated by the above groupings is presented in the following table taken from Richmond[1] and agreeing with Terman's classification:[2]

	Intelligence Quotient Range
Normal Intelligence	.90 or more
Subnormal or Low Intelligence	.75 to .90
High Grade Feeblemindedness (High Grade Morons)	.60 to .75
Low Grade Feeblemindedness (Low Grade Morons)	Below .60

The respective groups were then carefully analyzed in accordance with the tables given in the appendix to this paper, the tables showing both the numerical totals and the percentages for each item. From these tables, the significant facts and important percentages have been abstracted for use in the body of this discussion, thus obviating any need for constant reference to them.

DISTRIBUTION OF INTELLIGENCE

Since the recognition of the need of studying the criminal as an individual member of society, there has been a growing realization of the necessity of understanding and appreciating the extent and nature of his mental and intellectual endowment. With the development of standardized psychometric tests. a valuable means of estimating the intellectual endowment of the individual became practicable. The results of the application of these tests to the offenders included in this investigation show the following general distribution:

Normal Intelligence Group	50.41% of all cases
Subnormal or Low Intelligence Group	19.36% of all cases
High Grade Moron Group	24.14% of all cases
Low Grade Moron Group	6.09% of all cases

It is at once evident from the above figures that essentially fifty per cent of delinquents are definitely below normal in intelligence, if 1690 cases of adult white unselected criminals may be considered a fair sample. And undoubtedly they are. Unfortunately, any figures showing the distribution of the general population according to the above levels of intelligence are wholly unavailable. The use of the findings of the army tests is precluded since the very lack of standardization and the actual misinterpretation of the significance of various tests, according to Brigham,[3] and the absolute errors of selection, improper methods of application, and the use of untrained testers, according to Termam,[4] render the results of the army tests exceedingly unreliable and not a fair criterion of the intelligence of the general public. Common judgment would lead, however, to the conclusion that far less than fifty per Cent of the general public are subnormal. And this conclusion is substantiated by the findings of Terman who found less than 20% of a total of one thousand unselected school children with an I. Q. below 90,[5] and similar findings have been made by other investigators in the same field. While results obtained with children may not be strictly comparable with those obtained with adults, there can be little question of there significance, especially in regard to such a matter as intellectual endowment. Further, the above findings have been more than corroborated by Kuhlmann[6] working in the reformatories of Minnesota where he found, in a total of 1962 cases, 78% below normal intelligence, a considerably greater figure than that given by the above table. However, the delinquents studied by Kuhlmann, were, an the whole, considerably younger than those of this investigation which may account for the difference in percentages. Likewise in New York, Slawson[7] found a total of 77% below normal intelligence in a series of 553 juvenile male delinquents, and 60% below normal in another series of 98 cases. While these cases are not wholly comparable to those of adults, the indications of a direct correlation between delinquency and subnormal intelligence are exceedingly strong.

A second point very evident from the above table is the astonishingly high percentage of mentally deficient individuals among criminals, which is shown to be 30 % in this investigation. The significance of this high percentage is best appreciated by calling to mind the generally accepted estimate of feeblemindedness in the population at large, which places the ratio at one mentally deficient person in every two hundred of the general population, an estimate based an eight different surveys made by investigators in various states and confirmed in results by the findings in similar investigations in Europe.[8] Gillin, however, after a careful consideration of the literature an this question for this country, has estimated a proportion of 2% of the general population as feebleminded.[9] Thus, the ratio of feeblemindedness among criminals is here shown to be at least from fifteen to sixty times greater than that of the population at large! These findings have been repeatedly confirmed by other investigators. Kuhlmann has found an average of 29.1% of the inmates of the reformatories of Minnesota feebleminded;[10] Slawson, working with delinquent boys in New York State found 20% to 25% feebleminded;[11] Anderson, after his investigations in the Problem, reached a conclusion that 27% to 29% of all prisoners are feebleminded;[12] and the Wisconsin Psychiatric Field Service, in a total of over 8,000 examinations of the inmates of the various state penal and correctional institutions, has found an average of 27% of all offenders feebleminded, the percentages varying from 20% to 35% depending upon the particular institution

concerned.[13] Also, various investigations conducted among delinquents in California, Illinois, Indiana, New York, and West Virginia, Show percentages of mentally deficient among criminals ranging from 20% to 30%.[14] Accordingly, the genetic force of mental deficiency in the production of crime is not to be doubted. Indeed, Goddard, after his long study of feeblemindedness, reached the conclusion that every mentally deficient individual is a potential criminal, and further, that 40% of families manifesting feeblemindedness show criminality and that sex delinquency in such families is practically the rule.[15] The seriousness of this hardly needs mention! However, whether the role played by feeblemindedness in the production of crime is direct or indirect is not a proposition to be decided here, nor does that question lessen the grave significance of mental deficiency in relation to anti-social behavior and criminality.

Further, the above table shows that fully 20% of the total number of feebleminded among delinquents, or 6% of all criminals coming within the scope of this investigation, are low-grade morons. The significance of this will be better appreciated when it is realized that the defect of intelligence in low grade morons is so severe that authorities are well agreed that they can be cared for properly only within the confines of an institution designed for the care of the feebleminded.[16] Indeed, the capacity of low grade morons for social and moral responsibility at law is nil according to Richmond[17] and Kuhlmann[18] after long study of the problem, and these investigators feel that even in regard to the high grade moron, legal responsibility is very frequently "debatable and subject to proof." Yet there delinquents with such marked deficiency of intelligence are allowed to serve their terms unrecognized legally for what they are, and then are discharged and permitted to return to society for which they are absolutely unfit socially, morally, and economically, there to reproduce their kind and to repeat their contribution to the crime problem! And that they will is no matter of pessimistic speculation, since, to the low grade moron, consideration for others, altruism, probity, and moral and ethical principles are vague, incomprehensible things. And in his intellectual blindness he gropes and stumbles through the social maze of life wandering into forbidden paths all along the way, knowing no better and unable to know better.

CRIMINAL HISTORY

That there is a relationship between deficiency of intelligence and criminality has just been pointed out. Whether that relationship is direct or indirect, as would be shown by group comparisons, may be somewhat indicated in the following table which Shows the present extent of the criminal histories of the individuals of the various groups under examination:

Present Criminal History	Normal Intell. Group	Sub-Normal Intell. Group	High Grade Moron Group	Low Grade Moron Group
Misdemeanors	45.54%	49.54%	46.08%	49.52%
One Conviction.....	76.52%	78.59%	80.88%	84.47%
2-3 Convictions.....	20.31%	18.66%	17.89%	14.56%
4 or More Convictions.....	3.17%	2.75%	1.23%	.97%

Careful scrutiny of the above table suggests that, while the tendency toward crime does occur more often among the mentally deficient, the manifestation of that tendency in the individual does not vary in extent and frequency with the degree of intelligence possessed. In other words, while deficiency of intelligence allows for a greater number of individuals with criminalistic tendencies, the manifestation of those tendencies, in so far as the total number of offenses committed is concerned, varies in no degree from the manifestation of the criminalistic tendencies of the non-feebleminded. Indeed, the parity of the group percentages for each item of the above table very strongly suggests an indirect relationship between criminality and intelligence, and indicates that the criminal tendency is a thing apart from the intellectual endowment and hence little influenced directly by the degree of intelligence possessed. However, the degree of intelligence may play a role in the particular form of specific manifestations of anti-social behavior. As a conclusion, justified by the above findings, it may be stated that the tendency to criminal behavior appears to be dependent upon factors other than intelligence, and that deficiency of intelligence seems conducive to criminality only by virtue of allowing a more frequent occurrence of this tendency.

A second matter for consideration suggested by the above table is the extent of recidivism which amounts to an average of 17% when only actual convictions with prison terms are considered. With the inclusion of all offenses against the law, misdemeanors as well as felonies, percentages for recidivism are markedly increased. That the inclusion of misdemeanors, in calculating recidivism is entirely justifiable in a study of the nature of criminality is not to be doubted, since there is nothing inherent in an offense against the law which makes it either a felony or a misdemeanor.[19] Indeed, the mere circumstances of the situation often determine whether the particular manifestation of criminal tendencies constitutes a misdemeanor or a felony, [20] and in the vast majority of cases, the Standards of judgment are entirely arbitrary. Accordingly, the following table is given showing the percentages with the inclusion of all offenses:

Total Present Criminal History	Normal Intelligence. Group	Subnormal Intelligence. Group	High Grade Moron Group	Low Grade Moron Group
One Offense.....	39.44%	39.14%	41.93%	48.55%
2-3 Offenses.....	50.23%	50.16%	50.23%	45.63%
4 or More Offenses.....	10.33%	10.70%	7.84%	5.82%

In the foregoing table, for each individual, a history of misdemeanors, whether one or many, is considered as a single offense, and actual convictions of felonies constitute all additional offenses. Since all individuals included in this study have at least one conviction, the first item of the above table shows the percentages of those having one conviction with no history of misdemeanors, while the other two items show the percentages based upon the inclusion of misdemeanors with felonies.

Thus, it is shown above that the actual recidivism ranges from 45% for the low grade morons to 50% for the other there groups. These findings are quite in agreement with the findings of Anderson in his investigation of Wisconsin criminals among whom he found 45% recidivists .[21] Glueck, in an investigation at Sing Sing found a total of 66%

recividists,[22] while in Massachusetts for the years of 1921-1922, the percentage of recidivists among all offenders sentenced in the state ranged from 51.3% to 55.1%, [23] and in New York City 47% of the inmates of the workhouse were recidivists in a study conducted before 1916,[24] and 47% of all prisoners admitted to the state prisons in New York in 1921 were recidivists .[25] When it is considered that recidivism is one of the surest signs of the instinctive and incorrigible offender, [26] and that, according to a former head of Scotland Yard, a great part of the serious crimes are committed by recidivists,[27] the need of recognizing the recidivist as such and according him treatment designed for that class of offenders is at once apparent.[28] Further, the very fact there is such a high percentage of repeaters shows the ineffectuality of our present penitentiary system both for correction and intimidation.[29]

Likewise deserving of comment is the marked extent of habitual criminality, which ranges from for the low grade feebleminded criminals to 100% for those of normal intelligence, an average of 9.9% of all criminals. That one-tenth of criminals are habitual offenders emphasizes the seriousness of the problem constituted by such individuals alone, and renders at once apparent the need of some special socio-legal provisions for such unfortunate individuals. It is indeed, fortunate that the greater part of the crimes committed by habitual offenders are petty in nature.

A fourth consideration apparent from the above table is the extent of recidivism among the low grade morons. As has been mentioned above, 45% of the low grade morons have been in court and found guilty of crime two or three times. In addition, approximately 6% are habitual offenders. Yet there low grade morons have not been recognized for what they are and placed in the proper institutions. Likewise and to an even greater extent, the Same holds true for the high grade morons, hence rendering the social wrong much greater. Thus is the inadequacy of the present judiciary system made apparent as well as the inadequacy of present social provision for such individuals, since there are provided as yet neither the means of recognizing such social unfits nor the institutions to receive them. Indeed, a total of 6% of adult criminals coming into the courts are low grade morons who may be cared for properly only by institutionalization. Yet that they are not recognized as such, but are treated in the Same fashion as there fellows of unimpaired intellect constitutes, both a social tragedy and a severe criterion upon social enlightenment. Further, as shown above, 30% of all adult criminals are feebleminded and 56.7% of there are either recidivistic or habitual criminals. Hence they are obviously in need, at the very least, of constant and careful supervision from the standpoint of deficiency of intelligence alone, not to mention criminalistic tendencies, in order to conduct themselves and their affairs in a prudent social manner. These considerations render the appalling need of social and judicial recognition of this problem most apparent. When, eventually, the forces of social organization do take this problem into consideration there will be, in all probability, a marked alteration in the current of crime.

LENGTH OF SENTENCE

Serving to substantiate the points made above concerning recidivism and the inadequacy of present social and judicial provision in regard to the recidivistic mentally deficient are

the findings in regard to the length of the sentence imposed upon the offender by the court of trial, given in the following table

Length of Sentence	Normal Intelligence Group	Subnormal Intelligence Group	High Grade Moron Group	Low Grade Moron Group
1 year or less.....	8.45%	9.79%	10.54%	13.59%
2 years or less.....	26.52%	28.44%	30.39%	27.18%
3 to 4 years.....	27.11%	29.05%	24.50%	17.48%
5 to 9 years.....	21.48%	14.37%	16.43%	18.45%
10 years or more.....	14.44%	13.15%	14.95%	18.45%
Life imprisonment.....	2.00%	5.20%	3.19%	4.85%

From this table, it is at once evident that the general distribution of each group of offenders is very much the same, about 65% of each group serving sentences less than five years. The low grade morons, however, Show a tendency to depart from the general levels of distribution, and particularly is this marked in the percentages for the more drastic sentences, where the low grade morons show a decided increase above the other groups. While the severity of the sentence administered may not be taken as an accurate indication of the seriousness of the offense, nevertheless, inasmuch as sentences are determined in the main by statutes, the length of the sentence does constitute such a measure to a very considerable extent. Accordingly, the similarity of the percentages for the more drastic sentences strongly suggests that the feebleminded are fully as capable of committing very serious crimes as their fellows Of more normal intelligence, with a seemingly increased tendency an the part of the low grade moron. Especially does this appear to be the case since the feebleminded have the greatest percentage of life imprisonment sentences. And inspection of the records of the low grade morons serving terms of ten years or more or of life imprisonment reveals such crimes as murder, assault to murder, incest, and sexual assaults upon Small children, all crimes most heinous to social feeling. Hence, it is evident that of the criminal class the low grade moron is even more of a menace to society than his more normal but criminally inclined fellow, and that the high grade moron is fully as great a menace as his fellow delinquent of greater intelligence. Also, judging from the sentence imposed according to the restrictions of the statutes, pettiness of offense is not a characteristic of deficient intelligence. On the contrary, intelligence apparently plays little part in determining the seriousness of the crime committed except in regard to the low grade moron, and there it probably is the lack of intelligence which constitutes the important factor. Indeed, the gravely dangerous criminal tendencies in the mentally deficient are even more serious since they have not the saving grade of intelligence wherewith to hope for a control, even partial, of there anti-social tendencies. The gravity of this is further emphasized by reference to the preceding table which shows the failure of the courts to recognize the mentally deficient even upon the occasion of many court visits. All this stresses greatly the total inadequacy of the present court system, which falsely considers only the offense and not the offender, which is the empirical method of treating the symptoms without specifically considering the disease causing them. Thus the laws fail to protect society because they are concerned with the superficial criterion of the crime and not with the essential criterion of the nature of the delinquent[30] and hence there can be no treatment of the criminal in direct accordance with his own particular needs. The latter is an easy matter only in regard to

the mentally deficient where institutionalization or colonization might solve the problem most satisfactorily.

Illustrative to a still further degree of the point made above concerning the ineffectualness of the present penal system are the results of a comparison of the percentages for recidivism with those for long-term sentences. As may be seen above, although 56.7% of offenders are recidivistic or habitual offenders and hence incorrigible in the main, as has been mentioned above, only 16% to 23% are serving long term sentences. This fact, then, signifies that the greater per cent of recidivists are serving terms of more or less brevity. That little benefit to society may be expected from such terms is not to be doubted since sentences of there to five and even ten years are without effect upon recidivistic offenders and possess value only by virtue of segregating the offender for a while and thus sparing society a greater or less number of crimes.[31] At best such sentences, in so far as recidivists are concerned, constitute nothing more than a flimsy makeshift in dealing with the problem of repeated criminality. Indeed, the statistics of crime as well as the teachings of history confirm the absolute inadequacy of the present system of punishments against crime.[32] Especially is this so in regard to the feebleminded recidivists who are accountable for a full 25% of the entire problem of repeated criminality and whose deficiency of intelligence effectually and completely militates against any possibility of regeneration or correction. That penalties are established by statutes and are based wholly upon a consideration of the material act constitutes an actual social injury since society thereby derives a false sense of having adequately and securely provided against a danger. In reality, it has not, for the harm is merely postponed. Commitment to prison should be determined not by the nature of the offense but by the nature of the offender,[33] and with a view toward the causes of the delinquency, the effect upon the individual, and the moral prognosis.[34] Only in this way may adequate social provision be made for the warped, deficient, defective, and unregenerate enemies of the social order.

TYPE OF CRIMES COMMITTED

It is generally conceded that the particular crime committed, with few exceptions, is of no particular significance in the comprehension of the problem of the criminal. Blanc has very rightly said that the essence of crime does not lie in the material act but in the psychical state of the agent and that there are no crimes but only criminals.[35] Similarly, Aschaffenburg in his text-book an crime declares that criminals are not particular in their choice of crimes of psychologically equal value.[36] Indeed, crime is only a manifestation of an unsocial or anti-social nature, in reality, merely a symptom of disease or distortion of social relationships. The particular type of crime committed is, within the reasonable limits established by the fundamental nature and capacities of the individual, determined almost entirely by the circumstances serving to call forth the malefaction. Thus, the individual o£ criminalistic tendencies whose powers of volition are weak may become an habitual drunkard, or he may abandon his family, or, upon attaining a position of trust, he may become an embezzler. But by no means may he be classed according to the particular offense committed, since the essential thing is the constitutional defect of his nature permitting him to become guilty of an antisocial act. However, it must be

recognized that the constitutional defect may vary in extent with different individuals and, with this variation, there is a corresponding variation in the degree of criminality. Thus, one criminal is rendered more or less a petty offender while another with more marked defect may run the whole gamut of the criminal calendar. Very much in support of the proposition that there is no particular class of crimes for any particular group of criminals, except as determined by circumstances over which they have no control, is the following table listing the various crimes committed:

Crime Committed	Normal Intelligence Group	Subnormal Intelligence Group	High Grade Moron Group	Low Grade Moron Group
Crimes against:				
Property	57.04%	51.38%	46.08%	37.86%
Persons	6.69%	9.79%	7.84%	17.48%
Chastity and Morals.....	9.98%	11.62%	10.30%	16.51%
Automobile Thefts.....	8.10%	5.50%	5.88%	1.94%
Statutory Rape.....	8.10%	11.01%	15.20%	15.53%
Abandonment	6.34%	4.28%	8.82%	7.77%
Otherwise	3.75%	6.42%	5.88%	2.91%

It is evident from the above table that the distribution of offenses is essentially the same for each of the various groups with only slight group differences. Thus, automobile thefts occur more frequently among those of normal intelligence, in all probability because of the need of intelligence in conceiving and executing such a theft. The same interpretation probably holds true for the comparative decrease in the incidence among low grade morons of crimes against property, since many such crimes require good intelligence and careful planning. On the other hand, abandonments occur to a greater extent among the mentally deficient than among those not feebleminded, because of the increased difficulty entailed by deficiency of intelligence in bearing family responsibilities, as had been noted in a previous investigation.[37] The most significant differences in the table above are in regard to the crimes against persons and against chastity and morals, wherein, with the decrease in intelligence there is an increase in incidence. This is very suggestive that in crimes of passion intelligence may play an inhibitory role, or that the deficiency of intelligence tends to limit the expression of criminalistic tendencies to animal methods. However, outside of the limits of specified offenses and the natural handicaps of the individual, intelligence appears to have little significance in the determination of the nature of the offense committed, thus substantiating the proposition that the malversation committed is not a true criterion of the class of the delinquent. Further, the above table emphasizes again the seriousness of the part played in crime by the mentally deficient, for it shows that their criminality differs in no great wise from that of their more normal fellows. This is even more serious since there can be no good hope of regeneration of such offenders, particularly so with regard to the low grade morons, who manifest as a group the greater tendency toward the more socially injurious crimes.

SUBJECTIVE CAUSATIVE FACTORS UNDERLYING CRIME

Subjective causative factors underlying crime would be sought most naturally in the table of *Reasons, Excuse, or Explanation* offered by the offender. However, it must be

recognized from the very outset that the rationalized explanation of his crime given by the criminal upon inquiry, unless substantiated by case work, so desirable for accurate information, is most unreliable from a scientific point of view. Hence, conclusions drawn therefrom must be made cautiously. Nevertheless, the very remarkable agreement in percentages between the various groups so widely divergent on the scale of intelligence necessarily gives the explanations offered a significant, if not indisputable, cast of reliability. Therefore, the various outstanding reasons given are presented for consideration and their possible significance suggested

Reason Given:	Normal Intelligence Group	Subnormal Intelligence Group	High Grade Moron Group	Low Grade Moron Group
Economic Distress.....	20.31%	14.99%	12.25%	15.53%
Bad Company.....	6.93%	7.34%	5.39%	2.91%
Liquor	19.13%	23.24%	22.06%	20.39%
Miscellaneous	41.54%	43.42%	48.05%	51.46%
No Reason.....	12.09%	11.01%	12.25%	9.71%

Careful scrutiny of the above table shows no outstanding subjective causative factor peculiar to any one group. The feebleminded give the same reasons as those not feebleminded, and do so in approximately the same proportion of cases. Accordingly, the factors represented above must be considered as purely environmental in nature, or that the deficiency of intelligence in the feebleminded is of such nature as to prevent their true recognition of the impelling factors in their criminality. The latter is difficultly tenable as an explanation.

That such a reason as *Economic Distress* has practically the same percentages for each group is most surprising, for the lesser earning capacity of the feebleminded would lead to the presumption that individual poverty would be much more of a subjective Criminogenic factor among the mentally deficient than among their intellectual superiors. Especially so would this be the presumption since it is well recognized that poverty and lack of necessities often impel toward theft with the view of satisfying the individual's own needs.[38] However, this similarity of percentages for the various groups is highly suggestive that *Economic Distress* is a purely environmental factor in the production of crime. Thus, while poverty may have a subjective value in impelling toward anti-social conduct, its force is not determined by individual peculiarities or deficiencies but by the environmental force of circumstances.

That *Bad Company* constitutes a no more important subjective factor for the feebleminded than for those not mentally deficient as shown by the above table is presumably false, since the feebleminded are probably entirely incapable of properly appreciating the influence exercised over them by bad associates. The part played by evil companions is unquestionable, as individual cases frequently show, but the extent of that part is, in all probability, unmeasurable.

That *Alcoholism* is still a gravely potent factor in the production of delinquency would be a most ready inference if the percentages of the various groups giving *Liquor* as the subjective causative criminogenic factor could be accepted at face value. However, to

accept the percentages as given above would be a most dubious procedure, for the excuse of "I was drunk and didn't know what I was doing" or "I got to drinking and then I didn't care what I did" is too easily made and is too palliative from the individual's point of view for any great amount of reliance to be played upon it. That alcohol does play a part in individual cases and in crime in general is not to be questioned, for it has been proved conclusively by Pearson & Elderton,[39] and Howard.[40] But in how many individual cases it has played a part and to what extent is quite another matter, very probably unmeasurable with any degree of accuracy. Especially is this so since the most important relation between alcohol and crime is economic and social rather than physiological, the alcohol destroying economic efficiency, breaking down self-respect, and leaving the field open for bad conduct.[41] Nevertheless, in the above table, the marked extent of agreement between the various groups, so widely differing in intellectual endowment, in attributing delinquency to alcoholic indulgence indicates very strongly that liquor does play a definitely subjectively recognizable part in the causation of crime. Further, the equality of percentages for the various groups signifies that *Liquor*, like *Economic Distress*, is an environmental factor rather than a group peculiarity, which is quite contrary to expectations. That the low grade morons show scarcely any greater alcoholic indulgence than their mental superiors is indeed surprising, and the same holds true for the high grade morons. However, this may be due to the decreased earning capacity of the mentally deficient, thus preventing indulgence. But in general it appears that the degree of intelligence possessed bears no relation to the tendency toward alcoholic indulgence in so far as subjective appreciation is concerned.

MILITARY SERVICE AND DELINQUENCY

In the first part of his "Utopia," Sir Thomas More makes the earliest mention of the significance of war in the production of increased delinquency.[42] This opinion he based upon observations following the war with France. Since his time, following every war, the same general observation has been made. After the Civil War, an extensive investigation into this question was made, and a marked increase in crime incidence following the war was noted.[43] However, because of various errors of inclusion and selection of data, the reliability of the results of the investigation is somewhat questionable.[44] In this investigation, a history of participation in the World War seems to be of very considerable significance in regard to the criminogenic factors of delinquency, as may be gleaned from the following table:

	Service in the World War
Normal Intelligence Group.....	18.65%
Subnormal or Low Intelligence Group.....	14.68%
High Grade Moron Group.....	7.35%
Low Grade Moron Group.....	13.59%
WEIGHTED AVERAGE FOR ALL GROUPS.....	14.76%

To properly evaluate these percentages, it must be borne in mind that the criminal population is entirely unselected as regards physical perfection, age, and freedom from dependents, qualifications which obtain in the selection of men for military service. Accordingly, a percentage of the unselected criminal group exceeds in actual numerical

value the same percentage of the selected and hence smaller military group coming within the same general grouping of the population. Hence, 14.76% of the entire criminal group, as given above, in reality signifies a much higher percentage of the actual military group included by the criminal groups. How much higher it may be, is, of course, impossible of statement, but considering the military qualifications, an estimate of half again as much is, in all probability, entirely fair. Further, the number of white males coming within the age limits of 21 to 70 years established by the criminal classes herein under examination is 27,133,759,[45] and the total of white troops who saw service amounts to 3,306,178,[46] thus giving a proportion of 12.1% of the general comparable population in 1920 serving in the World War. In the eight years since 1920, vast numbers of minors have reached their majority, thus markedly changing the constituency of the general population. Hence the proportion of the present comparable population having a history of service in the World War is unquestionably and decidedly less than the 12.1% given above, as contrasted to the 14.76% of the present criminal population. Bearing this in mind, it is at once evident that the percentage of ex-service men among offenders against the law is disproportionately high, a fact holding true, essentially, for each of the various groups, and to a similar degree, showing no striking relationship between degree of intelligence and history of military service. That approximately one out of every seven criminals has served in the World War as compared to one out of every ten or more of the general population suggests a direct relationship between that service and the anti-social behavior of the individual. This same high percentage of ex-service men among the inmates of penal and correctional, institutions has been previously noted by Lorenz[47] who found a total of 25 % for Wisconsin in 1923. Accordingly, the potency of military service as a factor in delinquency is not to be doubted, whether directly as consequent upon the disorganization of personality due to military experiences, or indirectly either as consequent upon the difficulties of re-adjustment in civil life in the post-war period, or as a result of army-learned habits and morals carried over into civil life.[48] This disproportion of ex-service men among criminals may be appreciated to a still further degree by calling to mind the very significant facts that the age group of 21 to 24 years inclusive has the greatest crime incidence as shown by the census report of 1904.[49] and the census report of 1923,[50] and that the median age of those committed to penal servitude for a term of one year or more, which would include the 1,690 cases of this study, is 28 years.[51] Indeed, criminality is an attribute of personality which tends to show itself early in life.[52] These facts strongly emphasize the increased percentage of World War veterans inasmuch as they are, an the average, well beyond these ages. Accordingly, even for a long time afterwards, nearly ten years in this study, delinquency must be regarded as a due toll of war.

AGE DISTRIBUTION

Another matter of interest was the age distribution for the various groups under study, which is given in the following table:

	Age Groupings			
	21-30	*31-10*	*41-60*	*61—*
Normal Intelligence Group..……. .	58.32%	24.54%	14.79%	2.35%
Subnormal Intelligence Group…. .	57.19%	23.85%	15.29%	3.67%
High Grade Moron Group..…….. .	52.69%	23.29%	19.36%	4.66%
Low Grade Moron Group.…….	35.92%	36.90%	24.27%	2.91%

It is at once evident from the above table that there is a considerable degree of relationship between the amount of intelligence possessed by the offenders and there age distribution. The greater proportion of younger offenders is to be found in the more highly intelligent groups, while the greater proportion of older offenders is to be found in the groups of lowest intelligence. As shown above, 64% of the low grade morons have passed the age of 30 years, as compared to 42% of those of normal intelligence. Similarly, 49% of all feebleminded delinquents have passed that age as compared to 42% of those not feebleminded. Further, the per cent of mentally deficient delinquents included by the age period of 41 to 60 years is relatively 36% greater than the same percentage for those of more normal intelligence. This increase is even more marked in the case of the low grade feebleminded, who show a relative increase ranging from 25% above the high grade morons to 67% above the normal intelligence group. Apparently then, delinquency among feebleminded adults occurs at a considerably later age an the average than among those not feebleminded. An interpretation that may be suggested for this is that the passing of the years renders the problems of life more and more strenuous for the mentally deficient individual because of his naturally decreased powers of occupational adaptation and consequently decreased powers of social adaptation. Accordingly, he finds the burdens of life relatively more difficult than his fellow of more normal intelligence who is not compelled to confine his efforts to sustain life to the "drawing of water and the hewing of wood." And in individuals of already weak moral fiber, any added strain may be sufficient to break the slender threads holding the individual from wrong conduct. On the other hand, rather than a postponement of the age of incidence, it may be that the curve of crime incidence for the feebleminded, after reaching its highest point at the age group of 18 to 24 years, does not decline as does the curve for crime incidence in general.[53] Rather, it may be that it continues as a plateau, extending muck farther into the later age groups. This appears entirely reasonable since the deficiency of intelligence of the feebleminded negates any well-founded hope of regeneration of such an individual after he has once embarked upon a criminal career. Nor can there be any well-justified expectation of the feebleminded acquiring wisdom with one experience with penalization. On the contrary, it seems reasonable to expect that the tendency toward crime would remain unchanged and that the manifestations would continue unaffected and undiminished in number.

MARRIAGE AND DELINQUENCY

Marriage is well-recognized as a stabilizing influence for the individual,[54] and constitutes an actual moral force in the prevention of crime by providing happiness and stimulating worthy activity.[55] Accordingly, a decreased incidence of marriage or an increased disruption of marriage might reasonably be expected among criminals. In substantiation of this inference is the report of the Census Bureau which shows that the unmarried among criminals outnumber the married more than two times per 100,000 population of the age of 15 years or more.[56] However, this is probably a distortion of the real truth since the criminal population with that age limit contains an exceedingly great proportion of juvenile and young adult offenders, as is shown by the census reports mentioned above an the age of crime incidence. This investigation, however, includes only individuals of marriageable age, and their marital status has been investigated for any significant manifestations. The findings are given in the following table together with similar findings for the general comparable population of the United States:[57]

Marital State	*Normal Intelligence Group*	*Subnormal Intelligence Group*	*High Grade Moron Group*	*Low Grade Moron Group*	*U. S. General Comparable Population**
Single	43.67%	49.54%	45.59%	46.60%	25.1%
Married	56.33%	50.46%	54.41%	53.40%	68.3%
Separated	5.83%	4.84%	2.25%	3.63%	
Divorced	20.62%	18.78%	20.27%	18.18%	6.6% (S D&W)
Widowed	5.62%	12.72%	9.91%	7.27%	

*White race and 21 or more years of age.

As may be readily seen, there is no striking disproportion between the married and the unmarried of the criminal classes. The one state obtains essentially as frequently as the other, the married having a slight majority. Comparison, however, of the percentages for the criminals with those for the general population shows a decided decrease in the incidence of marriage among offenders of all types. Accordingly, the assumption of the stabilizing influence of marriage appears well substantiated. Or, it may be that the fundamental constitution of the delinquent is of such a nature that he is frequently antagonistic toward the assumption and maintenance of marital duties and thus fails even to experience contact with any presumably stabilizing influences of marriage. At any rate, marriage, together with any of the beneficial influences it may exert upon the individual, is of markedly less frequent occurrence among criminal classes than among the general population.

A second point concerning the decreased incidence of marriage among malefactors as shown above, is the similarity of the percentages for the various groups. There is no decrease in the extent of marriage concomitant with the decrease in the intellectual endowment as might be expected from the assumption that intelligence is a requisite for the assumption of matrimonial duties, moreover, the equality of the percentages for the feebleminded groups and the non-feebleminded groups demonstrates that even deficient intelligence is infinitely far from constituting an effectual barrier to the marriage of the unfit—even those unfit who manifest the combined defects of criminality and of mental deficiency!

That slightly over 50% of criminals, including even the low grade morons, are married with the consequently increased possibilities of the propagation of the species is somewhat disheartening. However, a more hopeful aspect of the matter is obtained by bringing into consideration similar statistics in regard to the marriage of college graduates who undeniably represent the better stock of the land. Investigation in the alumni records of Harvard and Yale for the period of 1851 to 1890 shows the percentage of male graduates married ranging between 74% and 78%.[58] A similar investigation at Syracuse University covering a period of 50 years reveals 81% of the male graduates married,[59] and similarly, Stanford University has a percentage of 73.2% of the men of the classes from 1892 to 19,00 married.[60] Thus, a comparison of those percentages with those of delinquents affords a hopeful eugenical outlook, and also, it shows the decreased incidence of marriage among delinquents. To be sure, the figures given in the table above are less than their true value inasmuch as more marriages will occur among the offenders herein under investigation, but the possibility of their marriage percentage ever reaching the level of that of college-bred men is extremely doubtful. Particularly is this so in regard to those of deficient intelligence wherein the average age is considerably beyond the usual age of marriage.

Another instructive aspect of the above table is the very great frequency of marital disruption among the criminal groups as compared with the general population. Divorce alone is accountable for three times as much marital disruption among criminal classes as divorce and death among the general population. However, it must be borne in mind that conviction of felony constitutes grounds for a divorce in Wisconsin and various other states. Although this fact probably does account for some of the increase, it is not conceivable that it would account entirely for the markedly increased incidence of divorce among criminals. Particularly does this seem to be that more tenable since the prevalence of divorce is practically the same for each of the various groups. This equality of incidence is strongly suggestive that the criminally inclined nature, regardless of intellectual endowment, is fundamentally lacking in those personal and social requisites essential for the assumption and maintenance of marital duties. Or it may be that this marked prevalence of divorce indicates the failure of the stabilizing influences of marriage and home life because of the inherent instability of the criminal classes preventing the reception of any such benefits. Both inferences are further substantiated by a consideration of the percentage of separations. This, for the two more intelligent groups, amounts to over 25% of the general divorce rate for those groups, thereby greatly increasing the percentage of disrupted married life. While comparable figures for the general population are not available to enable a proper evaluation of these percentages of separations, common judgment alone is sufficient to realize that figures for separations among the criminal classes are undoubtedly increased over similar figures for the general population. The same thing is true of the percentages for the widowed, as is shown by the figure above for the general population of 6.6%, which includes both the widowed and the divorced. As it is, the percentages of actually disrupted marriages range from 29% for the low grade morons to 36% for the group of subnormal intelligence and 32% for the normal intelligence group. And when it is considered that 36% to 58% of the groups respectively are still within the age group of 21 to 30 years, it is reasonable to suppose that a contrasting of these percentages with figures for a like proportion of the

general population would render the above figures comparably much higher. However, from a eugenical point of view as regards the propagation of the species, this high percentage of disrupted marriages is a most hopeful sign.

SOCIAL AND ECONOMIC RESPONSIBILITIES

Related in significance to the table above on *Marital Status* is the table on *Social and Economic Responsibilities*. This table includes data only for those individuals who are married or have been married at some time. Following is the table:

(Married Individuals Only)	Normal Intell. Group	Sub-normal Intell. Group	High Grade Moron Group	Low Grade Moron Group
Without children	32.29%	24.85%	21.17%	24.45%
With children				
With one child	26.04%	25.45%	27.94%	20.00%
With two children	20.21%	19.39%	20.27%	14.55%
With three children	8.75%	11.52%	9.00%	10.91%
With four/more (average of five)	12.71%	18.79%	20.72%	29.09%
AVERAGE NUMBER OF CHILDREN PER FAMILY	1.56	1.93	2.02	2.27

It will be noted at once that the greater number of children and the greater number of families with children occur in the groups of deficient intelligence, particularly so in the low grade moron group. This is quite in accord with the findings of other investigators and the generally conceived opinion of the greater fecundity of the classes of deficient intelligence.[61] While some consideration must be given to the greater average age of the feebleminded of the above table in evaluating the percentages, the significant distribution of the percentages, and the low percentages of childless marriages strongly suggest the justifiability of comparing them on an equality with the other groups. How serious is this fecundity of the criminal classes as shown here may be judged somewhat by comparable figures for other classes of society. Thus, an investigation of the families of 1,000 American men of science who had attained some degree of distinction showed 22% childless and an average of less than two surviving children for each one.[62] And an investigation conducted in regard to 1,986 prominent Methodist clergymen showed 97.44% married, with only 11 % childless, 12.5 % with one child, 20.4% with two children, 18.5% with three children, and the remaining 37.6% with four or more children, an average of 3.26 children for each individual.[63] Also, an inquiry made in regard to graduates of Harvard and Yale revealed an average of 2.17 children for each individual.[64] And another investigation of the Harvard Graduates of 1894 revealed 20% without children, 13.1% with one child, 18.1% with two children, 22.5% with three children, and 25.5% with four or more children.[65] This makes an average of 2.44 children for each individual, a figure which gives the college bred man of Harvard the lead over even the low grade moron delinquent. Further, it has been estimated by Kehrer that the proportion of childless marriages for civilized countries ranges between 10% and 15%[66] which means that the ordinary middle-class citizen, taking the criminalistic and the college-bred classes as the extremes, bears the burden of restocking the population. This renders

less alarming the belief of the overfecundity of the defective and deficient classes. Nevertheless, that over 50% of the criminal classes are married and tend, despite the prevalence of disrupted marriages to reproduce themselves to the same extent as our leading intellectual classes constitutes an indisputable ill to society. Nor can there be any doubt of the gravity of this when it is realized that for the 328,820 adult male delinquents in prison[67] there are only 508,714 men enrol1ed as students universities, colleges, and professional schools in the United States,[68] a figure including minors as well as adults.

INDIVIDUAL ECONOMIC STATUS

Possibly the first author to discuss the relationship between poverty and criminality was Sir Thomas More in his "Utopia."[69] Since his time poverty has become very widely recognized as more or less of an inseparable companion to crime in general.[70] The exact role played by poverty in its relation to crime is not known, but in all probability, its role is indirect since poverty general1y means low status, with little to lose, little to respect, little to be proud of, and little to sustain efforts at improvement.[71] In this study, poverty is strikingly manifest in regard to the individuals of each of the groups of offenders. Following is the table showing the *Economic Status* of the *Individual*:

	Poor	*Fair*	*Good*
Normal Intelligence Group	86.39%	13.38%	0.23%
Subnormal or Low Intelligence Group	86.24%	13.46%	0.30%
High Grade Moron Group	88.23%	11.77%	
Low Grade Moron Group	90.29%	9.71%	

In the above table, the term *Poor* signifies a hand-to-mouth existence, the term *Fair* signifies the possession of a smal1 amount of taxable property with slightly more than the bare necessities of life, and the term *Good* signifies a comfortable and reasonably secure living with educational and cultural opportunities available. Such designations, to be sure, are inexact and uncertain, but do possess a very considerable value in aggregate usage. While data showing the economic status of the general population on such a scale as the above is not available, it is, nevertheless, very reasonable to suppose that the percentage of hand-to-mouth existences would fall far short of that shown by criminals. This same opinion is concurred in by Gillin, Bonger, Garofalo, and Sutherland in their respective texts upon criminology, all of which tends to substantiate the reliability of the above table and the conclusions that may be drawn therefrom. Indeed, various investigations have shown that less than 50% of the general population is without property B compared to the 86% to 90% of criminals given in the table above.[72] Thus it is evident that a very considerable stabilizing force is lacking in the lives of the criminal class, since the possession of property serves as a preventative to crime by creating a sense of responsibility and reliability and by awakening the acquisitive instinct.[73]

It is to be noted, strikingly enough, that there are no real differences between the percentages for the various groups, and that the feebleminded show no greater incidence of poverty than those not mentally deficient. This similarity in percentages suggests very emphatically one of two things, and possibly both. The first of these is the environmental nature of poverty as a factor in delinquency. The second is the possibility of a

fundamental deficiency in the character of criminals which renders poverty a characteristic accompaniment in that it represents a level of existence to which they naturally descend.[74] Both of these interpretations are further suggested by the fact that of the vast numbers of the poor, only a comparatively small part become delinquent, and further by the fact that virtue may thrive as richly in poverty-stricken homes as in those of wealth. Nevertheless, poverty itself does weaken the moral sentiments and thus it does pave the way for anti-social behavior.[75] Moreover, it constitutes an obstacle to education, the want of which may prevent moral development.[76] However, that poverty may have a direct relationship to delinquency must not be overlooked, as individual cases will show, a relationship dependent upon individual factors and made manifest by circumstances. Accordingly, while the conclusion that there is a relationship between crime and poverty may be drawn justly in view of the above evidence, this conclusion does not signify that the disappearance of poverty would herald the end of crime nor even modify the extent of occurrence of social dereliction to any considerable degree.[77]

PARENTAL ECONOMIC STATUS

Parental poverty unquestionably shares in the production of delinquency, probably through the interference it occasions in the proper rearing of the child. Family poverty results often in the absence of the parents from home, the lack of proper and needed discipline, resort to the streets and bad companions, denial of safe and simple pleasures, lack of recreation, and consequent social starvation—all of which forms a wide background of deprivation in youthful lives with no instruction or opportunity of satisfying normal safe desire.[78] In addition, it results in bad environments, and the deprivation of educational and cultural opportunities.[79] Thus even those individuals capable of absorbing the sound principles of law and morality are all too often not even exposed to such teachings. Instead, they are exposed to the undesirable teachings and evil precepts of the wretched environments in which they are compelled to live. And in such environments bad habits are learned by imitation,[80] and actual delinquency is often directly attributable to the deleterious influence of community, as has been shown by investigations,[81] and court record,[82] for criminality, whether in the family group or in the community, always breeds crime.[83] The extent of parental poverty among criminal classes for this particular investigation is shown in the following table on the *Parental Economic Status*, the descriptive terms of which have the same significance as in the previous table on *Individual Economic Status*:

	Percent Having Parents with Economic Status of:—		
	Poor	*Fair*	*Good*
Normal Intelligence Group	29.34%	68.08%	2.58%
Subnormal or Low Intelligence Group	29.67%	70.33%	…
High Grade Moron Group	31.13%	68.63%	0.24%
Low Grade Moron Group	30.10%	69.90%	

The above percentages do not, in all probability, reflect the exact truth since they are based on remote memory, and especially would this be so in regard to the feebleminded. However, comparison of the percentages for the different groups leads to the conclusion

that they may be considered as fairly reliable, especially the first two groups. The general trend of the figures is in accord with common judgment and the various groups, so widely divergent in mental endowment, agree in general most consistently. Accordingly, the above table shows an obviously great dearth of homes affording educational and cultural opportunities and a distressfully large extent of hand-to-mouth existences in the parental home conditions. The influence of parental poverty in the production of anti-social behavior has been recognized repeatedly, and the above findings are fully substantiated by those of Breckenridge and Abbott,[84] and Baily.[85] Undoubtedly the influence of the parental home conditions is indirect, as has been suggested, with those of defective quality accomplishing an undesirable end through the faulty development of the individual, and by the continuance of those conditions of life which allow for the further reproduction and development of such faultily constituted individuals.[86] With homes of defective quality, the social harvest in a vast number of cases must necessarily be poor indeed!

DISRUPTED HOMES AND DELINQUENCY

Along with parental poverty, another factor, probably of much greater significance in the production of social derelicts, is the matter of broken or disrupted home conditions in the childhood and youth of the individual. The following table shows the status of the home previous to the eighteenth birthday of the offender:

	Percent of Homes Unbroken	*Percent of Homes Disrupted by Death, Divorce, Desertion, or Separation*
Normal Intelligence Group	63.97%	36.03%
Subnormal or Low Intelligence Group	62.08%	37.92%
High Grade Moron Group	60.54%	39.46%
Low Grade Moron Group	70.87%	29.13%

As may be readily appreciated from the above figures, the percentage of disrupted homes in the childhood of the individual offenders is surprisingly high for all except the low grade morons, the interpretation of which will be made later. Shideler has estimated, by a method accepted by criminologists in general as apparently sound and conservative, that 25% of all children come from disrupted homes, and that, from various of his studies made of delinquent minors, 40% to 70% of all juvenile offenders come from disrupted homes.[87] Healy,[88] Breckenridge and Abbott,[89] and Healy and Bronner[90] have shown in their studies that at least 50% of juvenile delinquents come from disrupted homes, and Sutherland, in his study of the literature, has reached the conclusion that the disrupted home occurs twice as frequently among delinquent minors as among non-delinquent.[91] Also, the census report of 1923 shows that 46% of all juvenile delinquents come from disrupted homes.[92] With such findings for juvenile offenders, it is only reasonable and logical to assume that the same conditions would hold true to a comparative extent for adult offenders, since practically all confirmed criminals begin their careers in their childhood or youth.[93] And this assumption is substantiated by the findings of Lorenz, who found, in his study of 300 cases of ex-service men in penal institutions, that 59% of those cases were individuals whose childhood home had been disrupted.[94] And Brace, in

his early study of adult offenders, found that 55% of the adult criminals in New York penitentiaries came from disrupted homes.[95] Thus, as a conclusion, it may be considered that the disruption of the home during the developmental period of the individual exerts an inimical influence upon normal social development, and may lead indirectly to the production of soil fertile for the growth of anti-social behavior. The reasons therefore are undoubtedly many and varied. Increased economic difficulties of life, deprivation of educational and developmental opportunities otherwise available, and the failure of the normal guiding influences of home training may each constitute serious handicaps to correct social development. In addition, disruption of the home frequently leads to child labor which causes delinquency by placing the individual under responsibilities and in situations with which the ability to cope is lacking or undeveloped, or by rendering the individual pecuniarily independent at an age when the need of guidance is greatest.[96] A still further consideration and one wholly unmeasurable but worthy of serious consideration is the probable inheritance of various undesirable traits of personality which served to disrupt the home in many instances, and which render social adaptation more difficult for the child of that home.

As will be noted from the table above, the percentage of disrupted homes for the low grade morons is considerably below that of the other groups, and is but little higher than Shideler's estimate for the general population. While the exact significance of this is difficult of determination, abstract reasoning suggests either that the home of the low grade moron is devoid of influence in the development of the individual, or that the influence is of such a nature that little difference is made whether the home is disrupted or not. Or it may be that the mental deficiency of the low grade moron is so severe that criminalistic tendencies are a matter of endowment rather than distortion of development as may be the case with those of better mental endowment. At any rate, disruption of the childhood home of the low grade moron appears to be without particularly marked effect Upon the individual of that home.

PARENTAL NATIVITY

A much contested but apparently important contributor to delinquency, especially so in regard to offenders of less than normal intelligence, is the element of unselected foreign stock in the population of the state. This may be judged from the following table showing the *Parental Nativity*:

	Parents Native-Born	*Parents Foreign-Born*	*One Native, One Foreign-Born*
Normal Intelligence Group	48.95%	38.36%	12.09%
Subnormal or Low Intelligence Group	47.40%	40.98%	11.62%
High Grade Moron Group	44.36%	44.86%	10.78%
Low Grade Moron Group	22.33%	73.78%	3.89%
United States Population in General[97] (white race only)	61.60%	31.00%	7.40%

The above table shows clearly that the foreign-born stock does produce more than its due quota of our specified delinquents, especially so in regard to those of deficient intelligence. This is most marked regarding the low grade morons, where the foreign-

born stock produces more than 235% of its due quota of offenders as determined by population ratios while the proportions for the other three groups ranges from 125% for the group of normal intelligence to 144% for the high grade feebleminded delinquents. This finding is substantiated by the findings of the Immigration Commission of 1910.[98] and also by Laughlin in his report to the Congressional Committee.[99] And similar findings have been reported by the Massachusetts Department of Correction.[100] In addition, Laughlin also found that the second generation of foreign stock had an increased crime incidence over and above that of foreign stock in general, probably because that generation represents the transitional stage between the discarding of the customs of the old country and the adopting of those of the new. Undoubtedly this fact accounts for a proportion of the increased percentages in the above table. Obviously then, there is an undeniable danger in the admission of unselected foreign stock, both from the aspect of their own undesirability and from the aspect of their reproduction of their kind. Hence, there is an unquestionable and appealing need of a closer and more intelligent supervision of immigration, with more ample provision for the means of so doing.

A second consideration evident from the above table is the increase among offenders of individuals having one parent foreign-born and the other native-born. The percentages given above nearly double that for the general population. Various investigations have shown that there is a decided tendency for the home of mixed parental nativity to produce delinquent.[101] This fact has been attributed to the conflict of standards within the home serving to destroy proper discipline.[102] This strongly substantiates inferences made above concerning the importance of the home in the proper rearing of the child, with defective home resulting in social loss and injury.

INDIVIDUAL CITIZENSHIP

That the individual of foreign birth himself, if not of unselected and inherently faulty stock, is not an undesirable citizen, is evident from the following table showing the *Individual Citizenship*:

	Native	*Alien*	*First Papers*	*Naturalized*
Normal Intelligence Group	84.28%	4.58%	3.05%	8.09%
Subnormal or Low Intelligence Group	82.87%	6.73%	3.06%	7.34%
High Grade Moron Group	78.92%	8.83%	5.88%	6.37%
Low Grade Moron Group	52.43%	26.21%	10.68%	10.68%
United States Population in General[103] (white race only)	85.50%	…	…	…

Here it is evident that the foreign-born individual, unless of subnormal or deficient intelligence, is responsible for no more than a fair share of delinquency as determined by population ratios, and that from a standpoint of potential criminality he is not one bit worse than his native-born brother. However, the increased incidence of crime among those of deficient intelligence suffices to raise the average of crime incidence for the foreign-born individuals far above that of the native-born, as may be ascertained from the above table. This finding is in accord with the general findings of the United States Immigration Commission of 1910,[104] and a similar finding has been made by the Census

Bureau in 1923, which reports, for adult white male delinquents, an actually increased criminality among those of foreign birth.[105] Particularly does the above table show that as the amount of intelligence possessed by the individual decreases, the foreign-born have a decidedly increased crime incidence, and especially is this so in regard to the low grade morons. It has been estimated by capable students that 6% to 7% of the many thousands of immigrants arriving yearly are feebleminded.[106] Moreover, it is reported that many of those declared unfit to land are permitted to enter this country.[107] Accordingly, it is easy to understand why so large a proportion of the criminal mentally deficient are of foreign extraction. Indeed, while but 14.5% of the population at large is of foreign birth, 47.57% of the low grade moron delinquents are of foreign birth, which places their proportion of crime, as determined by population ratios, at 327% of their fair quota. That this high incidence of crime may be due in part to the inability of the mentally deficient alien to adapt himself to the new social order of his adopted country, rather than entirely to inherent criminal propensities, does not alter nor palliate one iota the fundamental fact of his undesirability. Particularly in this table is the need made evident of an intelligent and selective system of immigration with adequate and complete facilities for culling the undesirables who constitute both a detriment and a menace to the social and economic welfare of the whole country.

Another revelation of the above table is that 26.21% of the low grade feebleminded delinquents are aliens and that an average of 10.41% of all criminals are aliens and hence subject to deportation. Were the proper and adequate provisions in existence to meet this problem fully, society would experience a most decided benefit, probably at no greater economic cost than that of their criminality. Nor does this conjecture take into consideration the item of the social cost of criminality, which, so often, is infinitely more than the economic.

A further matter of interest in the above table is the percentages of the feebleminded delinquents who have either applied for citizenship papers or who have been granted them. For the low grade feebleminded this percentage amounts to 21.36% and the weighted average for both groups of mentally deficient totals 16.66%. That such a large proportion of the feebleminded, particularly so of the low grade mentally deficient, have been granted citizenship constitutes an exceedingly severe criterion upon society. It evidences a. failure to provide the judiciary with the ways and means of evaluating, understanding, and classifying the individuals who come before it. Until society makes the adequate provision essential to enable the courts to understand with what sort of human material they are dealing, there can be no good hope for the dispensation of justice nor the protection of citizenship. Especially is this so in criminal cases—indeed, in all cases where the primary consideration is human nature itself!

SUMMARY OF CONCLUSIONS

The conclusions reached in this investigation and apparently justified by the data at hand are as follows:

1. There appears to be a very definite relationship between criminality and deficiency of intelligence. This relationship becomes decidedly more marked the greater the deficiency.
2. The feebleminded or mentally deficient constitute 30% of our specified delinquents, a proportion fifteen to sixty times greater than that of the general population.
3. The low grade feebleminded constitute 20% of the mentally deficient delinquents and 6% of all criminals.
4. The relationship between criminality and intelligence may be considered indirect since criminal tendencies are manifested to a similar degree and with a similar frequency by offenders regardless of intellectual endowment.
5. Recidivism appears unrelated to the intellectual endowment since it occurs with essentially the same frequency among the mentally deficient offenders as among those of better intellectual capacities.
6. Recidivism, both for the feebleminded and those not feebleminded, is responsible for 49% of crime, thereby indicating by its very extent the ineffectualness of the present penal system for both deterrence and correction.
7. Habitual criminality appears to be accountable for 9.9% of offenders, and is more frequently found in offenders of normal or nearly normal intelligence.
8. There appears to be none or slight relationship between the gravity of the offense committed and the degree of intelligence possessed since both high and low grade feebleminded commit crimes as serious as those of their more intellectually gifted fellows.
9. There appears to be a greater tendency on the part of the low grade feebleminded to commit a greater number of the more serious crimes as judged by the duration of the sentence administered.
10. The extent of feeblemindedness among recognized criminals and the marked recidivism among mentally deficient delinquents as well as among those not feebleminded indicates an utter inadequacy of the present social, judiciary, and penal systems to cope satisfactorily with the problems of criminality.
11. The feebleminded delinquents, despite the very questionable outlook of regeneration for them and regardless of their evident need of permanent segregation or supervision, receive the same sort of sentences and consequent treatment as their more normal brothers.
12. Only 16% to 23% of offenders, whether of normal, subnormal, or deficient intelligence, receive long term sentences despite the fact that an average of 56.7% are recidivistic or habitual offenders and hence difficult and doubtful in the main of regeneration.
13. There appears to be no relationship, except in certain specific instances and within the limitations imposed by the actual capacities of the individual, between

intelligence and the type of the crime committed. The distribution of offenses is essentially the same for each level of intelligence.

14. Economic distress has a subjective value, approximately equally so for each level of intelligence, in the causation of crime, and as such a factor, it appears to be entirely environmental in nature.
15. The influence of bad company has no greater subjective value in the causation of delinquency for the feebleminded than for those of more superior intelligence.
16. Alcoholism is a definitely recognizable subjective factor in delinquency. It is recognized to a similar extent at each level of intelligence, and hence may be considered as environmental rather than individual in nature.
17. For each level of intelligence, a disproportionately high percentage of ex-service men are included among delinquents, thereby indicting military service as a genetic force in crime.
18. There appears to be a considerable degree of relationship between the endowment of intelligence and the age distribution of offenders. The greater proportion of younger offenders is in the group of greater intelligence, and the greater proportion of older offenders is in the groups of lesser intelligence.
19. There appears to be a somewhat decreased incidence of marriage among criminals in general, which is manifest to a similar extent for each level of intelligence.
20. The combined defects of subnormal or deficient intelligence and criminality do not constitute an effective barrier to the marriage of the unfit.
21. The extent of conjugal incompatibility among criminal classes, as evidenced by divorce and separation, is markedly increased above that of the general population. This holds true for each level of intelligence, but least so for the lowest level.
22. The disruption of marital life may constitute a causative factor in the production of delinquency, or it may be coincidental evidence of additional inherent constitutional defects in the nature of the criminal.
23. The criminal classes tend to reproduce themselves to almost the same extent as do the college-bred classes, the greater fecundity of the criminal classes being shown by the groups of lowest intelligence.
24. Individual poverty appears to be a very definite factor in the causation of delinquency. As such a factor, it seems to be entirely environmental in nature since it is equally distributed for the various levels of intelligence.
25. Parental poverty appears to constitute an indirect and environmental factor in the production of crime, manifest to an essentially equal degree for each level of intelligence. And as a result of this parental poverty, there is a very great dearth of homes affording educational and cultural opportunities.
26. A significantly large percentage of criminals come from disrupted childhood homes, thereby suggesting that such homes are inimical to correct social development. With a decrease in intelligence there is a concomitant decrease in the percentage, with the low grade morons having the fewest number of disrupted childhood homes, thereby suggesting a lesser value for their type of homes.
27. Individuals of foreign parentage appear to be responsible for an increased quota of crime as determined by population ratios. This is increasingly manifest as the

endowment of intelligence decreases, the low grade moron of foreign parentage being responsible for more than 235% of the population quota of crime.

28. There appears to be an increased proportion of mixed percentage, one native-born, one foreign-born, among criminal classes thereby suggesting the probability of an unfortunate social result of such a home.
29. The foreign-born individual not of subnormal or deficient intelligence appears to be responsible for no more than a fair share of delinquency as determined by population ratios.
30. The foreign-born individual of subnormal or deficient intelligence appears to be responsible for an overwhelmingly increased incidence of crime as determined by population ratios. This increased incidence reaches the proportion of 327% of the fair quota for the low grade morons.
31. Of the low grade feebleminded offenders, 26% are aliens, and an average of 10% of all criminals are non-citizens.
32. Of the foreign-born feebleminded delinquents, a proportion equaling 16% of the entire number of mentally deficient have either applied for citizenship papers or have been granted them. This signifies a failure of the social provision of proper judicial machinery for the best handling of human material, and the protection of citizenship.

APPENDIX OF TABLES

TABLE I

GENERAL DISTRIBUTION ACCORDING TO INTELLIGENCE

	No. of Cases	*Percentage*
Total Number of Individual Cases Examined	1,690	100.00%
Cases Found of Normal Intelligence	852	50.41%
Cases Found of Subnormal or Low Intelligence	327	19.36%
Cases Found of High Grade Feeblemindedness	408	24.14%
Cases Found of Low Grade Feeblemindedness	103	6.09%

TABLE II

TOTAL CRIMINAL HISTORY

	No. of Cases	*Percent of Group*
Normal Intelligence Group		
Cases Guilty of Misdemeanors	388	45.54%
Cases Having:		
One Conviction	652	76.52%
Two or Three Convictions	173	20.31 %
Four or More Convictions	27	3.17%
Cases Having:*		
One Offense (a conviction)	336	39.44%
Two or Three Offenses	428	50,23%
Four or More Offenses	88	10.33%
Subnormal or Low Intelligence Group		
Cases Guilty of Misdemeanors	162	49.54%
Cases Having:		
One Conviction	257	78.59%
Two or Three Convictions	61	18.66%
Four or More Convictions	9	2.75%
Cases Having:*		
One Offense (a conviction)	128	39.14%
Two or Three Offenses	164	50.16%
Four or More Offenses	35	10.70%
High Grade Feebleminded Group		
Cases Guilty of Misdemeanors	188	46.08%
Cases Having		
One Conviction	330	80.88%
Two or Three Convictions	73	17.89%
Four or More Convictions	5	1.23%
Cases Having:*		
One Offense (a conviction)	171	41.93%
Two or Three Offenses	205	50.23%
Four or More Offenses	32	7.84%
Low Grade Feebleminded Group		
Cases Guilty of Misdemeanors	51	49.52%
Cases Having		
One Conviction	87	84.47%
Two or Three Convictions	15	14.56%
Four or More Convictions	1	.97%
Cases Having:*		
One Offense (a conviction)	50	48.55%
Two or Three Offenses	47	45.63%
Four or More Offenses	6	5.82%

*In these cases, a history of misdemeanors constitutes a single offense, and conviction for felony constitutes all additional offenses.

TABLE III

LENGTH OF SENTENCE

	No. of Cases	*Percent of Group*
Normal Intelligence		
One Year or Less	72	8.45%
More than One Year and Not More than Two	226	26.52%

Milton H. Erickson, M.D.

September 1962

This is Milton H. Erickson speaking. I have been asked to make a recording of an induction technique. After much thought on this matter, I believe I can be of much greater service in another way.

My own induction techniques are expressive of me, of my timing, my rhythm, my personality, my emotional feeling, my attitude toward my patient. So it is with anybody else. And so it should be with anybody else. An induction technique is not a series of words, phrases, sentences. Nor is it just a matter of suggestions, intonations, inflections, pauses and hesitations. An induction technique is both simply and complexly a matter communication of ideas and understandings and attitudes by the doctor to his patient.

Instead of an induction technique, what I wish to present to you is my understanding of how the doctor should feel when undertaking to induce a trance: what he should understand about the situation, what he should know about himself, what he should understand and know about the patient. I wish to make clear what the induction technique situation actually is, what the doctor should knowingly, and understandingly expect of himself, and what he should reasonably expect of his patient. Only by having a full awareness of the nature and the character of the induction situation, and of the nature and the character of the induction technique itself, and by having a full clear awareness of himself and his patients (as participants in a common undertaking) can the doctor establish for himself and for his patient and intercommunication of understandings and expectations basic to the induction of hypnotic states.

In that communication there needs to be freely an awareness by the doctor of many things. First of all, he needs to be aware that the patient is seeking his help because the patient does not understand or cannot help himself in his needful condition. One must always, with utter intensity, view the patient as someone who is seeking help from the doctor because he honestly believes that that doctor can be helpful to him. Not to be continuously aware of this aspect of the interpersonal relationship renders defective the very foundation of any induction technique.

Next of importance, in establishing a good interpersonal relationship with the patient, is the need to be continuously aware and alert to the patient's own need to say, to tell, to ask, to advise, to request, to verbalize in some manner, or if not that, by facial expression, by gesture, by hesitancy, even by baited breath, to communicate in some way something the patient considers important to the patient and therefore important to the doctor. Simply to take charge of the total situation and to reassure the patient that the total situation is well in hand is not enough to develop a good climate for an induction. The

patient needs to know from the doctor's manner, bearing, alertness, attentiveness that every word, phrase, sigh, wince, expression of any kind; whether verbal, a gesture, hesitation, tension or whatever form the communication may take, will be noted and respected and examined carefully. And that more information will be sought if necessary. So that the patient can feel completely secure in his understanding that the doctor is in charge, is adequate to meet the situation and its demands, intelligently and with a full willingness to know all that is needed.

One builds an induction technique upon this kind of an interpersonal relationship. A full readiness and willingness for complete interpersonal communication (whether verbal or symbolic) between the doctor and the patient. By virtue of the doctor gently, willingly, with simple, quietly emphatic assurance, and comfort taking over the awareness of the needfulness of full interpersonal communication, there is established a most favorable situation for trance induction.

From the very beginning of the patient-doctor relationship there needs to be given (simply, quietly, gently, but emphatically, and best by manner and attitude) an assurance of the doctor's complete interest in and awareness of all the communication (verbal or symbolic) that the patient feels is necessary. One can say meaningfully to the patient that he should try hard to communicate all those obscure and difficult matters that might be overlooked in a careful search hindered by needless emphasis upon the obvious. And nothing he says should then be brushed aside as inconsequential.

Next of importance in the essential setting for a good induction technique is the doctor's own awareness of his own ability, his own knowledge and skill, and his full awareness that his own personal honesty will lead him to call in others available should he himself lack any special knowledge. To confess a weakness is not a sign of inferiority. Only the weakling does not dare to admit to a weakness. The strong man can and does and thereby wins and deserves respect. With this inner feeling of self-respect, the doctor can view his patient with a ready awareness of what he can do. And sense within himself a feeling of confidence in his abilities and a willingness to do his tasks, and if needful, to call in others. Thus he knows that he will not remain in a state of doubt and uncertainty, to be communicated to his patient should there be something he cannot do. Every doctor needs (in his dealing with a patient, to have as a full part of his self-awareness) an intense feeling of, "This I can do. And this other I can have done. And all the rest, if there is any more, lies in the hands of fate aided by all the good that I can do." Out of such an attitude as this, the doctor can then begin an induction with an appropriate and a full self-confidence.

Also to be realized, as a part of the foundation for a good induction technique, is the doctor's awareness that no matter who his patient is or what his patient's condition is, he the doctor still knows more, is better prepared, is more competent than anybody else in that situation. Therefore, because he is the only one present at the place and time who is knowledgeable, and competent, and because he can comprehend the needs of the situation, he is entitled rightly, justly, properly to have a full and ready confidence in his ability to meet the situation and to provide intelligently for the patient's needs. To be

simply, earnestly, and fully aware of this is most vital for a technique of induction that will inspire a patient with confidence.

Next of basic importance is the doctor's own understanding of hypnosis as a phenomenon in itself. He should know with absolute certainty that hypnosis is a phenomenon common in human experience both as an induced and a spontaneous development. He should know with utter certainty that hypnosis has been induced in many different peoples, in many different times, in many different situations. That hypnosis is possible for the old and the young, the sick and the well. That all of human history discloses that hypnosis is a phenomenon common to all people. With this well in mind, he can reasonably expect his patient to do the same thing that countless thousands have done throughout history, what countless thousands of patients are doing today, tomorrow, and next week, are doing every day for his colleagues throughout the world. With this in mind, and with full respect for his patient, he can confidently expect of his own patient a better accomplishment than that of patients in less tutored hands.

Knowing then that he can reasonably and rightfully expect his patient to accomplish as much thousands of other average patients have achieved, he can radiate full confidence and expectation to his patient as a nonverbal but highly effective communication which in turn will affect most favorably the effectiveness of the induction technique. Of basic importance in any induction technique is that the doctor, from the very beginning of his induction, realize that what is needful for his patient is not the words, not the tones, but the understanding of hypnosis as state of learning and being. It is not the words used that induce the trance. Rather it is the understandings given to the patient that a trance state is inevitable. And the words are no more than a means of helping him learn an inner process of self-experience. To induce a trance, one needs to communicate by words, bearing, manner, emotional attitude, intellectual awareness that the patient is really and truly expected, confidently expected, to be as able to learn how to develop a trance as readily and as well as any of his fellows. That it is not a matter of argument or elaborate explanation any more than is pain and distress. That with attention given, the patient's mind, by itself, can use the words employed to discover its own understandings of what is necessary in that needful situation to develop a trance. Thus by manner, attitude, bearing, in every conceivable way of expression, one simply expects and wants the patient to develop a trance and the words employed are thus only the means of communicating this expectation and confidence.

CRITICAL EVALUATIONS
The Inhumanity of Ordinary People

Milton Erickson, M.D.
Diplomate, American Board of Psychiatry and Neurology; psychotherapist in private practice, Phoenix, Arizona.

Reprinted with permission from *International Journal of Psychology,* October, 1968, pp. 277-279

PSYCHOLOGY is often defined as the scientific study of human behavior. That this is not entirely true has been made apparent innumerable times by factionalism and enforced restriction of theoretical conceptualizations, but even more by avoidance of a large area of human behavior. That such avoidance has occurred is understandable, because this area is often ugly, unpleasant, even offensive, however, constant throughout human history; but such avoidance is obviously unjustifiable. Not only have psychologists been at fault, but even worse, so have psychiatrists—worse because psychology deals primarily with normal human behavior and psychiatry with. deviations therefrom. Any science worthy of being called a science cannot exclude a vast area requiring careful, thoughtful and intensive exploration, even though its exploration may lead to derogation, to misinterpretation, and to both deliberate and inadvertent confusion of issues.

It is my pleasure, both scientific and intellectual, to discuss briefly but, it is hoped, pertinently, the pioneer work done by Stanley Milgram. As a preliminary, I recall the old, old joke about the mother who rebukes her son for hitting his sister and pulling her hair, declaring it was the devil that made him do so; to which the son replies that maybe the devil did cause him to hit his sister and pull her hair, but it was really his own idea to kick her.

Throughout the ages everybody has tried to believe that normal psychological behavior includes only that which is good at the social level, and behavior adverse to the good of humanity has been attributed to various scapegoats. In recent times the murder of millions of people was attributed primarily to Hitler, and every "good" German defended his share in that effort at genocide as a proper carrying out of the orders of a superior. But we do not need to consider the offenses initiated by Hitler. We need only to look upon what happened to the aborigines of Tasmania, shot for food for the dogs of the settlers, to develop some unhappy but scientific thinking. One can recall in relatively recent history the nobility of the Puritans who came to New England and founded a colony so that they might establish the right of human beings to worship the Deity in freedom and without restraint imposed by others. But what about their persecution of Roger Williams? How did it happen that such noble purposes led to the discovery that "the only good Indian is a dead Indian"?

Or one may shudder at the horrors of the prisoner-of-war camps, both Japanese and German, as well as the concentration camps in Germany during World War II, but one must not forget to include, in that horror of man's inhumanity to man, the facts of Andersonville in the 1860's here in America, where Americans inflicted unbelievable atrocities upon Americans. Also, one need only look back upon the Ottoman Empire to realize that the crowning and life-expectancy of the

sultan was based upon the rapidity with which he caused the murder of all his brothers and half-brothers.

The world has been "kind" in overlooking the motivations of such examples as the treatment of Copernicus, the ravaging of the coast of Europe by the Vikings, or the sources of present day racial strife, preferring to discuss the behavior of humanity in terms of impersonal social forces. At times, man's inhumanity to man is given some euphemistic label, but no effort is made to investigate scientifically the extremes to which the normal, the good, the average, or the intellectual person or group will go if given the opportunity: consider the Spanish Inquisition, the Salem witch trials, or the introduction of slavery into a country dedicated to the right of everyone to equality and freedom.

Stanley Milgram has entered upon a program to discover the nature and character of what constitutes this psychological area and the forces which have been so blandly wrapped up in the undefined and disregarded phrase of "man's inhumanity to man." That his pioneer work in this field is attacked as being unethical, unjustifiable, uninformative, or any other derogative dismissal, is to be expected, simply because people like to shut their eyes to undesirable behavior, preferring to investigate memory, forgetting of nonsense syllables, conditioned reflexes, span of attention and similar kinds of behavior that do not arouse inner distress and anxiety.

But the need to discover and to study scientifically all forms of destructive behavior in men persists; such studies cannot be pushed aside because they disclose human behavior inconsistent with "good" understandings of "normal" behavior.

The fact is that Milgram, without employing duress or force, could create a situation in which an average, normal, intelligent individual would *of his own accord* inflict pain and misery upon a fellow human being, and, with sweating brow and inward fear and trembling, continue to inflict dire harm upon an innocent person, and continue grimly to the very limits possible of this behavior under no compulsion but a structured social situation.

It is time that society-particularly its psychologists and psychiatrists-takes a realistic view of the nature of undesirable and destructive human behavior and the extent to which, under stress or without stress, the individual, the group or an entire society can be led to enact it, so that understanding and perhaps eventually control of the ugly realities that have characterized human history since its beginning may result. Imperfections of research design are not the issue: Milgram is making a momentous and meaningful contribution to our knowledge of human behavior, much more important than the compartmentalized studies of units of behavior which may be more readily approved by society.

The capacity for behavior unacceptable both to the individual and to society is an area that has long been overlooked, and this area requires careful scientific investigation far more than does acceptable behavior. Unacceptable behavior is and has been the basis of the serious social disorders rampant throughout history. Now at last, here is a pioneer willing to say simply and emphatically, and to prove it by well-demonstrated scientific study in the laboratory, that normal and average human beings can be manipulated into inhumane behavior, and that the need is great to study the normal man from this aspect rather than to continue to regard such behavior either.

as incomprehensible or as evidence that the person involved is somehow aberrant, abnormal and atypical.

When Milgram's initial study appeared, he was already well aware that an area of scientific investigation was being opened which would lead to reproaches and condemnation and to f6rgetfulness of much that constitutes a part of human history that is looked upon, if at all, only after it has been obscured with rosy colors. To engage in such studies as Milgram has requires strong men. with strong scientific faith and a willingness to discover that to man himself, not to "the devil," belongs the responsibility for and the control of his inhumane actions.
